About the cover:

Within a star-forming region. This view is based in part on discoveries since the Protostars and Planets II meeting, including new infrared imaging. Approximately visual colors are used, except that deep red color sensitivity is extended as far as $2\text{ }\mu\text{m}$ into the infrared. A trapezium-like cluster of O and B stars has formed and cleared a cavity in the interstellar medium. Expansion has produced elephant trunk nebulae and globules. Infrared stars, both single and in groupings, can be seen within the densest portions of some of the globules. Several disk-shaped cocoon nebulae can be found, including one interacting pair. (Painting by William K. Hartmann)

PREFACE

Modern astrophysics began near the turn of the century with the study of stars grounded in fundamental understanding of the structure and behavior of matter. Since then, astrophysical frontiers have been pushed simultaneously in two opposite directions: toward larger and larger scales to understand what we know as our universe, and toward smaller and smaller scales to understand the formation of stars and planets. In some sense, astrophysics becomes a particularly humanistic endeavor as it pushes toward planets. Human beings are peculiarly a planetary phenomenon; life itself is likely to be a planetary phenomenon throughout the universe. Attempts to understand the mechanisms of planet formation appeal to several deep human motivations: to understand ourselves in relation to the universe of which we are part, and to grasp the possibilities that the universe offers for planets and life elsewhere.

During the past several decades, the study of planetary-system formation has occupied increasing attention and has advanced rapidly. A number of developments have contributed to the florescence of this investigation. The empirical basis of our understanding has expanded greatly over the past three decades as a result of complementary advances made in planetary science and in traditional astrophysics. Exploration of the solar system by spacecraft has brought previously remote planets within the reach of direct study with instruments capable of measurements not possible with astronomical methods alone. Technological advances in measurement capabilities have provided microscopically detailed information about solar system matter not available in previous decades. Advances in the techniques and spectral ranges of astronomical observations have vastly expanded our knowledge of the interstellar medium, of stars and stellar birth, and of probable protoplanetary disks [see Plate 7 for a possible example], as well of the planets in our own solar system. Astronomical measurement capabilities are expanding at a rate that allows us seriously to contemplate the possibility of discovering and studying numerous other planetary systems in the next few decades. Finally, advances in theoretical understanding facilitated in part by calculations feasible only with modern high-speed computers have crystallized a conceptual basis for thinking about the formation of planetary systems in relation to the formation of stars.

Protostars & Planets III is the third in a series of books begun in 1978. This series has tracked the development of our understanding of star and planet-system formation, reflecting both impressive advances and continuing

ignorance over the past two decades. The endeavor to understand planetary systems falls into the most modern of complex scientific categories. Planetary systems are too complex to have been predicted *a priori* from the basic equations of physics. It is unlikely that the formation of a star and planetary system will ever be modeled completely from first principles, tracking the evolution of some 10^{57} atoms from a diffuse interstellar assemblage to the highly structured state that is a star and planetary system. Instead, as in the study of all complex systems, we can expect that it will be the close interaction between observations, measurements, and theoretical investigations that fuels the continuing advance of our understanding. In recent years, observations have rendered the very cores of star-forming complexes open to astronomical scrutiny, revealing disk-shaped assemblages of dust and gas, which look for all the world like the precursors of planetary systems. New insights about distinct mechanisms of star formation at the high and low ends of the stellar-mass distribution have been gained through observations of molecular clouds. Seven years ago, when *Protostars & Planets II* was published, the nature of T-Tauri objects as forming stars with large amounts of surrounding gas and dust was understood, but little else was known about these curious systems. Today there is a whole taxonomy of T-Tauri stars (classical, weak, and naked), the various members of which may represent different stages of accretion and dissipation of the surrounding material. The “T-Tauri wind,” assumed in the past to selectively sweep gas from early planetary atmospheres, now appears to be part and parcel of the disk-accretion process itself; the wind’s role in setting the properties of the star and the environment of the surrounding planets remains unclear.

At the time of *Protostars & Planets II*, significant chemical and isotopic data on the solar system had already been accumulated, but little was yet known chemically about objects in the outer reaches of the solar system. Studies over the intervening seven years have produced inventories of molecular species in comets, Pluto, and the atmospheres and moons of Uranus and Neptune. Complementing these are increasingly sensitive observations of abundances in interstellar clouds including, for example, the first, and long-awaited, identification of methane in molecular clouds. Continuing accumulation of evidence about isotopic abundances and anomalies in meteorites (and, tentatively, in comets) has constrained further the timing of solar system formation against the tapestry of other events in our parent molecular cloud.

Multi-dimensional hydrodynamic and magnetohydrodynamic computer codes have advanced rapidly since *Protostars & Planets II*, facilitating calculations of molecular cloud dynamics, clump formation, cloud collapse, disk or binary star formation, disk evolution and dissipation, wind mechanics, giant planet formation through nucleated collapse of gas, grain and planetesimal accretional dynamics, tidal effects on disks, energetic plasma processes in disks, and impact-driven escape and evolution of atmospheres.

Close interaction between observations, measurements, theory, and nu-

merical modeling is playing an important role in advancing our understanding. Maps of temperature and density in molecular clouds constrain models of the collapse of cloud clumps. Disk-temperature profiles, inferred spectroscopically, challenge complex numerical simulations of the evolution of these planet-forming structures. Of particular interest is how protoplanetary disks transport mass and angular momentum; only recently have theorists tried to face this issue from the point of view of two- and three-dimensional hydrodynamical codes. Newly refined and detailed models of giant-planet interiors, coupled with improved knowledge of atmospheric abundances, pose fresh complications in the physics of planet formation. Models of molecular cloud grain evolution now possess a rich complexity, driven by the need to explain an impressive bulk of chemical and physical evidence. At the same time, icy grains which became part of comets, and perhaps Pluto, may have been spared some of the substantial processing associated with the grains captured by objects closer to the center of our solar system; models explaining the current composition of the outer-most objects in the solar system must therefore account for a combination of molecular cloud and planetary disk processes. Energetic processes in disks, ranging from those responsible for FU Orionis phenomena to the elusive nebular lightning, have only recently been subjected to theoretical study, and their role in planet formation remains unclear.

This volume summarizes a field in which progress has been substantial since the publication of its predecessor. The book was generated in the usual way for the Space Science Series, with a lively conference followed by a special issue of *Icarus* and writing of the chapters which follow. The chapters were formatted by the Space Science Series editorial staff, with the T_EXnical assistance of Mark McCaughrean. *Protostars and Planets III* is the first Space Science Series volume to be produced using T_EX.

It is now almost unnecessary to point out the tight coupling between the fields of astrophysics, observational astronomy, planetology and plasma physics which characterizes the search to understand stellar and planetary origins. The careful reader should come away from this book with an appreciation for the variety and intricacy of processes which, in creating stars and planets, drive much of the physical and chemical evolution of galaxies.

PART I
Clouds

THE COLLAPSE OF CLOUDS AND THE FORMATION AND EVOLUTION OF STARS AND DISKS

FRANK SHU, JOAN NAJITA, DANIELE GALLI, EVE OSTRIKER

University of California, Berkeley

and

SUSANA LIZANO

Universidad Nacional Autonoma de Mexico

We consider the interrelationships among the structure of molecular clouds; the collapse of rotating cloud cores; the formation of stars and disks; the origin of molecular outflows, protostellar winds, and highly collimated jets; the birth of planetary and binary systems; and the dynamics of star/disk/satellite interactions. Our discussion interweaves theory with the results of observations that span from millimeter wavelengths to X-rays.

I. OVERVIEW

This chapter gives a status report on the current astrophysical problems that confront the theory and observation of the collapse of clouds and the formation and evolution of stars and disks. The assignment contains too vast a topic to review in any detail in the allotted pages, and we have interpreted our task accordingly as setting the context for some of the following chapters by others. Parts of this review in essence can also be found in Shu (1991).

We start in Sec. II with the notion that two different modes seem to account for the birth of most stars in the Galaxy: a “closely packed” mode characterized by the more or less simultaneous formation of a tight group of many stars from large dense clumps of molecular gas and dust (see Chapters by Blitz and by Lada et al.), and a “loosely-aggregated” mode in which an unbound association of individual systems (some of which may be binaries) forms sporadically from well-separated, small, dense, cloud cores embedded within a more rarefied common envelope. We introduce the working hypothesis, adopted currently by many workers in the field, that the formation of sunlike stars by the second mode occurs in nearby dark clouds like the Taurus region in four conceptually distinct stages (Fig. 1).

Of the four stages *a–d* outlined in Fig. 1, the most surprising—the one totally unanticipated by prior theoretical developments—is *c*, the *bipolar outflow phase*. In Sec. III, we review the observational discoveries and

Figure 1. The four stages of star formation. (a) Cores form within molecular cloud envelopes as magnetic and turbulent support is lost through ambipolar diffusion. (b) Protostar with a surrounding nebular disk forms at the center of a cloud core collapsing from inside-out. (c) A stellar wind breaks out along the rotational axis of the system, creating a bipolar flow. (d) The infall terminates, revealing a newly formed star with a circumstellar disk (figure from Shu et al. 1987a).

interpretations that have led up to our current empirical understanding of this fascinating phenomenon. We pay particular attention to those aspects that set tight constraints on possible theories. In Sec. IV, we begin a theoretical discussion that indicates why, in retrospect, we should perhaps have known all along that the formation of stars would necessarily involve the heavy *loss* of mass. Given the angular momentum difficulty likely to be faced by any object which forms by contraction through many orders of magnitude from an initially extended, rotating state, the birth of stars (and, perhaps, galactic nuclei) through the accretion of matter from the surroundings may simply not be possible without the *simultaneous* accompaniment of powerful outflows.

Under the working hypothesis, gas and dust in the first stage (Fig. 1a) slowly contract under their own gravitation against the frictional support provided by a background of ions and magnetic fields via the process of ambipolar diffusion (see also Chapters by Heiles et al. and McKee et al.). The principal feature in this stage involves a *quasi-static evolution toward a $1/r^2$ density configuration* appropriate for a singular isothermal sphere. The

relative statistics of cores with and without embedded infrared sources, as well as the theory of ambipolar diffusion, suggests that the time scale over which the configuration is observable as a quiescent ammonia core before it enters dynamical collapse (i.e., before it contains an embedded infrared source) should span about 10^6 yr.

When the contracting configuration becomes sufficiently centrally concentrated, it enters stage 2 (Sec. V; cf. Chapter by Tscharnuter and Boss), wherein the cloud core gravitationally collapses from *inside out*. In such a situation, the inner regions form an accreting but otherwise secularly evolving protostar plus nebular disk. An infalling envelope of gas and dust that rains down from the overlying (slowly rotating) molecular cloud core covers the growing star plus disk. The visual extinction to the central star measures from several tens to a thousand or more, so the embedded source during this stage does not appear as an optically visible object, but must be studied principally by means of the infrared, submillimeter, and millimeter radiation produced by dust reprocessing in the surrounding envelope (see Chapter by Zinnecker et al.).

At some point during this phase of the evolution (see Sec. VI), a powerful wind breaks out along the rotational poles of the system, reversing the infall and sweeping up the material over the poles into two outwardly expanding shells of gas and dust. This stage (stage c) corresponds to the *bipolar outflow* phase observed spectroscopically at radio wavelengths by CO observers (cf. Chapter by Fukui et al.). Theory suggests that this stage features *combined* inflow (in the equatorial regions) and outflow (over the poles). Current consensus in the field holds that magnetohydrodynamic forces drive the wind sweeping up the molecular outflow. The main debate concerns whether the wind originates from the *star*, or from the *disk*, or from their *interface* (see Chapter by Königl and Ruden). From the mass infall rate as well as the statistics of numbers of embedded sources compared to revealed ones (T Tauri stars), we can estimate the combined time spent in stages *b* and *c* (when the system still gains mass in net) as roughly 10^5 yr, almost independent of mass.

As time proceeds, we envisage the angle occupied by the outflow to open up (like an umbrella) from the rotation axes and to spread, halting even the rain of infalling matter over the equator. At this point, stage d, the system becomes visible, even at ultraviolet, optical, and near-infrared wavelengths as a star plus disk to all outside observers (see Sec. VII; Chapter by Basri and Bertout). The location of the star in the Hertzsprung-Russell diagram yields a constraint on the accretion time scale (see Chapter by Stahler and Walter), and the numbers estimated by this method agree well with the dynamical calculations based on the concept of inside-out collapse from a molecular cloud core modeled as a (rotating) singular isothermal sphere. The principal questions during this stage then concern the mechanisms by which mass, angular momentum, and energy transport take place within the disk (see Chapter by Adams and Lin), and the nature of any companions (stellar or planetary) that may condense from such a disk (see Sec. VIII; Chapters by Bodenheimer et

al., Weidenschilling and Cuzzi, Lissauer and Stewart). Intimately tied to these issues are the estimates of disk masses that can be obtained from observational measurements at submillimeter and millimeter wavelengths (see Chapter by Beckwith and Sargent). Another important question concerns whether disk accretion mainly occurs episodically during FU Orionis outbursts or during the relatively quiescent (normal) states as well (see Chapter by Hartmann et al.). FU Orionis outbursts may have important connections with the meteoritic evidence for transiently high nebular temperatures (see Chapter by Palme and Boynton); however, the empirical need to appeal to such outbursts for geochemical peculiarities becomes less clear if nebular lightning truly offers a solution for the origin of chondrules (see Chapter by Morfill et al.).

For the purposes of this book, we may append a fifth stage to the above four: an epoch of disk clearing. The chapter by Strom et al. identifies this phase with planet making and sets disk lifetimes at 10^6 to 10^7 yr. We can usefully compare this astrophysical constraint with the models of giant planet formation that do not begin to accrete large amounts of gas until a critical core mass of solids has been reached (see Chapter by Podolak et al.). Edwards et al. in their chapter argue persuasively that the presence of an inner disk constitutes the crucial distinction between those T Tauri systems that drive extraordinary winds (classical T Tauri stars) and those that do not (weak-line or "naked" T Tauri stars). The absence of an absorbing wind (and inner disk) makes the magnetic activity on the surfaces of the latter objects observable as X-ray sources (cf. Chapter by Montmerle et al.). Spallation reactions driven by energetic particle fluxes associated with the enhanced flaring activity observed for these relatively gas-poor systems may help to explain some of the isotopic anomalies seen in the meteoritic record. Surviving dust grains from the protosolar core may have brought other anomalies intact into the solar nebula (cf. Chapters by Cameron, Swindle, and Ott).

In Sec. IX, we recapitulate by discussing the question of the origin of stellar and planetary masses. In particular, we emphasize the emerging view that in environments where there exist more than enough material to form the final condensed objects, stars and giant planets help, in part, to determine their own masses: stars, by blowing powerful winds that shut off the continuing infall from a molecular cloud; and giant planets, by opening up gaps that turn off the continuing accumulation from a nebular disk (see also Chapter by Lin and Papaloizou). A worrisome issue in the latter context concerns how the solar system managed to clear the debris left over in the disk from making the Sun and the planets. The Chapter by Duncan and Quinn makes clear that within the region of the giant planets the solid debris could have been cleared by gravitational interactions with the planetary bodies. The observations of remnant particulate disks around main-sequence stars (see Chapter by Backman and Paresce) demonstrate empirically, however, that planetesimal dispersal mechanisms become inefficient at large distances from the central star; such regions probably become the reservoir for (an inner belt of) comets (see Chapter by Mumma et al.). The gas appears to pose a greater

difficulty. The old view envisages nebular gas left over from planet building to be dispersed by a T Tauri wind. The new view suggests that T Tauri winds do not exist in the absence of (the inner portions of) nebular disks; thus, Edwards et al. argue that the former cannot get rid of the latter (however, see Sec. IX).

The above summary gives a sample of the rich diversity of physical processes that confronts the research worker in the field of star and planet formation. This variety arises for a simple and basic reason: the problem spans physical conditions ranging from the depths of interstellar space to the interiors of stars and planets, involving all the known states of matter and forces of nature, with observational diagnostics available across practically the entire electromagnetic spectrum, and experimental access to relevant primitive materials that has no parallel in any other branch of astronomy and astrophysics. To attack its problems, the field has developed a broad range of technical tools—observational, theoretical, and experimental; and the full exploitation of this range of tools during the past decade has led to rapid and impressive progress.

II. BIMODAL STAR FORMATION

The empirical notion that the birth of low- and high-mass stars may involve separate mechanisms has a long and controversial history (Herbig 1962*b*; Mezger and Smith 1977; Elmegreen and Lada 1977; Gusten and Mezger 1982; Larson 1986; Scalo 1986; Walter and Boyd 1991). The name “bimodal star formation” usually attaches to this concept, but, more recently, the emphasis has changed from “low mass versus high mass” to “loosely aggregated versus closely packed” (see Chapter by Lada et al.). The latter phrasing roughly coincides with the older one of “associations versus clusters,” except that it need not carry the connotation of “gravitationally unbound versus gravitationally bound.”

The theoretical distinction between “loosely aggregated” and “closely packed” refers to whether gravitational collapse occurs independently for individual small cores to form single stars (or binaries); or whether it involves a large piece of a giant molecular cloud to produce a tight group of stars created more or less simultaneously. This tight group need not form a bound cluster if the winds or other violent events that accompany the formation of stars expel a large fraction of the gas not directly incorporated into stars (Lada et al. 1984; Elmegreen and Clemens 1985).

The occurrence of two separate modes of star formation has a natural theoretical explanation (Mestel 1985; Shu et al. 1987*b*) if we adopt the point of view that magnetic fields provide the primary agent of support of molecular clouds against their self-gravity (Mestel 1965*a*; Mouschovias 1976*b*; Nakano 1979; see also Chapters by Heiles et al. and McKee et al.). The inclusion of a conserved magnetic flux Φ threaded by an electrically conducting cloud introduces a natural mass scale (cf. Mouschovias and Spitzer 1976; Tomisaka

et al. 1988a, 1989),

$$M_{\Phi} \equiv 0.13 G^{-1/2} \Phi \quad (1)$$

that is analogous to Chandrasekhar's limit M_{Ch} in the theory of white dwarfs. A critical mass arises whenever we try to balance Newtonian self-gravity by the internal pressure of a fluid which varies as the $4/3$ power of the density (because of ultrarelativistic electron degeneracy pressure in the case of a white dwarf; because of the pressure of a frozen-in magnetic field in the case of a molecular cloud). White dwarfs with masses $M > M_{\text{Ch}}$ cannot be held up by electron degeneracy pressure alone, but must suffer overall collapse to neutron stars or black holes. Molecular clouds with masses $M > M_{\Phi}$ (supercritical case) cannot be held up by magnetic fields alone (even if perfectly frozen into the matter), but, in the absence of other substantial means of support, must collapse as a whole to form a closely packed group of stars. The only trick in this case concerns how to get a supercritical cloud or clump from an initially subcritical assemblage (or they would have all collapsed by now). Theory and observation both suggest a natural evolutionary course: the agglomeration, with an increase of the mass-to-flux ratio, of the discrete cloud clumps that comprise giant molecular complexes (Blitz and Shu 1980; Blitz 1987b, 1990; Shu 1987; see also Chapters by Blitz and by Lada et al.).

The analogy between white dwarfs and molecular clumps breaks down for the subcritical case. White dwarfs with $M < M_{\text{Ch}}$ can last forever as uncollapsed degenerate objects (if nucleons and electrons are stable forms of matter) because quantum principles never weaken. Magnetic clouds with $M < M_{\Phi}$ initially cannot last forever because magnetic fields do weaken, and the local loss of magnetic flux from unrelated dense regions allows loosely aggregated star formation. In particular, in a lightly ionized gas, the fields can leak out of the neutral fraction by the process of *ambipolar diffusion* (Mestel and Spitzer 1956; Nakano 1979; Mouschovias 1978; Shu 1983). In Sec. IV, we shall examine in more detail the production of individual molecular cloud cores by this process. For the present, we merely note that theory predicts that self-gravitating cores sustained by magnetic fields will inevitably evolve to a state of spontaneous gravitational collapse. This prediction seemingly flies in the face of observations, which almost always find young stellar objects associated with outflows rather than inflows.

III. THE BIPOLAR OUTFLOW PHASE: OBSERVATIONS

At the heart of the central paradox concerning star formation lies the problem of *bipolar outflows* (for reviews, see Lada 1985; Welch et al. 1985; Bally 1987; Snell 1987; Fukui 1989; Rodriguez 1990). Astronomical visionaries (see, e.g., the reminiscences of Ambartsumian 1980) have long worried that forming astronomical systems frequently exhibit *expansion*, rather than the *contraction* that would be naively predicted by gravitational theories. Astronomical conservatives have long persisted in ignoring such warnings, doggedly pursuing

the theoretical holy grail that bound objects, such as stars and planetary systems, should form from more rarefied precursors by a process of gravitational contraction. The reconciliation of this fundamental dichotomy remains the central challenge facing theorists and observers alike (see the review by Lada and Shu 1990).

In 1979, Cudworth and Herbig discovered that two H-H objects in a nearby dark cloud L1551 (Lynds 1962) exhibit very high proper motions (corresponding to $\sim 150 \text{ km s}^{-1}$) that trace back to an apparent point of origin near the location of an embedded infrared source IRS 5 found by Strom et al. (1976). Knapp et al. (1976) had earlier found that CO millimeter-wave spectra in this region possess linewidths of the order 10 km s^{-1} , too large according to Strom et al. to correspond to gravitational collapse. The latter authors suggested instead that the disturbance in the ambient molecular cloud material might be produced by a powerful outflow from IRS 5. Snell et al. (1980) mapped the CO emission in the L1551 region and verified this conjecture in a dramatic fashion. They found that the high-velocity CO surrounds the tracks of the fast H-H objects, taking the form of two lobes of gas moving in diametrically opposed directions from IRS 5 (see Fig. 2). Putting together all of the empirical clues, Snell et al. made the prescient proposal (Fig. 3) that a stellar wind must blow at 100 to 200 km s^{-1} from IRS 5, in directions parallel and anti-parallel to the rotation axis of a surrounding accretion disk, and that this collimated wind sweeps up ambient molecular cloud material into two thin shells, which manifest themselves as the observed bipolar lobes of CO emission. The thin-shell nature of the CO lobes of L1551 has since received empirical validation in the investigations of Snell and Schloerb (1985) and Moriarty-Schieven and Snell (1988). Except for the further interpretation that IRS 5 represents a *protostar*, which, apart from suffering mass loss in the polar directions, accretes matter from *infall* occurring in the equatorial regions (see panel *c* in Fig. 1), the proposal of Snell et al. (1980) corresponds in every detail to the theoretical model that we shall pursue in Sec. VI.

Shortly after the original suggestion, however, events moved to a different interim conclusion. In common with the central source of several other bipolar outflows (see reviews of Cohen 1984; Schwartz 1983), IRS 5 lies along a chain of HH objects (Strom et al. 1974; Mundt and Fried 1983) that may just constitute the brighter spots of a more or less continuous optical jet (Mundt 1985; Reipurth 1989*c*).

The emission knots probably arise as a result of the interactions of a highly collimated ionized stellar wind with the surrounding medium (possibly another [neutral] wind; see Stocke et al. [1988] and Shu et al. [1988]). The free-free thermal emission from the ionized stellar wind resolves itself in VLA radio-continuum measurements as a two-sided jet centered on IRS 5 (Bieging et al. 1984). It was natural to suppose that this ionized wind represents the driver for the bipolar molecular outflow. Unfortunately, the momentum input provided by the ionized wind, integrated over the likely lifetime of the system, falls below the value required to explain the moving CO lobes by one to two

Figure 2. Contour map of the antenna temperature of the $J = 1 - 0$ transition of ^{12}CO at high velocities, superposed on an optical photograph of the L1551 dark cloud. The cross indicates the position of IRS 5; also shown are the directions of the proper motions of two Herbig-Haro objects, HH 28 and HH 29 (figure from Snell et al. 1980).

orders of magnitude (for the likely case of momentum-driven rather than energy-driven flows), a conclusion that holds as well for all other well-studied bipolar flow sources (Bally and Lada 1983; Levreault 1985). By comparing the required momentum input to the photon luminosity divided by the speed of light, the same authors argued persuasively against the possible importance of radiation pressure in the outflow dynamics.

The claim by Kaifu et al. (1984) of the detection of an extended, rotating, molecular disk encircling IRS 5, contributed to the puzzle. This result, and the inability of ionized stellar winds to drive the observed molecular flows, motivated Pudritz and Norman (1983, 1986) and Uchida and Shibata (1985) to suggest that bipolar outflows originate, not as shells of molecular cloud gas

Figure 3. Schematic model for the bipolar flow in L1551 driven by a stellar wind emanating from IRS 5. At the bottom is depicted expected CO line profiles for different line of sights across the source (figure from Snell et al. 1980).

swept up by a stellar wind, but, following the work of Blandford (1976) and Lovelace (1976), as gaseous material driven magneto-centrifugally directly off large ($\sim 10^{17}$ cm) and massive ($\sim 10^2 M_{\odot}$) circumstellar disks. This suggestion seemingly received support from reports that one limb of the blueshifted lobe in L1551 exhibits rotation (Uchida et al. 1987a). However, subsequent observational studies have failed to confirm the presence of large and massive disks around young stellar objects with the properties required by the theoretical models (see, e.g., Batrla and Menten 1985; Menten and Walmsley 1985; Moriarty-Schieven and Snell 1988). Moreover, the claim of rotation in the blueshifted lobe may have been contaminated by confusion with another bipolar flow source in the same field of view (Moriarty-Schieven and Wannier 1991). Finally, from a theoretical point of view, the original large-disk models have severe energetic problems (Shu et al. 1987a; Pringle 1989a).

Recently, a number of different groups have attempted to salvage the disk model by postulating smaller and less massive disks, with the bulk of the wind emerging from radii much closer to the central star. This revised picture, however, suffers from the lack of a plausible injection mechanism. The paper by Blandford and Payne (1982) illuminates the basic difficulty.

Blandford and Payne consider a thin disk threaded by a poloidal magnetic field \mathbf{B} in which rotation balances the radial component of gravity. If \mathbf{B} has sufficient strength and a proper orientation, it can fling to infinity electrically conducting gas from the top and bottom surfaces of the disk. A freely sliding bead on a rigid wire anchored at one end to a point ϖ in a disk rotating at the angular velocity $\Omega_{\text{disk}}(\varpi)$ provides a useful analogy (Henriksen and Rayburn 1971). In such an analogy, the termination of the wire at the free end corresponds to the Alfvén surface, beyond which the magnetic field can no longer enforce corotation, even approximately, and the super-Alfvénic fluid motion becomes essentially ballistic. For the flinging effect to take place in a Keplerian disk (one in which all of the gravitational attraction comes from a central mass point), the poloidal field must enter or leave the disk at an angle larger than 30° from the normal. (The component of the centrifugal force parallel to the field [wire] in the meridional plane has no excess compared to gravity if the field [wire] makes too small an angle with respect to the rotation axis, e.g., if it points vertically through the disk.) However, the magnetic field on the two sides of a disk cannot *both* bend outward by a nonzero angle without generating a large kink across the midplane of the disk, one that would result in a very large $\nabla \times \mathbf{B}$, and which would yield, by Ampere's law, a very large current (infinitely large in a disk of infinitesimal thickness). The Lorentz force per unit volume,

$$\mathbf{f}_L = \frac{1}{4\pi} (\nabla \times \mathbf{B}) \times \mathbf{B} \quad (2)$$

needed to produce order-unity departures from Keplerian motion above the disk (in order to drive a wind) must then have even bigger values inside the disk. The tendency for the field lines to want to straighten vertically (thereby shutting off the magneto-centrifugal acceleration) can be offset only by a heavy radial inflow through the disk, maintained, for example, by ambipolar diffusion in the presence of sub-Keplerian rotation inside the disk (Konigl 1989). Sub-Keplerian rotation everywhere in the disk necessitates the continuous removal of angular momentum from it (the role of the wind), but the postulated deficit of centrifugal support in the disk then works against lift-off of the gas in the first place. Indeed, no one has yet succeeded in constructing a self-consistent cool model of this type, demonstrating a smooth connection from the region of the sonic transition (near the disk surface) to the region of the Alfvénic transition (far from the disk surface).

Blandford and Payne themselves adopt another strategy. They accept the conclusion that the symmetry of a disk geometry naturally forces any poloidal magnetic field to thread vertically through the midplane of the disk, from where it *gradually* bows outward (see Fig. 4). To lift the material off the disk

Figure 4. A schematic representation of a possible field geometry close to the disk (figure from Blandford and Payne 1982).

to heights where the magnetic field bends over sufficiently for the magneto-centrifugal mechanism to operate, they invoke the thermal pressure of a hot corona above (and below) the disk. In other words, their final model starts off as a *thermally driven wind*. A hot gas with thermal speeds comparable to the virial speeds characteristic of the depth of the gravitational potential in the inner parts of a protostellar disk, however, suffers tremendous radiative losses at the injection densities needed to supply the observed mass outflows. While astrophysical systems with highly luminous compact objects at their centers, such as active galactic nuclei or binary X-ray sources, might well provide sufficient energy to sustain analogous radiative losses, we cannot expect the same bounty from the central machine of protostellar systems (cf. the discussion of DeCampli [1981] that even the relatively low-powered T Tauri winds cannot be thermally driven).

In summary, at radii $\gtrsim 10^{17}$ cm, disks *can* maintain thermal speeds that compete with the local virial speeds, but such regions lack enough rotational energy to drive the observed flows. Greater centrifugal power exists at smaller radii, but lift-off from the disk then requires an unidentified nonthermal injection mechanism. Compounding these difficulties is the unlikelihood of strong magnetic fields in thin disks. Recall that the energy density of the field at the Alfvén surface must equal the kinetic energy density of a wind flowing close to its terminal velocity. But magnetic buoyancy effects probably limit the generation of fields by dynamo mechanisms acting within disks to energy densities comparable to or less than the prevailing thermal values (Stella and Rosner 1984). The inability of disks to retain large *toroidal* fields (Parker 1966; Matsumoto et al. 1988) limits the viability of mechanisms like those of Lovelace et al. (1991) that rely on the pressure gradient of such fields in the z -direction for the initial vertical acceleration of the gas.

Other theoretical arguments suggest that disk fields must be weak. Umebayashi and Nakano (1988) have computed the ionization state of a minimum-mass solar nebula. The large nebular densities encountered even in a minimum-mass model lead to very low ionization fractions, so low that magnetic fields would be safely decoupled by several orders of magnitude from the nebular gas throughout the disk, except for the innermost and outermost regions. Even in disks where Ohmic dissipation and ambipolar diffusion do not present severe obstacles, difficulties exist in supposing that magnetic fields acquire strengths sufficient to drive the observed outflows. For example, if accretion disks owe their viscosity to the powerful MHD instability recently discussed by Balbus and Hawley (1991) and Hawley and Balbus (1991), the *poloidal* component of the field cannot have energy densities much higher than thermal gas values. Indeed, the instability itself may serve as one of the ingredients of a self-consistent dynamo mechanism responsible for generating the poloidal component of the disk field in the first place. In addition, dynamically strong fields (energy densities comparable to that contained in the *rotation* of the part of the disk supplying the matter for the outflow) cannot have been dragged in and amplified by lightly ionized gas that collapsed from interstellar dimensions by ambipolar diffusion (see Sec. IV below), because mass infall at rates and speeds (free-fall) comparable to the inferred outflow values had to overcome the interstellar field to form the disk in the first place. Finally, even if we could surmount the above problems and drive a disk wind, we would *still* be left with an angular-momentum problem for the accreting central star (cf. the discussion in Sec. V). For all of these reasons, we believe that Snell et al. (1980) intrinsically had the right idea when they speculated that *stellar winds* must constitute the basic driver for bipolar outflows in young stellar objects.

The issue then reverts to the original question: how can stellar winds drive the observed molecular outflows when the *ionized* component lacks the requisite power? Many researchers arrived independently at the obvious answer: perhaps young stellar objects possess *neutral* winds that supply the missing momentum input. Detection of fast neutral winds would require the spectroscopic observation of broad and shallow radio emission lines, a difficult task because so little mass resides within the telescope beam at any particular time. Nevertheless, the search for *atomic* hydrogen winds has now succeeded in at least three sources: HH 7–11, L1551, and T Tau (Lizano et al. 1988; Giovanardi et al., in preparation; Ruiz et al. 1991). Fast neutral winds are also indicated through the detection of CO moving at velocities of ± 100 to 200 km s^{-1} in HH 7–11 and several other sources (Koo 1989; Margulis and Snell 1989; Masson et al. 1990; Bachiller and Cernicharo 1990; J. E. Carlstrom, personal communication). The mass-loss rate measured in HH 7–11 is especially impressive, $\dot{M}_w \approx 3 \times 10^{-6} M_\odot \text{ yr}^{-1}$, more than sufficient to drive the known bipolar molecular outflow associated with this source. Thus, the discovery of massive neutral winds from (low-mass) protostars solves one of the principal remaining mysteries concerning bipolar outflows, namely, the

ultimate source for their power. However, this empirical discovery pushes to the fore another puzzling question: how and why are stars born by *losing* mass at such tremendous rates?

IV. ROTATING, MAGNETIZED, MOLECULAR CLOUD CORES

A major breakthrough occurred in the field when Myers and Benson (1983) identified the sites for the birth of individual sunlike stars in the Taurus cloud as small dense cores of dust and molecular gas that appear as especially dark regions in the Palomar sky survey or as regions of NH_3 and CS emission (cf. the references in Evans 1991). One theory for the formation of such cores begins with the view that large molecular clouds are supported by a combination of magnetic fields and turbulent motions (see Shu et al. 1987*a*; Myers and Goodman 1988*a, b*). Because magnetic fields directly affect only the motions of the charged particles, magnetic support of the neutral component against its self-gravity arises only through the friction generated when neutrals slip relative to the ions and field via the process of ambipolar diffusion (Mestel and Spitzer 1956). This slippage occurs at enhanced rates in localized dense pockets where the ionization fraction is especially low. As the field diffuses out relative to the neutral gas, the Alfvén velocity $B/(4\pi\rho)^{1/2}$ drops, and the turbulence must also decay if fluctuating fluid motions are to remain sub-Alfvénic. Thus, both processes—field slippage relative to neutrals and the lowering of turbulent line widths in regions of increasing mass-to-flux—reinforce the tendency for quiet dense cores to separate from a more diffuse common envelope.

Assuming axial symmetry (no φ dependence) in spherical polar coordinates (r, θ, φ) as well as reflection symmetry about the midplane $\theta = \pi/2$, Lizano and Shu (1989) performed detailed ambipolar diffusion computations, using the ionization balance calculations of Elmegreen (1979*b*) and including empirically the effects of turbulence with the scaling laws found by radio observers (cf. Chapters by Blitz, by Lada et al. and by McKee et al.). They find that the time to form NH_3 cores, $\sim 10^6$ to 10^7 yr, and the additional time to proceed to gravitational collapse, a few times 10^5 yr, agree roughly with the spread in ages of T Tauri stars in the Taurus dark cloud (Cohen and Kuhi 1979) and with the statistics of cores with and without embedded infrared sources (Fuller and Myers 1987). Toward the end of its quiescent life, a molecular cloud core tends to acquire the density configuration of a (modified) singular isothermal sphere:

$$\rho(r, \theta) = \frac{a_{\text{eff}}^2}{2\pi Gr^2} Q(\theta) \quad (3)$$

where a_{eff} is the effective isothermal sound speed, including the effects of a quasi-static magnetic field \mathbf{B}_0 and (as modeled) an isotropic turbulent pressure. The dimensionless function $Q(\theta)$, >1 toward the magnetic equator and <1 toward the poles, yields the flattening that occurs because the magnetic field

contributes no support in the direction along \mathbf{B}_0 . We define $Q(\theta)$ so that it has a value equal to unity when averaged over all solid angles, i.e.,

$$\int_0^{\pi/2} Q(\theta) \sin \theta \, d\theta = 1 \quad (4)$$

hence, a_{eff}^2 in Eq. (3) gives the angle-averaged contributions of thermal, turbulent and magnetic support.

Myers et al. (1991a) have used statistical arguments to deduce that many cloud cores have prolate, rather than oblate, shapes. They note that this result poses difficulty for the above view that cloud cores represent quasi-equilibrium structures in which quasi-static (poloidal) magnetic fields play an important part in the support against self-gravitation (see also Bonnell and Bastien 1991). Tomisaka (1991) points out that equilibrium clouds with prolate shapes become possible if they possess toroidal magnetic fields of substantial strength. Even without toroidal fields, oblate shapes represent a natural theoretical expectation only if we model the effects of molecular-cloud turbulence as an *isotropic* pressure. If “turbulent” support arises, instead, from the propagation and dissipation of nonlinear Alfvén waves in an inhomogeneous medium (see Arons and Max [1975], as well as the discussion on pp. 36–37 of Shu et al. [1987a]), then the largest amount of momentum transfer might well occur *parallel* to the direction of the mean field \mathbf{B}_0 , rather than perpendicular to it. For example, if ambipolar diffusion causes \mathbf{B}_0 to become nearly straight and uniform, as occurs in the detailed calculations before collapse ensues, then the mean field exerts little stress on average, and the anisotropic forces associated with the fluctuating component $\delta\mathbf{B}$ in total $\mathbf{B} = \mathbf{B}_0 + \delta\mathbf{B}$ may actually cause cloud cores to assume prolate instead of oblate shapes. This tendency for condensations to stretch out along the direction of the mean field would only be enhanced by tidal forces if cloud cores tend to form as individual links on a magnetic “sausage” (cf. Elmegreen 1985a; Lizano and Shu 1989). Bastien et al.’s (1991) study of the fragmentation of elongated cylindrical clouds into such individual links differs from that of Lizano and Shu (1989) in that the former authors ignore magnetic effects and they assume that the core-formation process occurs by dynamical collapse rather than by quasi-static contraction.

Apart from the delicate question of the sense of elongation of the shape function $Q(\theta)$, the prediction (Eq. 3) with regard to the *radial* variation of ρ agrees reasonably well with observations of isolated cores and Bok globules (see, e.g., Zhou et al. [1990b], who comment particularly that the *outer* velocity fields are more representative of quasi-static contraction than dynamical collapse). The solution as written represents an asymptotic result; actual configurations become gravitationally unstable in their central regions before a singular density cusp develops there. However, because the phase of quasi-static contraction produces very high central concentrations in the numerical models, the resulting dynamical behavior would probably closely resemble the inside-out collapse known analytically for the (exact) singular

isothermal sphere without rotation (Shu 1977). Such a collapse solution builds up a central protostar at a rate,

$$\dot{M}_{\text{infall}} = 0.975 a_{\text{eff}}^3 / G \quad (5)$$

that remains constant in time as long as the external reservoir of molecular cloud gas (with a r^{-2} density distribution) continues to last. For L1551, where $a_{\text{eff}} \sim 0.35 \text{ km s}^{-1}$, $\dot{M}_{\text{infall}} = 1 \times 10^{-5} M_{\odot} \text{ yr}^{-1}$.

The solution requires modification in the presence of rotation. Because ambipolar diffusion occurs relatively slowly, one might imagine that magnetic braking has time to torque down the cloud core sufficiently during the quasi-static condensation stage to allow even the direct formation of single stars, without subsequent angular momentum difficulties (see, e.g., Mouschovias 1978). Realistic estimates yield a somewhat different picture. Before the onset of dynamical collapse, magnetic braking can enforce more or less rigid rotation of the core at the angular velocity Ω of its surroundings (Mestel 1965a, 1985; Mouschovias and Paleologou 1981). Once dynamical collapse starts, however, the infall velocities quickly become super-magnetosonic, and any initial angular momentum possessed by a fluid element carries into the interior. In the inside-out scenario presented above, dynamical collapse is initiated while much of the mass still has an *extended configuration*. For example, to contain $1 M_{\odot}$, the wave of falling must typically engulf material out to $\sim 10^{17} \text{ cm}$. Even if such a core were perfectly magnetically coupled to its envelope before collapse, it would typically rotate at too large an initial angular speed Ω to allow the formation of just a single star with a dimension of $\sim 10^{11} \text{ cm}$. The simplest solution to the core's residual angular momentum problem is to form a star *plus a disk*.

Probably as a consequence of cloud magnetic braking, Arquilla and Goldsmith (1986) and Fuller and Myers (1987) find empirically that rotation does not usually play a dynamically important role on scales of a molecular cloud core and larger. This fact suggests the possibility of a perturbational analysis for the dynamical collapse problem (Terebey et al. 1984), with core rotation at an initially uniform rate Ω treatable as a small correction, in the outer parts, to the spherical self-similar solution for the collapse of a singular isothermal configuration. Large departures from sphericity occur only at radii comparable to or smaller than a centrifugal radius,

$$R_C \equiv \frac{G^3 M^3 \Omega^2}{16 a_{\text{eff}}^8} \quad (6)$$

where $M \equiv \dot{M}_{\text{infall}} t$ equals the total mass that has fallen in at time t . Typical combinations of a_{eff} , Ω , and M yield values for $R_C \sim 10^{15} \text{ cm}$.

For $R_* \sim 10^{11} \text{ cm} \ll R_C \sim 10^{15} \text{ cm}$, the bulk of the freely falling matter (on parabolic streamlines because of the nonzero values of the specific angular momentum) does not strike the star directly, but forms a disk of size

$\sim R_C$ that swirls around the protostar. Radiative transfer calculations for the emergent spectral energy distribution in an infall model of this type give quite good fits to the data for IRS 5 L1551, if we choose $a_{\text{eff}} = 0.35 \text{ km s}^{-1}$, $\Omega = 1 \times 10^{-13} \text{ rad s}^{-1}$, and $M = 1 M_\odot$ (Fig. 5).

Fermi is supposed to have remarked that with three free parameters, he could fit an elephant. Figure 5 gives an empirical proof of this claim. Indeed, one can readily discern a tail at millimeter frequencies, attached to a broad back at far- and mid-infrared frequencies, with a $10 \mu\text{m}$ silicate absorption feature separating the shoulder from the head and a $3.1 \mu\text{m}$ water-ice feature defining a tusk. The trunk of the elephant emerges from the droop to optical frequencies, although the models do not reproduce the slight raising of the trunk seen in the data points because they do not properly account for the presence of scattered near-infrared and optical light. By Fermi's standards, then, our failure to catch the trumpet call of the elephant, without the need to introduce additional free parameters, prevents us from claiming a complete victory.

However, we note that the three independent parameters that go into the fits, a_{eff} , Ω , and M , represent an irreducible set from an *a priori* theory, which have fundamental dynamical implications apart from the spectral energy fits. For example, the value $a_{\text{eff}} = 0.35 \text{ km s}^{-1}$ well describes the properties of the core density distribution around L1551 (cf. Eq. [3] and the review of Evans [1991]). The agreement between the size of the spatial maps at millimeter and submillimeter wavelengths (Walker et al. 1990) and at infrared wavelengths (Butner et al. 1991) with the predictions of the radiative-transfer calculations of our model also bodes well for the values of a_{eff} and M , derived in the spectral energy fits on the basis of providing the correct overall optical depth to the central star and the absolute luminosity scale (from protostar theory). Finally, the numerical value of Ω , chosen to fit the depth of the silicate absorption feature, yields a predicted size for the circumstellar disk, $R_C = 42 \text{ AU}$, which compares well with the limits $45 \pm 20 \text{ AU}$ deduced for this source by Keene and Masson (1990) from radio interferometric measurements of the thermal emission from dust grains in the putative disk. More recently, Goodman et al. (1991; see also Menten and Walmsley 1985) report the detection of a velocity gradient $\sim 4 \text{ km s}^{-1} \text{ pc}^{-1}$, localized to the core region of L1551, consistent in magnitude with the model value $\Omega = 1 \times 10^{-13} \text{ s}^{-1}$, although the result may have been contaminated by the velocity shear introduced by the outflow.

A similar modeling of the spectral energy distribution of HH 7–11 suggests that this source also possesses infall at a rate $\dot{M}_{\text{infall}} \gtrsim 1 \times 10^{-5} M_\odot \text{ yr}^{-1}$ (F. C. Adams, personal communication). Our ability to fit the spectral energy distribution of famous *outflow* sources like L1551 and HH 7–11 with pure *inflow* models bears directly on the fundamental paradox of Sec. III. Many of the observed embedded systems (those in stage *c* of Fig. 1) must possess *both* outflow and inflow, with the blowing off of a small polar cap in deeply embedded sources making little difference for the problem of infrared reprocessing in the rest of the infalling envelope. The challenge to observers

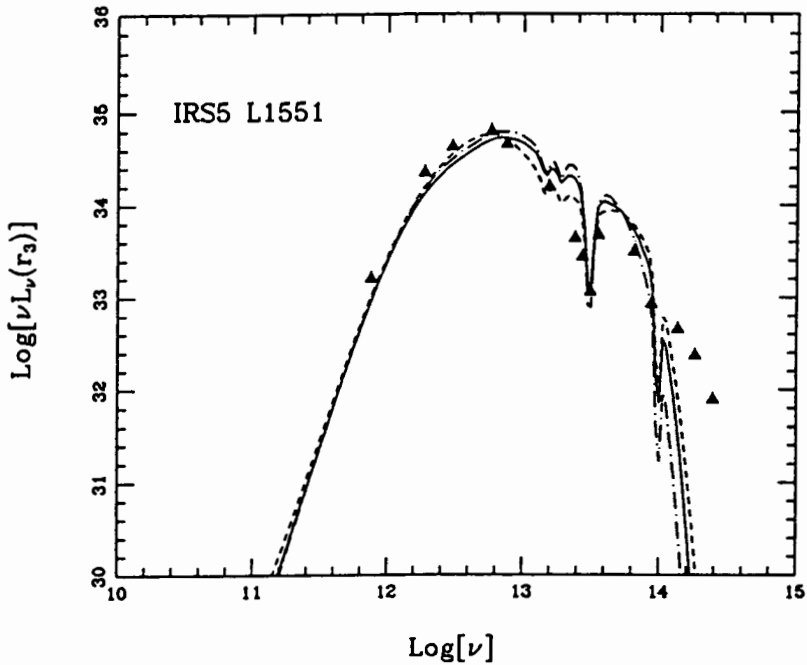

Figure 5. Spectral energy distribution for the bipolar outflow source L1551. The best fit for the data points (solid curve) results from choosing $a_{\text{eff}} = 0.35 \text{ km s}^{-1}$, $\Omega = 10^{-13} \text{ s}^{-1}$, and $M = 0.975 a_{\text{eff}}^3 t / G = 1 M_{\odot}$ (figure from Adams et al. 1987).

is to find spectroscopic evidence, in the low-luminosity sources, for the (rotating) collapse along the equatorial directions in an analogous manner that this task has been accomplished for high-luminosity protostars (see, e.g., Ho and Haschick 1986; Keto et al. 1987; Welch et al. 1987; Rudolph et al. 1990). In any case, here then lies a possible answer to the question: how can a star (SVS 13, the driving source in HH 7–11) form if it loses mass (through a neutral wind emerging from the poles) at the enormous rate $\dot{M}_w = 3 \times 10^{-6} M_{\odot} \text{ yr}^{-1}$? Clearly, a net gain can still take place if the star is being “force-fed” (through the equatorial regions) at a rate \dot{M}_{infall} which is $\gtrsim 3$ times larger yet. This empirical finding answers the “how” of our original question, but it does not address the question “why” a new-born star should be losing mass. A clue to the resolution of the latter issue lies in an examination of the very different way in which a star, in contrast to a disk, may deal with its angular momentum legacy.

V. PROTOSTAR FORMATION BY DISK ACCRETION

Notice that no mass scale that we can identify with stars emerges naturally in the theoretical picture of infall summarized in the previous section. To obtain a stellar mass $M_* \sim \dot{M}_{\text{infall}} t_{\text{infall}}$ from an object (a giant molecular cloud typically), whose characteristic mass scale much exceeds anything that we normally associate with stars, requires us to choose a small total duration t_{infall} (say, 10^5 yr) over which infall occurs. This duration might be set, for example, by the time required for an incipient outflow from the star to completely reverse the inflow. In spherical simulations of protostar formation and evolution (Stahler et al. 1980; Palla and Stahler 1990), the only event of significance to take place on such a time scale concerns the onset of deuterium burning and the establishment of an outer convection zone at the bottom of which the deuterium burns at a rate equal to that which accretion brings in a fresh supply. In low-mass protostars ($< 2 M_\odot$, i.e., precursors to T Tauri stars), deuterium burning occurs only slightly off-center; in intermediate-mass stars (2 to $8 M_\odot$, i.e., precursors to Herbig Ae and Be stars), it occurs in a thin shell. In either case, the important feature is that the process induces an outer convection zone—a condition, when combined with rapid stellar rotation, that Shu and Terebey (1984) speculated would be conducive to dynamo action and to the appearance of strong magnetic fields on the surface of the star.

Calculations by Picklum and Shu (in preparation) demonstrate that accretion through a disk rather than by spherical infall does not modify the above conclusions appreciably, except to lower by a significant factor the emergent photon luminosity for a given rate of mass accretion. The latter effect may alleviate the discrepancies in time scales inferred for embedded protostars and revealed pre-main-sequence stars noted by Kenyon et al. (1990; see also Hartmann et al. 1991).

For star formation via the collapse of a cloud core modeled initially as a uniformly rotating singular isothermal sphere, the fraction of mass that suffers direct infall onto the star compared to that which first lands in the disk equals $1.29 (R_*/R_C)^{1/3}$ (Adams and Shu 1986). This expression yields a small number (several percent) for stars with radii \sim a few R_\odot and disks with radii ~ 10 to 100 AU. The small cross-sectional area of stars in comparison with their disks leads us to expect generically that most of the mass from a collapsing molecular cloud core, which eventually ends up inside the star, must first make its way through the disk (an original point of view argued first by Cameron [1962]; see also Mercer-Smith et al. [1984]).

The process of disk accretion is not well understood in any astrophysical system. The most frequently invoked mechanism involves the inward transport of mass and the outward transport of angular momentum by the friction associated with some form of anomalous viscosity in a differentially rotating disk (see, e.g., Lynden-Bell and Pringle 1974). In the case of the nebular disks that surround young stellar objects, Lin and Papaloizou (1985; see also Ruden and Lin 1986) identified thermal convection in the disk as a

plausible source of the turbulent viscosity, and this may well hold for the optically thick dusty disks believed to surround all classical T Tauri stars. More recently, Balbus and Hawley (1991; see also Hawley and Balbus 1991) have rediscovered a powerful magnetohydrodynamic instability (Chandrasekhar 1960, 1965; Fricke 1969) that afflicts weakly magnetized differentially rotating systems in which the angular velocity of rotation decreases outwards (as occurs in all known astrophysical disks). These developments hold great promise for providing a physical foundation for the central assumption of standard accretion-disk theory that the viscosity has an anomalous magnitude much higher than molecular values (for a review, see Pringle 1981).

However, in the most extreme cases (so-called “flat spectrum sources”; see Sec. VII; the Chapter by Beckwith and Sargent), the far-infrared radiation (relative to the near-infrared values) exceeds by a factor approaching 10^3 , the value one would have naively predicted by the steady-state viscous model (Adams et al. 1988). The observed disks also have masses, as estimated from their submillimeter and millimeter emission, that compare favorably with those contained in the central stars (Adams et al. 1990; Beckwith et al. 1990; Keene and Masson 1990).

The above considerations suggest an interesting scenario for protostellar disk accretion (see also Chapter by Adams and Lin). The overall time scale for viscous transport of mass and angular momentum scales roughly as

$$t_{\text{vis}} \sim \alpha^{-1} (R/H)^2 t_{\text{rot}} \quad (7)$$

where (R/H) equals the aspect ratio of the disk (radius to vertical scale height), t_{rot} is the rotation period at the outer edge of the disk, and α is a dimensionless parameter in the so-called “alpha” prescription for the anomalous viscosity. For application to nebular disks, typically, $R/H \gtrsim 10$, $t_{\text{rot}} \sim 10^3$ yr, and $\alpha < 1$ (e.g., $\alpha \sim 10^{-2}$ in the convection models of Ruden and Lin [1986]); thus, $t_{\text{vis}} > 10^5$ yr. The statistics of disks around classical T Tauri stars sets a lifetime of $\sim 10^6$ to 10^7 yr (see Chapter by Strom et al.). This represents only a lower limit for t_{vis} because the disappearance of near-infrared radiation only implies the disappearance of small dust particles surrounding the central star, and not necessarily the viscous transport of all of the material, gas and dust, from the entire disk.

Suppose rotating infall piles matter into the disk faster than viscous accretion can transfer it to the central star. (Models for the main accretion phase of low-mass protostars suggest that $M/\dot{M} \sim 10^5$ yr.) The disk would then build up mass relative to the star until the disk becomes comparably massive. At this point, strong gravitational instabilities (nonaxisymmetric density waves) may develop in the disk that result, in the nonlinear regime, in the inward transport of mass and the outward transport of angular momentum. The energy dissipation associated with this “wave dredging” differs, however, from the viscous mechanism, and we might expect to see a different resultant radial distribution of temperature in the disk and a different emergent spectrum

(see Sec. VII). In particular, for the transport to occur *globally* (as indicated by the observations of flat-spectrum sources), from the star-disk interface to the outer edge of the disk $\sim 10^4$ times larger, we can restrict our search of unstable modes in nearly Keplerian disks to one-sided disturbances, in which circular streamlines distort to elliptical ones with foci at the star (Adams et al. 1989).

Unless such instabilities run away catastrophically to form a companion star (a possible origin for binary systems), we may speculate that they self-regulate the amount of mass in the disk during the infall phases (Fig. 1*b*, and *c*) so that it never consists of a large fraction of the total. Thus, we expect that some appreciable fraction f_1 of the total infall rate onto the system (mostly onto the disk), \dot{M}_{infall} , must make its way through the disk at an accretion rate \dot{M}_{acc} , eventually to be deposited onto the star,

$$\dot{M}_{\text{acc}} = f_1 \dot{M}_{\text{infall}}. \quad (8)$$

As the detailed calculations of Adams et al. (1989) demonstrate, disks with temperature profiles consistent with the observational requirements suffer a strong one-armed spiral instability (see Fig. 6) if they have masses equal, say, to one-half or one-fourth of the total; thus a reasonable estimate for f_1 ranges from 1/2 to 3/4. We emphasize that this estimate for f_1 represents a *time-averaged* value; the instantaneous rate at which mass from the disk actually empties onto the star may suffer large fluctuations about an average value. In particular, the arguments of Sec. VII suggest that disk accretion induced by global gravitational instabilities may have intrinsic tendencies to occur in a nonsteady manner.

VI. STELLAR WINDS AND BIPOLAR FLOWS: THEORY

The matter entering the protostar from the disk at the rate \dot{M}_{acc} carries a relatively large specific angular momentum. For example, compared to the specific angular momentum of disk matter circling in orbit just outside of a star's equator, the angular momentum per unit mass of a uniformly rotating polytrope of index 1.5 (a good model for a fully convective low-mass protostar) is a small number $b = 0.136$, even if the star were to rotate at the brink of rupture (James 1964). Thus, the disk feeds material to the star that contains, per gram, about $b^{-1} \sim 7$ times more angular momentum than can be absorbed dynamically by the star. Hence, once the star begins to accrete matter from a centrifugally supported disk, it can increase its mass M_* , at most, only by an additional small fraction b before it reaches breakup. In practice, the star may be able to accept even less matter from the disk because even the matter accumulated by the star through direct infall carries nonzero values of specific angular momentum (see, e.g., Durisen et al. 1989*b*).

As the mass that can be accumulated by a star through direct infall from a realistically rotating molecular cloud core amounts to only several percent

Figure 6. Contour plot of the lowest-order, growing, $m = 1$, mode in a star/disk system where the disk's mass equals the star's mass, but the disk's radius is 10^4 times larger than the star's radius (figure from Adams et al. 1989).

of a solar mass, and as the additional amount that can be accreted from a disk amounts to a small fraction of this tiny value, how do stars of sunlike masses and larger ever form?

Paczynski (1991) and Popham and Narayan (1991) calculated star plus disk models where the star, spun to (slightly faster than) breakup, can viscously transport angular momentum to an adjoining disk, and thereby continue to accrete an indefinite amount of mass. This model presumes the existence of a sufficiently efficient viscous coupling between star and disk as to transport away the excess specific angular momentum (above the fraction b) brought in by disk accretion, an assumption that may not hold if the mechanism of disk accretion is gravitational rather than viscous. In any case, their mechanism of continuous outward angular-momentum transport cannot work for T Tauri stars, which are observed to rotate at speeds significantly less than breakup. Furthermore, the almost ubiquitous presence of energetic bipolar flows among deeply embedded sources suggests that quiescent viscous torques do not provide the primary source of relief for the angular momentum difficulty of protostars in their main accretion phase.

Such objects evidently find a more spectacular way of shedding the excess angular momentum brought in by disk accretion. Shu et al. (1988) proposed that the protostar could fling off the excess in a powerful wind once the

protostar gets spun to breakup by the disk, if the star possesses sufficiently strong surface magnetic fields (see also Hartmann and MacGregor 1982).

Schematically, the process works as follows. Like other rotating stars with outer convection zones, a protostar probably has a network of open and closed magnetic field lines that protrude from its surface (Fig. 7). An ordinary (ionized) stellar wind blows out along the open field lines; this *O*-wind may have a higher intensity than that characteristic of a normal star of the same spectral type, luminosity class, and rotation rate, because of the enhancement of stellar dynamo action associated with circulation currents induced by the disk through Ekman pumping (see Sec. VII).

Figure 7. Schematic model for heavy mass-loss driven magnetocentrifugally from the equator of a protostar which is forced to rotate at breakup because of accretion through a Keplerian disk. All streamlines to the right of the critical equipotential (marked as a dashed curve) correspond to possible "downhill" paths for electrically conducting gas attached to magnetic lines of force that rotate rigidly with the star. The large slip velocities present in the interfaces between the *X*-wind and the *O*-wind and between the *X*-wind and the disk may lead to turbulent mixing layers that have observable radiative signatures (figure adapted from Shu et al. 1988).

If open field lines circulate into the equatorial regions of the protostar, which spins at breakup by assumption, the *O*-wind may intensify even more via the *X*-celerator mechanism (Shu et al. 1988) and become an extraordinary wind. The magneto-centrifugal acceleration in the *X*-wind takes place much as described in Sec. III on the Blandford-Payne mechanism for disk winds, except that the geometry here no longer selects against field lines (equivalent

to streamlines for a conducting gas) that emerge in the “downhill” directions of the effective (corotating) potential. To carry away the requisite mass-loss rate \dot{M}_w , the sonic transition of the X -wind must occur typically in the photosphere of the star, where the material, being cool, has a relatively low ionization fraction. Thus, the X -wind is predominantly a *neutral* or *lightly ionized* wind (Natta et al. 1988; Ruden et al. 1990).

Consider the quasi-steady state wherein spinup by disk accretion at a rate \dot{M}_{acc} is balanced by spin-down via a magnetized stellar wind at a rate \dot{M}_w in such a way that at each stage of the process the star continues to rotate exactly at breakup. Suppose the specific angular momentum carried away in the X -wind, measured as an average over all mass-carrying streamlines, equals some multiple \bar{J} of the specific angular momentum of the material in circular orbit at the equator of the star. If we further assume the equatorial radius to be proportional to the stellar mass, as roughly true for a star actively burning deuterium at its center, we find that the requisite mass-loss rate \dot{M}_w equals some fraction f_2 of the disk accretion rate \dot{M}_{acc} (cf. Eq. 1 of Shu et al. 1988):

$$\dot{M}_w = f_2 \dot{M}_{\text{acc}} \quad \text{with} \quad f_2 = \frac{1 - 2b}{\bar{J} - 2b} \quad (9)$$

where $b = 0.136$ is the pure number defined earlier. (If only the equator of the protostar rotates near breakup, the effective value of b that appears in Eq. [9] could be [much] smaller.) To derive the above expression for f_2 , we have assumed that all of the excess angular momentum brought in by accretion above that needed to keep the star exactly at breakup is carried away by the wind, i.e., that none of it is viscously transported to the disk.

The extent by which \bar{J} exceeds unity depends on the strength of the stellar magnetic field in the neighborhood of the X -point of the equipotential. For escaping streamlines to have a finite terminal velocity v_w at infinity, the (rotating) magnetic field lines must exert sufficient torque as to make \bar{J} exceed $3/2$. For example, in order for the terminal velocity of the X -wind to have a measured value equal to the breakup speed at the equator of the star (typically $\sim 150 \text{ km s}^{-1}$ for low-mass protostars), \bar{J} must have a value at least equal to 2. In fact, because some of the angular momentum is asymptotically carried away by magnetic stresses rather than all by the fluid, detailed numerical calculations suggest that the actual needed value of $\bar{J} \sim 3.6$, implying a fiducial value for $f_2 \sim 0.2$. Combining Eqs. (8) and (9), we now obtain a relationship between inflow and outflow rates,

$$\dot{M}_w = f \dot{M}_{\text{infall}} \quad (10)$$

with $f \equiv f_2 \sim 0.1$ to 0.2 typically, in very rough agreement with the observations.

On the other hand, if the magnetic field emerging from the neighborhood of the X -point of the effective potential had infinite strength, X -wind gas would be flung to infinity in the entire sector from the equator to the critical

equipotential surface (the dotted curve in Fig. 7). Because this equipotential surface (the last rigid “wire” to which an attached bead could still slide “downhill”) bends up to turn asymptotically parallel to the rotation axis of the star (at a radius $= \sqrt{3}R_c$), the strong X -wind could act to focus and collimate an otherwise isotropic and more mild O -wind into an (ionized) optical jet (one on each side of the equator).

Figure 8. Spreading of streamlines for an X -celerator driven wind in the meridional plane, computed in a frame that corotates with the star. The bottom-most streamline has been constrained to flow horizontally across the surface of a perfectly flat disk; the uppermost streamline has also been taken to be straight for sake of simplicity. In a more realistic model, the slip interfaces between the X -wind and the O -wind and between the X -wind and the disk surface are likely to be turbulent. A dashed curve marks the Alfvén surface, where the magnetic stresses no longer dominate over the gas inertia. The dotted curve marks the location of the critical equipotential surface that, together with its counterpart in the lower half of the diagram (not drawn), crosses the stellar surface at an X -point. (figure from Shu et al., in preparation).

For stellar magnetic fields of finite strength, the situation becomes more complicated. The method of matched asymptotic expansions provides a tractable approach to the resultant magnetohydrodynamic problem if we adopt the assumption of axial symmetry (Shu et al. 1991). Figure 8 gives a sample solution for a case with a dimensionless stellar field strength that produces Alfvén crossing at a distance equal to one additional stellar radius from the equator of the star. In this calculation, we have used upper and lower boundary conditions that artificially constrain the limiting streamlines, $\psi = 0$ and $\psi = 1$, to be perfectly straight (see below). Interior to the Alfvén surface defined by $\mathcal{A} = 0$, where \mathcal{A} is an Alfvén discriminant, the stream function ψ satisfies an elliptic partial differential equation:

$$\nabla \cdot (\mathcal{A} \nabla \psi) = \mathcal{Q}. \quad (11)$$

This equation has the formal structure of steady-state heat conduction; here, however, we are concerned with the spreading of streamlines, and not the spreading of heat. The source term \mathcal{Q} responsible for streamline spreading in the meridional plane equals a sum of three terms that are each proportional to the derivatives (across streamlines) of quantities that are conserved along streamlines: Bernoulli's constant $H(\psi)$, the ratio of magnetic and mass fluxes $\beta(\psi)$, and the specific angular momentum carried in both matter and field $J(\psi)$. Smooth passage through the sonic transition near the X -point of the effective potential yields $H(\psi)$; for the part of the problem much beyond the immediate neighborhood of the X -point of the critical equipotential, $H(\psi)$ goes to 0 in the limit of a cold flow. The requirement that the flow accelerates smoothly through the Alfvén surface, $\mathcal{A} = 0$, places a constraint on the normal derivative of ψ , $\nabla \mathcal{A} \cdot \nabla \psi = \mathcal{Q}$, that determines the spatial location and shape of the Alfvén surface and the functional form of $J(\psi)$ if we are given $\beta(\psi)$. In other words, the geometry of the problem is entirely determined if we know the strength of the stellar magnetic field and the way that mass is loaded onto the open field lines at the equatorial belt of the protostar.

For the dimensional parameters that approximately apply to HH 7–11 or L1551, we find that a poloidal speed of $\sim 150 \text{ km s}^{-1}$ (corresponding to $\bar{J} \sim 3.6$) can be achieved at the Alfvén surface when the equator of the protostar has open photospheric magnetic fields of the strength ~ 4 kilogauss. Such fields appear reasonable if we extrapolate from the product of field strength and filling factor, 1 to 2 kilogauss, inferred for weak-line T Tauri stars by Basri and Marcy (1991) from the Zeeman broadening of spectral lines with high Landé- g factors.

It may be informative to elucidate why we believe the X -celerator mechanism to work for a star, but not for a disk (Sec. III). To carry the observed mass-loss rate, the density of the wind at the sonic surface must be large, close to photospheric values. Thus, the sound speed is low, and the sonic transition can occur only near X -points where the effective gravity vanishes, because in a frame which corotates with the footpoint of the magnetic field, the magnetic stresses cannot help the gas make a sonic transition (see Eq. [3] of Shu et al. 1988). On the other hand, if the gas is to continue to accelerate to higher speeds by magneto-centrifugal flinging after having made the sonic transition, the Lorentz force must be able to overcome both inertia and gravity. Because the densities are very high at the sonic surface, a smooth transition from a gas-pressure driven flow to a magnetohydrodynamically driven flow requires either the magnetic field \mathbf{B} , or its curl, $\nabla \times \mathbf{B}$, to be large, or both (cf. Eq. [2]). The geometry of a thin disk requires $\nabla \times \mathbf{B}$ to be large, but to keep the gas sub-Alfvénic in the post-sonic-transition region, \mathbf{B} also has to be large. This combination proves fatal, we believe, to disk-wind models in the protostellar context.

An X -celerator driven wind from a protostar (or star-disk interface) fares better, because we require only \mathbf{B} to be large, and we can relatively easily believe that magnetic fields *rooted in the deep convection zones of a rapidly*

rotating star could achieve the requisite values. High-mass stars that lack outer convection zones have greater theoretical difficulty generating surface magnetic fields, although the instability mechanism discussed by Balbus and Hawley (1991; see also Fricke [1969] for specific application to the case of stars) offers a promising mechanism for such objects to generate moderate-to-small magnetic fields provided only that they suffer differential rotation of dynamical significance for the structure of the star (with Ω decreasing radially outward). Indeed, X-celerator driven winds in such a situation may offer an explanation why the terminal velocities of winds from high-mass protostars have such low values (100 to 200 km s⁻¹) in comparison with the high values (1000 to 2000 km s⁻¹) that characterize (probably radiation-driven) winds from main-sequence and evolved stars of early spectral type (see, e.g., Chiosi and Maeder 1986).

Figure 9. Field lines (dotted curves) and trajectory of a fluid element (dashed curve) for an X-celerator driven wind in the equatorial plane of an inertial frame of reference. The protostar rotates in a counter-clockwise sense, so that open field lines form spirals that trail in the sense of rotation. The dashed circle marks the location of the Alfvén surface in a calculation where we have explicitly assumed axial symmetry (figure from Najita et al., in preparation).

In Fig. 9, we plot magnetic field patterns and fluid trajectories of the flow in the equatorial plane of our X-celerator model. In a frame that rotates with the same angular speed as the star, streamlines and field lines coincide (dotted curves). In a stationary frame, however, the trajectory of an element of electrically conducting gas takes the form indicated by the dashed curve. The fluid element starts by making a sonic crossing close to the photosphere of the star. The acceleration to sonic speeds (7 or 8 km s⁻¹ typically) can occur purely by the outward push of photospheric gas pressure in a small equatorial belt where the effective gravity nearly vanishes because we have assumed that the protostar rotates at breakup speeds. As the open magnetic

line of force to which the gas is tied rotates in a counter-clockwise direction with the star, the excess rotation (above local Keplerian values) enforced by the field accelerates the gas along the field line (with negligible slip for the typical degrees of ionization computed by Ruden et al. [1990]), until the gas reaches the Alfvén velocity at the position of the dashed circle. At this point, if the gas speed exceeds the local escape velocity by a significant margin, the Alfvén speed will also typically equal a healthy fraction (say, $\sim 90\%$) of the final terminal speed. Because the magnetic field does not have infinite strength, it cannot keep the gas corotating indefinitely with the star, and the pattern of field lines (in either the rotating or inertial frame) form trailing spirals. The field lines and streamlines form a similar lagging pattern at other latitudes, except that they climb in the vertical direction (toward the rotational poles) as the gas flows away from the protostar.

As already mentioned, the boundary conditions in Fig. 8 on the uppermost and bottom-most streamlines have been taken to be perfectly straight so as not to bias the results for the interior. When we do this, the intermediate streamlines have a tendency also to remain straight, with the gas at higher latitudes having larger densities and slower terminal speeds (for a magnetic field distribution that starts off approximately uniform at the sonic surface). We are currently trying to compute the amount of bending which takes place when the shape of the upper streamline is left more realistically as a free boundary (pressure balance between an *X*-wind and an *O*-wind). When such a calculation becomes available, we will be able to estimate the degree of collimation of the *X*-wind; in particular, we will be able to compute the angle dependence $P(\theta)$ of the rate of momentum injection (needed for any *a priori* calculation of the shapes of the swept-up shells of molecular gas):

$$\frac{\dot{M}_w v_w}{4\pi} P(\theta). \quad (12)$$

Even without detailed knowledge of $P(\theta)$, a simple order of magnitude estimate using the theory developed so far yields the velocity of the swept-up bipolar lobes of molecular gas roughly as the geometrical mean between the terminal speed of the wind v_w and the effective sound speed of the ambient molecular cloud core a_{eff} (Shu et al. 1991; see also Chapter by Königl and Ruden). For v_w measuring hundreds of km s^{-1} , and a_{eff} ranging from a fraction of a km s^{-1} (low-mass cores) to greater than 1 km s^{-1} (high-mass cores), we would then predict typical lobe speeds $\sim (v_w a_{\text{eff}})^{1/2} \sim 10 \text{ km s}^{-1}$, in rough agreement with the observations.

For well-collimated flows, $P(\theta)$ will have values larger than unity for a small range of angles θ near the two poles, 0 and π . Our previous discussion leads us to suspect that younger sources, which may have stronger magnetic fields, possess more highly collimated outflows. We speculate that as the sources age, their rotation speeds progressively fall below the critical rate (see Sec. VII), their magnetic fields weaken, and their outflows fan out more in

polar angle and sweep out an increasingly greater solid angle of the overlying envelope of gas and dust. In this fashion may the protostars in stage *c* of Fig. 1 become optically revealed as the T Tauri stars of stage *d*.

VII. REVEALED T TAURI STARS

The ability to study T Tauri stars at optical and near-infrared wavelengths has yielded tremendous observational dividends. Foremost in importance among the discoveries of the past decade has been the realization that many of the photometric and spectroscopic peculiarities (variability, strong emission lines, infrared and ultraviolet excesses, strong outflows) long known to characterize these systems (cf. the reviews of Herbig 1962*b*; Kuhi 1978; Cohen 1984; Imhoff and Appenzeller 1987; Bertout 1986, 1989; Appenzeller and Mundt 1991) may owe their explanation to the presence of circumstellar disks. Several independent lines of evidence lead to the conclusion that circumstellar disks surround many young stellar objects, e.g., the large polarizations often seen in these sources (Elsasser and Staude 1978; Bastien and Menard 1988; Bastien et al. 1989), or the asymmetry of forbidden O I line profiles (Appenzeller et al. 1984; Edwards et al. 1987), or the motions of SiO masers (Plambeck et al. 1990). Here, however, we shall concentrate on the nature and implications of the infrared and ultraviolet excesses in T Tauri stars.

We begin with the ultraviolet excess (Kuhi 1974; Herbig and Goodrich 1986), which has been plausibly linked by Hartmann and Kenyon (1987*a*), and Bertout et al. (1988) to the action of a boundary layer between the star and the disk (see also Chapter by Basri and Bertout). For a conventional boundary layer to arise (gas heated to high temperatures by the frictional rubbing of a rapidly rotating disk against a slowly rotating star), a disk must abut the star.

Cabrit et al. (1990; see also Chapter by Edwards et al.) find an interesting correlation between the strength of the near-infrared excess (a measure of the amount of disk just beyond the boundary layer) and the strength of H α emission (a measure of T Tauri wind power). Systems inferred to be missing inner disks (radii equal to a few stellar radii) exhibit relatively little wind power (weak-line T Tauri stars), whereas systems with appreciable inner disks have relatively strong winds (classical T Tauri stars). As millimeter and submillimeter investigations reveal no strong biases with respect to the question of whether weak-line and classical T Tauri stars possess outer disks (radii equal to thousands of stellar radii), Edwards and her colleagues interpret their finding to imply that pre-main-sequence and protostellar winds are driven by disk accretion (one that extends virtually right up to the surface of the star). At first sight, this interpretation seems to bode well for the *X*-celerator theory, which pinpoints the interface between star and disk as the source of the wind. In particular, theories that use self-similar solutions for disk winds (Blandford and Payne 1982; Konigl 1989) have a difficult time explaining why missing just a small portion (the innermost part) of a disk should completely change the nature of the solution. However, a deeper probing of the T Tauri results

shows that they also pose a severe problem, potentially fatal, for *X-celerator* models.

For the *X-celerator* model of Sec. VI to work, we need to posit that the equator of the star, to which the open magnetic field lines are tied, rotates at breakup. The very fact that T Tauri stars possess boundary layers (if this is the correct interpretation for the ultraviolet excess) demonstrates, however, that their equatorial regions are not rotating at breakup. Even more damaging, direct spectroscopic investigation shows that most T Tauri stars rotate at speeds about an order of magnitude *slower* than breakup (Vogel and Kuhi 1981; Bouvier et al. 1986a; Hartmann et al. 1987; see the review of Bouvier 1991). Yet, Edwards et al. (see also Chapter by Hartmann et al.) deduce that T Tauri stars also satisfy an inflow-outflow relationship of the form of Eq. (9), $\dot{M}_w = f_2 \dot{M}_{acc}$, with f_2 numerically not very different from the value that we have deduced from *X-celerator* theory ($f_2 \sim 0.2$).

How can we resolve the discrepancy? Galli and Shu (in preparation) propose that a partial solution may be found by asking how an accretion disk actually tries to spin up a slowly rotating star. Their answer involves, not the inward diffusion of vorticity as in the models of Paczynski (1991) and Popham and Narayan (1991), but *Ekman pumping*. The mathematics for Ekman pumping is fairly involved; however, the basic physics is simple, and easily explained by analogy to spinup in a cup of tea.

Suppose we place a cup of tea on a turntable spinning at angular speed Ω , and we ask how long it takes for the liquid, initially at rest, to spin up to the same angular speed as the boundaries of the cup. If spinup occurred by the diffusion of vorticity from the boundary layer to the interior, the theoretical answer, in order of magnitude, would be given by the familiar formula:

$$t_{diff} \sim L^2/\nu \quad (13)$$

where L represents the typical dimension of the cup, and ν gives the kinematic viscosity of tea. Putting in characteristic numbers, we would deduce $t_{diff} \sim$ tens of minutes. In fact, the actual spinup time empirically measures more in the neighborhood of tens of seconds, and is theoretically given as the geometric mean between the viscous diffusive time scale Eq. (13) and the overturn time scale Ω^{-1} :

$$t_{spinup} \sim (t_{diff}/\Omega)^{1/2}. \quad (14)$$

The formula (14) represents essentially the time that it takes tea to circulate from the interior of the cup to the boundaries, where it can quickly match its rotational speed to that of the cup (Fig. 10a). In other words, Ekman pumping sets up a secondary circulation that brings the tea to the boundary layer rather than waiting for the effects of the accelerating agent to diffuse to the interior. Because the bottom of the cup speeds up the tea in contact with it relative to the tea in the interior, the pressure gradient needed to balance

Figure 10. (a) Ekman pumping in a teacup (schematic). A thin Ekman layer δ_{EK} forms above the bounding surface perpendicular to the axis of rotation. (b) Ekman pumping in a T Tauri star modeled via the spinup of a (uniformly rotating) polytrope of index 1.5 with turbulent viscosity estimated by convective mixing-length theory. A secondary circulation pattern sets up in the meridional plane when the star is subjected to a shear stress at its surface that is highly concentrated toward the equatorial plane. The velocity scale corresponds to a model in which $M_* = 0.8 M_\odot$, $R_* = 3 R_\odot$, $\Omega_* R_* = 20 \text{ km s}^{-1}$, and $\nu = 10^{14} \text{ cm}^2 \text{ s}^{-1}$. The radial scale from $0.9 R_*$ to $1.0 R_*$ has been expanded for clarity of display (figure from Galli 1990).

the centrifugal force of rotation differs in the two regions. The difference in pressure distribution outside and inside the boundary layer then pumps the fluid from the former to the latter in such a way as to set up the secondary circulation depicted in Fig. 10a.

We believe an analogous situation to hold for the case of T Tauri stars, except that gravity, in addition to pressure and inertial terms, enters the equation for force balance. Schematically, the presence of an abutting disk tries to spin up the equatorial regions of a star faster than its poles. The excess of centrifugal support in the equatorial regions necessitates less vertical pressure support against gravity there than elsewhere. As a consequence, the unbalanced horizontal pressure gradients will push gas from the surface layers of the rest of the star toward the equator. Continuity requires those streamlines converging onto the equator of the star that do not blow outwards in a wind to

resubmerge into the interior of the star, establishing a circulation pattern that looks as depicted in Fig. 10b.

Figure 10b represents a detailed calculation from Galli's (1990) doctoral thesis of Ekman pumping in a polytrope of index 1.5 (to represent a fully convective star). The calculation, however, contains only one of two possible effects that can lead to a secondary circulation: the *barotropic* response to the spinup induced by the frictional torque of an adjacent disk highly concentrated toward the equatorial regions. The rotational evolution, with $d\Omega/dt > 0$, is assumed to proceed keeping the zeroth-order rotation spatially uniform, which leads to perturbations in the angular speed of the stellar interior that are stratified across cylinders. If the true surfaces of constant Ω in T Tauri stars correspond—as they do in the case of the convection zone of the Sun (Dziembowski et al. 1989)—not to cylinders, but to radial cones, a second effect can arise because the surfaces of constant pressure do not then correspond to surfaces of constant density. In this situation, the *baroclinic* generation and maintenance of meridional mass flow may compete with or even dominate over the barotropic part. In other words, the meridional flows induced by a quasi-steady balance between spinup through a disk and spin-down via a wind may make the application of Fig. 10b to actual T Tauri stars somewhat oversimplified.

Nevertheless, Fig. 10b shows a robust qualitative feature of great importance to our current discussion: the circulation of matter in the photospheric and subphotospheric layers toward the equator. If such layers carry stellar magnetic field lines along with them, then we can easily visualize how open field lines of kilogauss strength might be brought from the rest of the star that rotates slowly (as required to satisfy the spectroscopic observations of T Tauri stars) to an equatorial band that rotates quite rapidly (by definition, at “breakup” when we enter the disk proper). Conceivably, the Doppler imaging (Vogt 1981) of classical T Tauri stars could test whether circulation currents of this geometry cause starspots to migrate toward the equator on time scales (radius of star divided by photospheric circulation speed) of weeks to months. If so, the resulting ejection of matter in a powerful magnetocentrifugal wind along open field lines might then qualitatively proceed, more or less, as we described in Sec. VI for an *X*-celerator-driven flow. As it takes on the order of a day for circulation-driven, inhomogeneous, magnetic structures to migrate through the sonic surface of a wind originating from an equatorial belt equal to a few percent of the radius of the T Tauri star, we can now understand why optical spectral lines believed to be wind diagnostics (in contrast to general photospheric diagnostics) should show profiles that vary wildly on that sort of time scale (G. Basri, personal communication).

The above speculation, that T Tauri winds originate basically in a highly magnetized and rapidly rotating boundary layer, amounts essentially to a compromise solution between a stellar-driven wind and a disk-driven wind. In this compromise, we make use of the known ability of a star to hold onto very strong magnetic fields, and we take advantage of the natural tendency

for disks to possess very rapid rotation. More work, however, needs to be done on this problem before we can claim that we can safely import to this complex situation the main features of the solutions for more simple models.

We should note, however, that *closed* field lines may play a competing role to open ones. If stellar circulation currents force closed field lines of sufficient strength to thread through the disk (a process made easier at a late stage when the disk accretion rate onto the star drops to small values), and if the star becomes magnetically coupled largely to those parts of the disk that rotate fairly slowly, then we might have another explanation as to why T Tauri stars have projected rotational speeds $v \sin i \lesssim 15 \text{ km s}^{-1}$ (see Konigl [1991]). For this braking mechanism to work, however, the same magnetic torques associated with fields threading the gaseous disk need to empty out much of the rapidly rotating inner portions of the disk, which would otherwise act to spin up the star, rather than spin it down. Weak-line T Tauri stars may represent (evolved) systems missing such inner disks, and it is interesting to note that they do not possess the powerful (*X*-celerator-driven) winds that classical T Tauri stars do.

We turn now to the dynamics of the disk proper, and the origin of the infrared excesses of T Tauri stars. Since the pioneering work of Mendoza (1966,1968), astronomers have known that T Tauri stars emit significantly more infrared radiation than other stars of their spectral type (typically K subgiants). From the start, thermal emission from circumstellar dust has been suspected as the culprit; however, the geometry of the dust distribution remained obscure until Lynden-Bell and Pringle (1974) suggested that it might lie within a viscous accretion disk. In particular, Lynden-Bell and Pringle pointed out that an optically thick disk, vertically thin but spatially extended in distance ϖ from the rotation axis over several orders of magnitude, and possessing a power-law distribution of temperature,

$$T_D \propto \varpi^{-p} \quad (15)$$

would exhibit a power-law infrared energy distribution,

$$\nu F_\nu \propto \nu^n \quad \text{where} \quad n \equiv 4 - \frac{2}{p}. \quad (16)$$

Viscous accretion-disk theory for a system in quasi-steady state predicts $p = 3/4$, i.e., $n = 4/3$.

Rucinski (1985) examined the observational evidence and he concluded that, while the infrared excesses of T Tauri stars did well approximate a power-law distribution, the mean value of n is appreciably smaller than $4/3$ (see also Rydgren and Zak 1987). Adams et al. (1987) noted that the presence of considerable infrared emission without a correspondingly large visual extinction of the central star implies that the circumstellar distribution of dust must exist in orbit in virtually a single plane about the star. In

such a situation, a *non-accreting*, optically thick, flat, and radially extended disk would intercept 25% of the starlight and reprocess it to near- to far-infrared wavelengths, with disk-temperature and spectral-energy distributions also very nearly satisfying Eqs. (15) and (16), except that the coefficient of proportionality would be exactly known. Unshielded large dust particles at a distance r from a star would, of course, have a temperature distribution that satisfies $T_D \propto r^{-1/2}$. However, astronomers believe that young nebular disks are completely thick at optical wavelengths even vertically through the disk, so that starlight cannot shine directly on dust particles by propagating through the midplane, but must come at oblique angles from near the limbs of a star of size R_* . This effect introduces an extra geometrical factor of essentially R_*/r into the relation between absorbed starlight ($\propto [R_*/r]r^{-2}$) and emitted infrared radiation ($\propto T_D^4$), which makes the reprocessing temperature law $T_D \propto r^{-3/4}$ rather than $r^{-1/2}$. To remind ourselves of this important difference between the reprocessing in an opaque flat disk with faces perpendicular to the z direction and in an airless planetary surface with projected area perpendicular to r , we write the former law as $T_D \propto \varpi^{-3/4}$.

Adams et al. (1987) also demonstrated that the few cases of T Tauri systems that did show the canonical value $n = 4/3$ could indeed be explained in terms of *passive* or *reprocessing* disks; whereas, those disks that have the most extreme infrared excesses and, therefore, exhibit the most quantitative evidence for a nonstellar contribution to the intrinsic luminosity, correspond, not to $n = 4/3$, but to $n = 0$ (Adams et al. 1988; see Fig. 11a,b). Flat-spectrum sources with $n = 0$ require $p = 1/2$, i.e., $T_D \propto \varpi^{-1/2}$. A comprehensive survey by Beckwith et al. (1990; see also Chapter by Beckwith and Sargent) fitted temperature power-laws to the infrared excesses of classical T Tauri stars, and found that the derived values for the exponent p range from the extremes $p = 3/4$ (steep-spectrum sources) to $p = 1/2$ (flat-spectrum sources), with more sources having the latter value than the former. Strom claims, however (see his chapter in this volume), that the “flatness” of the spectra of many of the sources disappears if one uses long-wavelength measurements with smaller beams than the IRAS measurements.

Kenyon and Hartmann (1987) proposed that *geometric flaring* in purely reprocessing disks could flatten out the spectral energy distributions of the spatially flat models that predict $n = 4/3$, and thereby remove much of the discrepancy between theory and observation. A greater interception and scattering of stellar photons would also better account for the relatively large fractional polarization detected for some T Tauri stars (Bastien et al. 1989). In contrast, Hartmann and Kenyon (1988) note that the source FU Orionis, which may be undergoing enhanced accretion through a disk (for a dissenting view, see Herbig 1989a), *does* show the canonical value $n = 4/3$ (see also Adams et al. 1987), and they conclude that nebular disks may transfer much, if not most, of their mass onto the central stars through such recurrent episodic outbursts. Finally, Kenyon and Hartmann (1991) conclude that, as a class, many of the FU Orionis variables may still be surrounded, not by flared disks,

Figure 11. (a) A steep-spectrum T Tauri star, SR 9. The dashed curve shows the expected spectrum for a star alone; the solid, for a star plus a spatially flat, but radially extended, disk that locally reprocesses the starlight that falls on it (figure from Adams et al. 1987). (b) A flat-spectrum T Tauri star, T Tau itself. The curves show models (from Adams et al. 1988) for a star plus a spatially flat disk, with the latter heated by stellar photons as well as possessing an intrinsic source of luminosity with a temperature distribution, $T_D \propto \varpi^{-p}$, where $p = 0.515$. The disk extends from the stellar surface to a radius $R_D = 120$ AU, the minimum value needed to fit the extent of the flat portion of the infrared data points (triangles). The actual size also cannot be much larger before suffering truncation by the companion. (The system corresponds to a binary, but the model is insensitive to which star has the flat-spectrum disk, or even if both stars have disks.) The disk model in the solid curve has infinite mass and is optically thick at all frequencies; the dotted curves that turn over progressively toward higher frequencies because of declining optical depth have disk masses, respectively, of 1, 0.1, and 0.01 M_\odot . Measurements at submillimeter and millimeter frequencies (data points with error bars) can establish the disk mass, provided the dust opacities in the disk correspond with those of the model (figure from Adams et al. 1990).

but by dusty (infalling?) envelopes that contribute significant amounts of far-infrared emission through the reprocessing of starlight.

There exists a difficulty with explaining the most extreme flat-spectrum T Tauri stars (which includes some of the most famous examples in the class: T Tauri itself, HL Tau, DG Tau, etc.) as passive, geometrically flared disks. To reprocess the starlight into the observed amounts of infrared excess would require unrealistic ratios of the dust photospheric height H to disk radius ϖ . Appendix B of Ruden and Pollack (1991; see also Kusaka et al. 1970) gives the temperature of a flared disk illuminated by a central star of radius R_* and effective temperature T_* (at a radius $\varpi \gg R_*$) as

$$T_D(\varpi) = T_* \left[\frac{2}{3\pi} \left(\frac{R_*}{\varpi} \right)^3 + \frac{1}{2} \left(\frac{R_*}{\varpi} \right)^2 \left(\frac{H}{\varpi} \right) \left(\frac{d \ln H}{d \ln \varpi} - 1 \right) \right]^{1/4}. \quad (17)$$

Notice that the canonical law $T_D \propto \varpi^{-3/4}$ dominates at small radii ϖ (where $H \ll R_*$), while shallower temperature gradients can arise at larger radii if H varies as a power of ϖ with an exponent s greater than unity (a geometrically flared disk). If the dust does not settle to the midplane but remains suspended in the gas (an inconsistent assumption if reprocessing disks are not turbulent), vertical hydrostatic equilibrium requires $H \propto \Omega^{-1} T_D^{1/2}$, so that $s = 9/7$ and $p = 3/7$ in the outer parts of a self-consistent, Keplerian, reprocessing disk. Such a disk typically requires $H/\varpi \gtrsim 1/3$ at large ϖ to produce an appreciable departure from the canonical case (Kenyon and Hartmann 1987). A circumstellar layer of dust with such an aspect ratio would conflict, however, with the observed fact that unobscured T Tauri stars are an order of magnitude more numerous than heavily extincted sources (in the Taurus molecular cloud). Moreover, for sources not seen *through* the disk, since $n = +4/3$ for $p = 3/4$ but $n = -2/3$ for $p = 3/7$, the spectrum would *fall* from the near- to mid-infrared but then *rise* toward the far infrared. Reprocessing of starlight in either flared disks or warped disks cannot generally reproduce the *single* power-law index, $n = 0$ from the near infrared to the far infrared, observed for the most extreme flat-spectrum sources.

Binarity is known to add complications in the case of T Tauri, and other sources of confusion may contribute to the observed departure from the expected spectral slope of $n = 4/3$. Taking the point of view, however, that physical significance could be assigned to the frequent occurrence of the single exponent $n = 0$, which neither viscous accretion nor passive reprocessing adequately explains, Adams et al. (1988) speculated that the flat-spectrum T Tauri stars must have *active* disks where the processes of transport of mass (inward) and angular momentum (outward) involve *nonlocal* mechanisms. Adams et al. (1989; see also Chapter by Adams and Lin) worked out one such mechanism: the generation of one-armed spiral density waves ($m = 1$ disturbances) by eccentric gravitational instabilities that involve the displacement of both star and disk from the center of mass of the system. Shu et al. (1990) gave an analytic demonstration, under a restrictive set of

circumstances, that such modal eccentric instabilities would arise whenever the disk mass as a fraction of the whole (star plus disk) exceeds $3/4\pi \sim 0.24$. They also pointed out that the temperature law $T_D \propto \varpi^{-1/2}$ plays a special role in the linear theory of $m = 1$ disturbances in that this distribution keeps the fractional amplitude of the wave (ratio of disturbance to unperturbed surface densities) constant throughout much of the disk. As the fractional amplitude in a full theory provides a measure of the nonlinearity of the wave, Shu et al. (1990) speculated that nonlinear propagation and dissipation of excited $m = 1$ waves would provide the feedback that accounts for the temperature law $T_D \propto \varpi^{-1/2}$ in the first place. Ostriker and Shu (work in progress) are pursuing the correct nonlinear derivation of this result, and they are also investigating the possibility that stellar companions in binary systems may provide an alternative source for the excitation of $m = 1$ density waves.

We find it informative to comment on the basic reason why either low-frequency unstable normal modes or fairly distant companions can provide, in principle, a redistribution of mass and angular momentum of a different qualitative nature than viscous accretion. A disturbance which rotates at a uniform angular speed Ω_p (see Sec. VIII) contains excess energy E_{wave} and angular momentum J_{wave} above the unperturbed values. These are related to each other by the formula (cf. Lynden-Bell and Kalnajs 1972),

$$E_{\text{wave}} = \Omega_p J_{\text{wave}}. \quad (18)$$

The same proportionality applies *locally* to the wave energy densities $\mathcal{E}_{\text{wave}}$ and angular-momentum densities $\mathcal{J}_{\text{wave}}$ (per unit area),

$$\mathcal{E}_{\text{wave}} = \Omega_p \mathcal{J}_{\text{wave}} \quad (19)$$

if the spiral waves are tightly wrapped (Lin and Shu 1964; Toomre 1969; Shu 1970), as they inevitably are for disturbances in most of a radially extended nebular disk (cf. Adams et al. 1989; Shu et al. 1990). Moreover, $\mathcal{E}_{\text{wave}}$ and $\mathcal{J}_{\text{wave}}$ are both positive or both negative depending on whether the wave rotates faster or slower than the matter; i.e., $\mathcal{E}_{\text{wave}}$ and $\mathcal{J}_{\text{wave}} > 0$ outside corotation, $\Omega_p > \Omega$, whereas $\mathcal{E}_{\text{wave}}$ and $\mathcal{J}_{\text{wave}} < 0$ inside corotation, $\Omega_p < \Omega$, where $\Omega(\varpi)$ represents the local angular speed of the disk.

On the other hand, in order for a gas element to remain in *circular* orbits when some external torque changes its angular momentum at a rate \dot{J} , its energy must change at a rate

$$\dot{E}_{\text{circ}} = \Omega \dot{J}. \quad (20)$$

When spiral density waves inside (outside) corotation dissipate they give a negative (positive) amount of angular momentum to the local gas, causing that gas to move to a radially smaller (larger) orbit. However, the energy lost (gained) by the gas element (a factor of Ω_p times the angular momentum lost

[gained]) in the process of damping the wave will generally be inappropriate for the gas to remain in a circular orbit with the modified angular momentum. The excess orbital energy will be converted to heat at a rate

$$\dot{H} = (\Omega_p - \Omega)\dot{J} \quad (21)$$

when the orbit of the gas element circularizes by hydrodynamic dissipative mechanisms.

Note that as the gas loses (gains) angular momentum inside (outside) corotation, the rate of conversion of energy into heat, \dot{H} , is everywhere positive. Note also that deep inside the disk where $\Omega \gg \Omega_p$, the rate of heat gain is very large per unit rate of angular momentum transferred. In other words, although a slowly rotating disturbance in the outer part of the disk (either a normal mode or a companion star) cannot directly supply much energy to the inner disk (only a factor $\Omega_p \times \dot{J}$), it potentially comprises a huge reservoir for dumping the angular momentum of the system. Removing angular momentum from the part of the disk inside of corotation (by direct near-resonant coupling in $m = 1$ density waves) results in accretion. When the basic orbits cannot become very noncircular (because tightly wrapped waves cannot yield highly eccentric orbits without producing either radiative damping or streamline crossing and dissipative shocks), the heat released by this nonviscous form of accretion will provide, we believe, the luminosity excess that one sees in the flat-spectrum T Tauri stars.

In the inner portions of the disk, where $\Omega \gg \Omega_p$, but still much beyond the star-disk boundary layer, we note that Eq. (21) for the disk heat input differs only by a factor of 3 from the corresponding formula given by viscous accretion-disk theory. (A much bigger difference exists beyond the corotation circle, where $\Omega_p \gg \Omega$, but the physical dimensions of realistic disks may not extend to regions where the wave energy much dominates over the accretion energy.) The ability of wave transport (perhaps) to produce flat-spectrum sources may then depend critically on the fact that $m = 1$ wave dissipation yields a nonuniform rate of local disk accretion \dot{M}_{acc} , with $\dot{M}_{\text{acc}} \propto \varpi$ needed to produce a flat-spectrum source.

It might be argued that viscous-accretion disk models could also accommodate flat-spectrum sources if we allow ourselves the luxury of assuming $\dot{M}_{\text{acc}} \propto \varpi$. Hartmann and Kenyon (1988) dismissed this possibility on the grounds that it would require mass accretion rates in the outermost parts of a disk three or more orders of magnitude higher than the innermost regions. Compare the required behavior with theoretical models of viscous accretion. Independent of the details for the specification of the viscosity, the diffusive nature of the viscous process (if stable) inevitably yields in the relevant portions of the disk, a long-term evolution that satisfies the approximate condition, $\dot{M}_{\text{acc}} = \text{a spatial constant}$ (cf. Ruden and Lin 1986; Ruden and Pollack 1991). The same result need not apply to accretion disks driven by global instabilities. Indeed, the dynamics of quasi-steady wave generation, propagation, and dissipation will generally *not* correspond to the condition of steady-state accretion.

The implication that the (self-gravitating) disks in flat-spectrum T Tauri stars have much larger accretion rates in their outermost parts (say, $\sim 10^{-5} M_{\odot} \text{ yr}^{-1}$) than their innermost parts (say, 10^{-8} to $10^{-7} M_{\odot} \text{ yr}^{-1}$) may have important observational consequences. In particular, the tendency to pile up matter at a bottle-neck at the smallest radii leads, for a temperature distribution fixed by wave dissipation independent of the surface density distribution (see Shu et al. 1990), to a local lowering of Toomre's (1964) Q parameter. If Q falls sufficiently, violent $m > 1$ gravitational instabilities may make an appearance (see, e.g., Papaloizou and Savonije 1991; Tohline and Hachisu 1990). Such modes act over a much more restricted radial range than $m = 1$ modes, but they may induce a sudden release of the piled-up material onto the central star. Two very different gravitational modes of mass transport may therefore act: $m = 1$ waves, driven by distant orbiting companions or mild instabilities characteristic of the outer disk; and $m > 1$ instabilities with high growth rates characteristic of the inner disk. The relative ineffectiveness of the first mechanism for inducing mass transport at small ϖ leads to large amounts of matter caught in the "throat"; the clearing of this material by the second mechanism may then yield the sporadic "coughs" that Hartmann et al. identify in their chapter as FU Orionis outbursts. Much more work would have to be performed on this scenario, however, before we could characterize it as more than an interesting speculation.

VIII. BINARY STARS AND PLANETARY SYSTEMS

In their studies, Adams et al. (1989) and Shu et al. (1990) suggested that the existence of binary systems among the T Tauri stars may itself represent a manifestation of the prior action of $m = 1$ gravitational instabilities (see Chapters by Bodenheimer et al., and by Adams and Lin). Recent numerical simulations using smooth-particle-hydrodynamics codes (Lattanzio and Monaghan 1991; Bastien et al. 1991; F. C. Adams and W. Benz, personal communication) indicate that the formation of companion objects by non-axisymmetric disturbances (in particular, $m = 1$) in massive nebular disks may indeed be a viable physical process. Nevertheless, because the actual accumulation of mass occurs, at least in some systems, via *gradual* infall of a single molecular cloud core (cf. Secs. IV and V), we should not directly apply the results of simulations of fully accumulated stars plus disks to the actual binary-formation process. We believe it much more likely that *both* stars start off small (perhaps as the result of a runaway $m = 1$ gravitational instability), that the two protostars separately acquire inner accretion disks, that they may also jointly acquire a circumbinary disk, and that buildup of the entire system occurs substantially while the system lies deeply embedded within a common infalling envelope. Haro 6-10 and IRAS 16293-2422 may represent examples of such systems (see Zinnecker 1989a; G. A. Blake and J. E. Carlstrom, personal communication; for a review of alternative formation scenarios, see Pringle 1991).

An interesting aspect of the realization that binary-star formation may occur in the presence of circumstellar, or even circumbinary, disks concerns the eccentricity of the resulting orbits. Duquennoy and Mayor (1991) and, especially, Mathieu et al. (1989) have emphasized the important observational point that most binaries are probably born with eccentric orbits, and that the shorter-period ones only later become circularized by stellar tidal processes. This state of affairs should be contrasted with that applicable to planetary systems, where current belief holds that most planets are born with nearly circular orbits. How do we reconcile this difference if we believe that companion stars and planets are both born from disks?

A qualitative answer to this question may come from the work of Goldreich and Tremaine (1980) on the interactions of satellites and disks (see also Ward 1986; Chapter by Lin and Papaloizou). For satellite orbits of small eccentricity e and inclination i , a Fourier expansion of the potential associated with the satellite's gravity introduces a series of disturbances that have wave frequency ω given by (cf., e.g., Shu 1984)

$$\omega = m\Omega_s \pm n\kappa_s \pm p\mu_s \quad (22)$$

where m , n , and p are positive integers, with κ_s and μ_s being the epicyclic and vertical oscillation frequencies, respectively, when we expand the satellite's eccentric and inclined orbit about the circular orbit with angular rotation speed Ω_s . The integer m yields the angular dependence $\propto e^{-im\varphi}$ of the disturbance potential, whereas n and p represent the number of powers of e and $\sin i$ that enter the coefficient of the specific term in the series expansion. We refer to the terms corresponding to $n = p = 0$, which can arise even if the satellite orbit is circular, as being of *lowest order*; higher-order terms depend on the orbit having nonzero eccentricity e or inclination i .

As the time dependence of the disturbance potential $\propto e^{i\omega t}$ and the angular dependence $\propto e^{-im\varphi}$, the pattern speed of the disturbance equals

$$\Omega_p = \omega/m. \quad (23)$$

In a steady state (including dissipation), the satellite potential excites a density response in the disk that remains stationary in a frame that rotates at the pattern speed Ω_p . This response achieves its highest values at various resonance locations. *Corotation resonances* occur at radii ϖ where

$$\Omega(\varpi) = \Omega_p \quad (24)$$

Lindblad resonances occur where

$$\Omega(\varpi) \pm \frac{1}{m}\kappa(\varpi) = \Omega_p \quad (25)$$

and *vertical resonances* occur where

$$\Omega(\varpi) \pm \frac{1}{m}\mu(\varpi) = \Omega_p \quad (26)$$

with $\Omega(\varpi)$, $\kappa(\varpi)$, and $\mu(\varpi)$ representing, respectively, the circular, epicyclic, and vertical oscillation frequencies of the local gas. *Inner* resonances occur where the minus sign is chosen in Eqs. (25) and (26); *outer* resonances, where the plus sign is chosen. For a nonaxisymmetric disturbance with given pattern speed Ω_p , we generally encounter in succession an inner resonance, a corotation circle, and an outer resonance, as we move radially outwards through the disk. For a Keplerian disk, all three frequencies are equal, $\Omega = \kappa = \mu$, and special significance attaches to $m = 1$ disturbances because the entire disk can be in near-inner Lindblad or vertical resonance with a distant companion (where $\Omega_p \sim 0$).

Consider now the gravitational back-reaction of the density response in the disk on the exciting satellite. The gravitational potential associated with the density response, being nonaxisymmetric and time dependent in an inertial frame (but time independent in a frame that rotates at Ω_p), conserves neither the orbital angular momentum J_s nor the orbital energy E_s of the satellite; however, the combination $E_s - \Omega_p J_s = \text{Jacobi's constant}$ is conserved. As a consequence, the back-reaction from the disk pumps energy and angular momentum into the orbit of the satellite in the ratio Ω_p , $\dot{E}_s = \Omega_p \dot{J}_s$, with \dot{J}_s equal to minus the torque on the disk. For the strongest resonances (corotation or Lindblad), where $n = p = 0$, Eqs. (22) and (23) state that $\Omega_p = \Omega_s$; consequently to zeroth order in e (and $\sin i$), these strong resonances contribute energy and angular momentum to the satellite in a ratio as to keep circular orbits circular. To linear order in e^2 , however, the strongest resonances change the satellite's eccentricity at rates comparable to the weaker resonances that have $n = 1$ and $p = 0$. The former always lead to eccentricity damping (growth) for inner (outer) Lindblad resonances; the latter contribute to eccentricity changes depending on the sign in $\Omega_p = \Omega_s \pm \kappa_s/m$ and on whether the Lindblad resonances are inner or outer ones. The torque exerted by corotation resonances (and therefore their contribution to eccentricity changes) depends on the sign of the gradient of the vorticity divided by the surface density.

In an untruncated Keplerian disk of uniform surface density, Goldreich and Tremaine (1980) demonstrate that the sum of the effects of all resonances has a slight dominance of eccentricity-damping resonances over eccentricity-exciting ones (see also Ward 1986 for estimates of the effects of surface-density gradients). This presumably explains why planets embedded in nebular disks acquire nearly circular orbits, although gap opening adds to uncertainties (see Lin and Papaloizou 1986*a, b*). The ability of strong resonances to open gaps is observed in the Saturnian ring-moonlet system (see the discussion of Cuzzi et al. 1984). For a massive companion such as another star, however, not only may the companion be born with an initial eccentricity, but wide gaps opened up on either side of the secondary star may lead to the disappearance of the strongest $m \neq 1$ resonances. The remaining resonances may amplify orbital eccentricities under some circumstances; for example, Artymowicz et al. (1991) find eccentricity growth in a numerical simulation of a binary surrounded by a circumbinary disk that is dominated

by a $m = 2$ outer-Lindblad resonance with $\Omega_p = \Omega_s - \kappa_s/2$. On the other hand, the system GW Ori appears to be a binary with a circular orbit and with circumstellar and circumbinary disks (Mathieu et al. 1991). The inferred gap surrounding the companion eliminates the stronger $m \neq 1$ resonances; if true, the circumstellar disk may provide a circularizing influence on the binary orbit through the action of $m = 1$ inner-Lindblad near-resonances (Ostriker et al. 1991). In any case, if a companion star acquires large eccentricities, it may have a high efficiency for sweeping up the matter of the disk in which it is embedded.

In summary, the orbital characteristics of newly formed planets and companion stars might qualitatively differ from one another because the two types of objects originate by completely different processes (cf. Pringle [1991] for this point of view). On the other hand, even if they both descend from disks, we see that good mechanistic reasons exist why binary stars might acquire appreciably eccentric orbits, whereas planets usually do not. The difference in outcomes—binary stars or planets—might then depend on differences in initial conditions, namely, the total amount of angular momentum J_{tot} contained in the collapsing system. If J_{tot} is small, a substantial central mass could accumulate by direct infall before disk formation occurs. The stabilizing influence of a massive center of attraction may then prevent any runaway gravitational instabilities in the disk, leaving only the possibility of planetary condensation by chemical or physical means. If J_{tot} is large, the ratio of disk to star mass may reach order unity before the central object has grown sufficiently to prevent the gravitational fragmentation of the disk to form another body on an eccentric orbit. In this case, continued infall builds up a binary-star system.

IX. THE ORIGIN OF STELLAR AND PLANETARY MASSES

As the primary transformers of the simple elements that emerge from the big bang, stars constitute the fundamental agents of change in the visible universe. Of all its properties, a star's mass most affects its main-sequence appearance and later evolution. Given that giant molecular clouds, the raw material for forming stars, contain much more mass than required to make the final products, the most basic problem posed for theories of stellar origin concerns, then, how these objects acquire the masses that they do. At one time, astronomers sought for an answer to this important question in terms of a picture of hierarchical fragmentation, but severe doubt about this possibility has been cast by the realization that giant molecular clouds are not collapsing dynamically and have, in fact, generally a very low efficiency for stellar genesis (Zuckerman and Evans 1974).

The discovery that massive outflows ubiquitously accompany the birth pangs of stars has led to an alternative explanation, that forming stars might help to define their own masses. From this point of view, star formation represents basically an accretion process (a theoretical point of view with modern origins in the work of Larson [1969]), with the mass of the star

continuing to build up until a powerful enough wind turns on to reverse the infall (first, over the poles, and later, even in the equatorial directions) and shut off the accretion. Indeed, given the basic angular-momentum difficulty faced by any condensing and rotating object which needs to contract by several orders of magnitude in linear scale, perhaps theorists should have anticipated all along that stars would not be able to form without simultaneously suffering tremendous mass loss. As it is, however, theorists from Laplace onwards managed to predict, in one form or another, only three of the four stages of star formation depicted schematically in Fig. 1.

A parallel situation holds for the issue of planetary masses, which we know today probably also results from a process of accumulation. At one time theorists sought to skirt the issue by postulating that the primitive solar nebula had only the amount of mass, when reconstituted to solar composition, needed to build the known planets. The planets then incorporated the masses that they did, essentially because that was all the material there was. (We exaggerate the degree to which “input equals output” in the so-called “minimum-mass model” because theorists still had the chore of explaining why the solar system formed with *nine* major planets, and not one, or a hundred.)

The modern view suggests that the birth of a star must indeed almost always proceed with the accompanying appearance of a disk. However, it also claims that the masses of the growing star and disk are unlikely to have a ratio of anything like 100 to 1. In the early stages, at least, the solar nebula may have had a comparable mass to the proto-Sun. Such a situation places sharp focus on the question how planets acquire the masses that they do if most disks have available more mass than needed to make the known planets.

A partial answer may have been supplied by the suggestion by Lin and Papaloizou (1985, 1986a; see also their Chapter) that *tidal truncation* limits the maximum amount of mass acquirable by a *giant* planet. Tidal truncation works because a circularly orbiting body has a basic tendency to want to speed up more slowly rotating material exterior to its own orbit, and to slow down more rapidly rotating material interior to it. This tendency to give angular momentum to the matter on the outside and to remove it from matter on the inside (as already discussed for resonant interactions in Sec. VIII) secularly pushes gas on either side of a protoplanet away from its radial position, opening up a gap centered on the body's orbit. Viscous diffusion tends to fill in this gap, and for a true gap to form, the tidal torques have to dominate, leading, for a given level of turbulent viscosity, to a minimum protoplanetary mass that can open up a gap larger than its own physical size. (See Chapter by Lin and Papaloizou on the additional criterion that arises in a *gaseous* disk because the gap width must also exceed the vertical pressure scale-height, if gas pressure is not to close the gap.)

The observational knowledge that the tidal force of moonlets can clear analogous gaps in planetary rings (see, e.g., Showalter 1991) shows that this mechanism does have empirical validity; however, the simplest formulations of gap opening and shepherding theories do not yet yield good quantitative

comparisons with observations of planetary rings and their moonlets (see, e.g., Goldreich and Porco 1987). Moreover, this mechanism applied to the solar nebula will not work to define the masses of the *terrestrial* planets, nor does it explain what happens to the excess disk material that does not go into planets. As already discussed in Sec. I, the fate of the solid debris may not pose a great problem given the demonstration that most of the space between the major planets yields secularly unstable orbits (see Chapter by Duncan and Quinn); however, the dispersal of the remnant gaseous component remains a serious problem, especially if massive protostellar and pre-main-sequence winds are driven by disk accretion.

A possible resolution of the problem may rest with Elmegreen's (1978*b*, 1979*c*) proposal that stellar winds erode disks, not by blowing the gas away (Cameron 1973), but by inducing turbulence in the wind-disk interface that enhances the *inward* viscous transport of matter. If, in turn, disk accretion drives powerful stellar winds, the process could continue to operate, in principle, until the disk has completely emptied onto the star. Indeed, the existence of a feedback loop—disk accretion drives wind → wind drives disk accretion, etc.—together with time delays, leads to the possibility of instabilities and limit cycles (see Bell et al. [1991] for an example of a negative feedback cycle leading to chaotic oscillations). Such feedback loops—modulated perhaps by magnetic cycles on the star itself—yield yet another possible mechanism for FU Orionis outbursts.

Finally, we note that disk accretion can be dammed by the formation of giant planets and the appearance of gaps across which matter does not flow. The removal of the gas from the outer regions of dammed disks may then require slow evaporation by ultraviolet radiation (Sekiya et al. 1980*a*; Hayashi et al. 1985; see review of Ohtsuki and Nakagawa 1988). The abundance of possibilities regarding the dispersal of the remnant gas in nebular disks yields a specific demonstration that we still possess ample problems to wrestle with before *Protostars and Planets IV* is written.

NUCLEOSYNTHESIS AND STAR FORMATION

A. G. W. CAMERON

Harvard-Smithsonian Center for Astrophysics

Discussions are given of the stellar nucleosynthesis sites of several extinct nuclides: ^{26}Al , ^{60}Fe , ^{135}Cs , ^{53}Mn , ^{92}Nb , ^{107}Pd , ^{129}I , ^{146}Sm , ^{182}Hf and ^{244}Pu . The mean lives of these nuclides range over 2 orders of magnitude, from 1.07 to 149 Myr. These are interpreted to include 1 equilibrium process product, 2 *r*-process products, 2 *p*-process products, 1 product of hot hydrogen burning, and 4 *s*-process products. It is shown that their abundances in the early solar system are consistent with the following postulated local history of the Galaxy. About 130 Myr before the formation of the solar system an OB Association was formed in a nearby molecular cloud, and the ultraviolet radiation from the more massive O stars destroyed the cloud, caused very large-scale mixing in the interstellar medium, and created new molecular cloud complexes. In the nearest of these, roughly 25 Myr before the formation of the solar system, a new OB Association again caused large-scale mixing and formed new molecular cloud complexes, including the one in which the solar system would be born. An AGB star in the last stages of its evolution wandered into our cloud shortly after its formation; its planetary nebula stage triggered a chain of formation of new stars that propagated through strong stellar wind and bipolar ejection processes occurring in the new stars themselves.

I. INTRODUCTION

The solar system, when formed, possessed interesting amounts of now-extinct radioactivities whose abundances have been preserved as isotopic anomalies in some phases of meteorites. If we know how a nuclide was made and what kind of stellar scenario was involved, then in principle we can date the interval between the last event or few events making the nuclide and the formation of the solar system. This chapter constitutes an attempt to do that, within a rather generalized model of the interstellar medium and of the molecular cloud complexes formed within it.

There is no significant body of literature on this subject. Papers announcing the discovery of various extinct nuclides have usually included an estimate of the production rate of the nuclide relative to some reference nuclide during the course of stellar nucleosynthesis, and have noted the time implied by the radioactive decay interval needed to reduce the isotope production ratio down to the observed value of the isotope ratio. But such estimates rarely include a serious attempt to deal with an appropriate astrophysical scenario in which the decay could have occurred. Thus, when the editors of this book asked

me to write on this subject, in effect they challenged me to bring together information about the interstellar medium, star formation, stellar evolution, and nucleosynthesis to create a general scenario in which all of these ages would become meaningful. This chapter is my attempt to do this; my effort has extended over the past two years as interesting new information and new ideas have come to the fore. The relevant fields of research are very active, and it is hoped that the general scenario derived here will be useful to others as they test various parts of it and make appropriate modifications.

Table I shows the extinct radioactivities that have been measured in primitive solar system material, the comparison isotope (normally stable) used as a measure of the abundance of the extinct nuclide, and the ratios of the decay products measured in primitive material to their comparison isotopes. It also shows the mechanism of stellar nucleosynthesis which appears to have been primarily responsible for the production of the nuclide, at least in the general scenario adopted in this chapter. Most of the data has been taken from the review by Wasserburg (1985), but the data for ^{146}Sm is from Prinzhofer et al. (1989), the data for ^{53}Mn is from Birck and Allègre (1987), and the data for ^{60}Fe is a tentative detection by Birck and Lugmair (1988). Very new data from Harper et al. (1991*a, b, c, d*) on the radioactivities ^{182}Hf , ^{135}Cs and ^{92}Nb has contributed in an important way to the analysis given in this chapter. There is a considerable range of uncertainty in the observed abundance of ^{182}Hf , mostly due to uncertainties in the corrections that must be made; Harper prefers an abundance near the lower end of this range; the upper limit is from Ireland (1991) as interpreted by Harper (personal communication). The detections of ^{135}Cs and ^{92}Nb are also tentative and require confirmation. See also the Chapter by Swindle.

During the last few years there has been an intensive investigation of star formation taking place in dense molecular cloud complexes, primarily by collapse of denser cores which form in such clouds. The shorter-lived extinct radioactivities give some information about these events. However, typical lifetimes that have been estimated for these cloud complexes are usually in the range between 10 and 200 Myr (see, e.g., Myers 1990). The longer-lived extinct radioactivities have mean lives in this general range, and they thus tend to give information about the state of the interstellar medium prior to the formation of a molecular cloud complex in which it is hypothesized that the solar system was born. If the picture that we attempt to put together does not produce a self-consistent scenario, then we would be forced to conclude that the solar system was formed in some other, much rarer, way. It is likely that several of these alternative paths exist and are responsible for a small part of the star formation in the Galaxy.

II. FORMATION AND DESTRUCTION OF CLOUDS

It is generally accepted that a molecular cloud complex is formed through an extensive flow of interstellar gas along the magnetic field lines. The

TABLE I
Data Concerning Extinct Radioactivities

Nuclide	Mean Life ^a	Ref. Nuc.	Obs. Ratio	Abundance ^b	Process
²⁶ Al	1.07	²⁷ Al	5.0×10^{-5}	4.3	hot H-burning
⁶⁰ Fe	2.2	⁵⁶ Fe	1.6×10^{-6}	1.3	s-process
¹³⁵ Cs	3.3	¹³³ Cs	3	1.2×10^{-5}	s-process
⁵³ Mn	5.3	⁵⁵ Mn	4.4×10^{-5}	0.41	equilibrium
¹⁰⁷ Pd	9.4	¹⁰⁸ Pd	2.0×10^{-5}	7×10^{-6}	s-process
¹⁸² Hf	5.3	¹⁸⁰ Hf	$8 - 80 \times 10^{-6}$	$4 - 40 \times 10^{-7}$	s-process
¹²⁹ I	23.1	¹²⁷ I	1.0×10^{-4}	1.3×10^{-4}	r-process
⁹² Nb	50	⁹³ Nb	2.0×10^{-5}	1.8×10^{-5}	p-process

^b Initial solar system abundance on the scale silicon = 10^6 .

classical mechanism proposed for this process is known as the Parker (1968) mechanism; while the details of this mechanism are not considered today to be correct (see Chapter by Elmegreen), it makes a good conceptual starting point for our discussion. In this mechanism it is assumed that a section of the magnetic field lines lying in the galactic disk becomes elevated above the plane. The matter on the field lines is tied to them, at least on dynamic time scales, and feels a force tending to pull it toward the galactic plane. It responds by sliding down the field lines toward the plane. In this way, it is expected that molecular cloud complexes will be formed in the areas where the field lines rejoin the plane. The time required to form a molecular cloud complex is of the order of 20 Myr (Parker 1968). The mean number density of matter in the interstellar medium is about 1 cm^{-3} , and in a molecular cloud the mean density is usually in the range 10^2 to 10^3 cm^{-3} ; it can be smaller in diffuse clouds and parts of giant molecular clouds (Myers 1990). Thus the characteristic distance through a cloud complex with a mass in the range 10^4 to $10^6 M_\odot$ is from 5 to 70 pc.

It requires an energetic event to dissipate a molecular cloud. This event probably involves the formation of a number of O and B stars, which will flood their surroundings with ultraviolet radiation, thus ionizing the nearby gas. This will raise the temperature of the gas from 10 K to about 10^4 K, thus raising the thermal pressure by a similar factor above the mean in the interstellar medium. Under steady-state conditions around a typical O star, a Strömgren sphere of ionized hydrogen would be formed with a radius of 0.1 to 1 pc (Strömgren 1939). But the major pressure imbalance produced by the heating will cause the region to expand. Under steady-state conditions at a density of 1 cm^{-3} , the radius of the Strömgren sphere would become 100 times larger and it would ionize 1000 times as much material. Thus as the overheated gas expands more material becomes ionized. The dynamics of the process involves the propagation of an ionization front (Vandervoort 1963). Thus O stars with a range of masses would ionize anywhere from 10^2 to $10^6 M_\odot$ of material in a cloud. The lower-mass O stars would disrupt star formation in a part of the cloud, and the higher mass ones would disrupt the cloud completely. Strong winds from O and B stars are also locally quite disruptive.

The disruption of the cloud would certainly be complete if star formation in it has produced an OB Association, as this would contain at least a few stars in the higher-mass range. In such a case, the cloud must respond by exploding. The expansion velocity will be comparable to sound speed at 10^4 K, or 10 km s^{-1} . Assuming momentum conservation, the expanding gases will slow to 1 km s^{-1} or less, thus mixing with at least ten times the mass of the molecular cloud. In the later stages of the expansion, when the overpressure is not too great, it should be expected that the galactic magnetic field will resist compression perpendicular to the field lines, and so there will be a preferential expansion along the direction of the field lines. The field lines also tend to inhibit actual mixing in the transverse direction, but the field

lines can intermingle with one another and then mixing can occur by relatively short-range diffusion.

If the cloud mass was as much as $10^6 M_{\odot}$, and if the total mass of the interstellar medium is about $4 \times 10^9 M_{\odot}$, then this one energetic event will have mixed 0.025% of the interstellar medium. Such events are undoubtedly the primary causes of large-scale mixing in the interstellar medium. The time interval between these events is probably comparable to the lifetimes of cloud complexes themselves, or one to two hundred Myr, or possibly less.

The most massive stars have main sequence lifetimes of about 3 Myr; in these stars the luminosity is proportional to the stellar mass and the mass fraction that burns hydrogen into helium on the main sequence is approximately constant (see, e.g., Shapiro and Teukolsky 1983). For stellar masses of about $10 M_{\odot}$, the main sequence lifetime has increased to about 10^7 yr. But by that time the massive stars will have evolved to the end-points of their evolution; this means that most of them will have become Type II supernovae. To the high pressures generated by ionizing hydrogen will be added the "mechanical luminosity" of the supernovae. This causes a rapid inflation of the volume containing the supernovae ejecta and the embedded magnetic field lines. Hydrodynamic studies of this event have been carried out by Tomisaka (1990), and more recently by M. Norman and his colleagues (personal communication), who describe the inflated region as a superbubble in the interstellar medium. Tomisaka (1990) estimates the duration of the event as about 25 Myr, including the time for the beginning of the inflation.

The general expansion accompanying this energetic event will not only lift many field lines above the plane, but will also cause a substantial sideways displacement of the magnetic field lines, thus causing the pinched field to squirt the embedded gas along the field lines, unless these field lines are quite tangled, in which case star formation may be forced in the small cloud that is thus formed. The gas on the elevated field lines will fall down the lines due to the gravitational attraction of the plane. This scenario is a substantial modification of the original Parker instability scenario. There is thus a variety of ways in which the gas flow along the field lines can lead to the formation of molecular cloud complexes. Because the field lines act as individuals, the actual processes involved are bound to be very complex, and twisting and crossing of the field lines can lead to mixing in the resulting clouds (Chapter by Elmegreen).

Because stars in OB Associations are generally observed to be expanding from a common point in space, it is likely that the stars in an Association were formed within a short period of time well after the formation of their cloud complex. Because some giant clouds have cores as massive as $10^4 M_{\odot}$ (Myers 1990), the collapse of these cores is likely to form an unbound cluster, many members of which are quite massive. In such a case the stars in the cluster are born at essentially the same time, and we shall so assume. Therefore the formation of the superbubble, the large-scale interstellar mixing, and the formation of new molecular cloud complexes all should be well under way

before stars in the OB Association of $10 M_{\odot}$ and below have evolved off the main sequence. This has profound consequences for nucleosynthesis. Studies of the r -process and related nucleochronology (see, e.g., Cowan et al. 1991) have found that r -process elements do not appear in the most ancient stars until the abundance ratio of iron to hydrogen has risen to 10^{-3} of the present value, and s -process elements do not appear until the ratio has increased by a further factor of 10. Mathews and Cowan (1990) have attempted to compare these trends with a variety of galactic nucleosynthesis models, and they find that they cannot fit the trends by assuming that all supernovae contribute to the r -process, but they can get a reasonable fit if they assume that only the lower mass supernovae contribute to the r -process. The upper limit to the mass range producing the r -process is roughly $10 M_{\odot}$. The shortest evolutionary time in which the r -process can be produced is thus about 10 Myr. It follows that the creation of the superbubble and the formation of new molecular clouds incorporates the products of the massive supernovae, including the products of the equilibrium process, but it does not incorporate the products of the r -process. The latter products will be blown off from lower mass supernovae in due course, but there will be only relatively local mixing processes available to distribute these products until the next large-scale mixing event occurs, probably 100 to 200 Myr later.

The most detailed recent estimate (Kennicutt 1984) is that main-sequence stars with masses below $8 M_{\odot}$ lose enough mass so that they will end their lives by forming a white dwarf remnant (see discussion of AGB stars in Secs. VI and VII). Thus the spread in stellar mass that appears to contribute to the r -process is quite small. From the point of view of time scales, an $8 M_{\odot}$ star has a main sequence lifetime of about 25 Myr (Shapiro and Teukolsky 1983), with subsequent evolution taking only a relatively short time, and thus this would be the longest period of time over which the r -process would take place following the formation of an OB Association.

III. ^{53}Mn

With a mean life of 5.3 Myr, ^{53}Mn is the fourth shortest lived of the extinct radioactivities. It is a product of what is called the equilibrium process, in which stellar material is processed at temperatures of 4×10^9 K or higher to a condition of nuclear statistical equilibrium. (Woosley et al. 1973). This processing occurs explosively, which means that the ^{53}Mn is a product of a supernova explosion. Such stellar material starts with a near equality of the numbers of neutrons and protons in the nuclei, and in the thermonuclear runaway there is not sufficient time for any significant number of beta decays to take place. Under these circumstances, the most abundant nucleus is ^{56}Ni , which subsequently decays to ^{56}Co and ^{56}Fe , thereby releasing the energy that appears in the supernova lightcurve. Mass number 53 is produced as ^{53}Fe and ^{53}Mn , and the mass number 55, leading to the reference nuclide ^{55}Mn is produced as ^{55}Co and ^{55}Fe .

Because of the equilibrium character of the resulting abundances, the relative production ratios (after beta decay) of ^{53}Mn , ^{55}Mn and ^{56}Fe are determined by their abundances in solar matter. The ^{53}Mn abundance comes from the abundance of its decay product, ^{53}Cr . These give a production ratio of $^{53}\text{Mn}/^{55}\text{Mn}$ of 0.13. The latest abundance compilation of Anders and Grevesse (1989) gives two values for the iron abundance, one derived from solar spectrum lines, and the other lower value derived from carbonaceous meteorites. I prefer to use the meteoritic value, giving a $^{53}\text{Mn}/^{56}\text{Fe}$ ratio of 0.00147 and a $^{55}\text{Mn}/^{56}\text{Fe}$ ratio of 0.0113.

Because of the short lifetime of ^{53}Mn , we are only interested in processes that transfer it quickly from production sites to the site of formation of the solar system. The prompt supernovae resulting from the massive stars in the OB Association that inflated the superbubble and formed the molecular cloud in which the solar system would be born are thus suitable production sites. The supernova explosions contributing to the interstellar superbubble should all take place within about a mean life of ^{53}Mn . These massive stars are each expected to produce about $0.1 M_{\odot}$ of iron-peak elements (for a discussion of these iron masses see Thielemann et al. [1992]). If we assume that there were 40 such supernova explosions contributing to the superbubble (the number assumed by Norman and his colleagues in their simulations), then about $4 M_{\odot}$ of fresh iron peak material would be contained in the superbubble, along with $0.045 M_{\odot}$ of ^{55}Mn .

The $^{53}\text{Mn}/^{55}\text{Mn}$ abundance ratio observed to have been present in meteorites in the early solar system is 4.4×10^{-5} . This is but one of several quantities that we need to know in order to characterize the scenario unambiguously, so we must assume some of them in order to derive the remainder. Assume that there was a time delay of 25 Myr between the Type II supernovae formed by the massive stars from the OB Association and the formation of the solar system, utilizing the time scales associated with a Parker instability and found for the hydrodynamics of an interstellar superbubble by Norman, as discussed in the previous section. During this interval, the ^{53}Mn would have decayed by a factor 112, meaning that the initial $^{53}\text{Mn}/^{55}\text{Mn}$ ratio would be 0.0049 as geometrically diluted by mixing into cloud material but without any radioactive decay. The first geometric dilution factor is then $0.13/0.0049 = 26$.

The second geometric dilution factor consists of the ratio of the amount of ^{55}Mn produced by the supernovae to the amount of this nuclide in $1 M_{\odot}$, or $0.045/1.92 \times 10^{-5} = 2350$. The product of these two factors gives $6.2 \times 10^4 M_{\odot}$ for the amount of material into which the supernovae ejecta is mixed. If the interstellar superbubble formed two molecular cloud complexes at the two ends of the lines of force of the magnetic field threading the superbubble, then each cloud complex would have a mass of at least $3 \times 10^4 M_{\odot}$. Because the radioactive debris can mix across lines of force only with difficulty, the actual masses of the cloud complexes could be considerably larger. What we get from this calculation is only the radioactively contaminated mass in

the clouds. The calculation assumed that the solar system formed very soon after the cloud complex in which it was situated was formed. If there was a significant delay in this event, then further decay of the ^{53}Mn would have occurred, and the early solar system abundance could then only be obtained by reducing the amount of mass subject to radioactive contamination.

IV. *r*-PROCESS NUCLIDES

^{244}Pu is a product of the *r*-process. Because it is an actinide element, it cannot be produced by some relatively weak source of neutrons; a large source of neutrons is required. Studies by the author (unpublished) have shown that in order to produce many tens to more than one hundred neutrons per seed nucleus in the *r*-process production region, the source material must be compressed to about $10^{12} \text{ g cm}^{-3}$, where the neutrons are produced by electron capture, or to about $10^{10} \text{ g cm}^{-3}$ at much higher temperatures. But studies of the supernova explosion mechanism have indicated that the "mass cut," which marks the point of separation between ejected matter and that which falls back onto the forming neutron star, has been compressed only to about $10^{10} \text{ g cm}^{-3}$ (Mayle and Wilson 1988). The implication of this is that nuclei like ^{244}Pu must be formed in a small amount of matter asymmetrically ejected in the form of a jet if from high densities below the normal mass cut, or in a small amount of matter in a shell at the mass cut for very high temperatures; this is consistent with the *r*-process material requirements in the Galaxy which are satisfied if the average supernova ejects about $10^{-5} M_{\odot}$ of *r*-process material. The mechanism by which either of these events might happen are not known, but the empirical fact that the *r*-process occurs only in stars of mass less than about $10 M_{\odot}$, mentioned above, should be an important clue.

The following section on *p*-process nuclides describes a continuous production method for estimating the yields of the radioactivities that are long enough lived so that averaging procedures can be applied. But we have seen above that *r*-process nuclei are produced in a narrow range of stellar masses, 8 to $10 M_{\odot}$, during a period of 10 to 25 Myr after formation of the OB Association. Then there will be a delay of order 10^8 yr before the next major mixing event occurs driven by a new OB Association. Thus in a local region of the Galaxy the *r*-process production is better represented by a series of spikes of production. Such a spike model for making abundance estimates will be used here.

There is no stable isotope of plutonium relative to which the abundance of ^{244}Pu can be measured. Therefore the usual reference isotope is ^{238}U , which, while not stable, is at least long-lived, with a mean life a little longer than the age of the solar system (6.5 Gyr). Wasserburg (1985) recommends a value for the ratio of $^{244}\text{Pu}/^{238}\text{U}$ of 7×10^{-3} at the time of formation of the solar system. This is close to the expected average value at that time in the interstellar medium. However, the relative formation rates of ^{244}Pu and ^{238}U

are not very well known, except that they must be within a factor of a few of unity. Each of these nuclides has several progenitors which decay to it by emitting α -particles. If the r -process yields are strongly peaked at or beyond mass 244, then the ^{244}Pu and ^{238}U yields would be similar, but if the peak is well below mass 244, or if the yield curve is quite uniform, then ^{244}Pu would have a lower abundance. The value obtained in the author's unpublished r -process calculations for the $^{244}\text{Pu}/^{238}\text{U}$ production ratio is 0.7, and this value will be used here.

The mean life of ^{244}Pu is 1.18×10^8 yr. A simple spike model would assume a constant rate of production of the nuclide (and also of its reference nuclide ^{238}U) for a period of 10^{10} yr; this has been spike approximated by taking 100 spikes at 10^8 yr intervals and determining how much of the ^{244}Pu and ^{238}U that have ever been produced remain after the last spike. In a second modified spike model, the production rate has been multiplied by the weighting factor $\exp(-t/10^{10})$, where t is the time since the start of production, and a third modified model used the square of this weighting factor. Using the relative production ratio given above, at the time of the last spike the $^{244}\text{Pu}/^{238}\text{U}$ ratio is found to lie in the range 0.0166 to 0.0238 due to variations in the weighting factors. The observed $^{244}\text{Pu}/^{238}\text{U}$ ratio for the solar system is 0.007. To reach this value primarily by ^{244}Pu decay thus requires some 99 to 122 Myr, depending on which of the above two values of the post-spike abundance ratio is chosen. This decay interval has some further uncertainty owing to uncertainties in the production ratio of the two nuclides.

Four of the extinct radioactivities, ^{107}Pd , ^{129}I , ^{135}Cs and ^{182}Hf , are candidates to be made by the r -process, because they lie on the neutron-rich side of the s -process capture path and would not be traversed by an s -process event taking place with a relatively small neutron number density. However, the s -process at a high neutron number density would make large amounts of these nuclides. Here we first consider whether they can be r -process products.

Let us first make the hypothesis that the ^{129}I present in the early solar system was primarily made by the galactic r -process. This nuclide sits on top of the large r -process abundance peak associated with the 82 neutron closed shell, as does its comparison isotope ^{127}I (Cameron 1982). Thus we can consider r -process production of ^{129}I on the same basis as ^{244}Pu . The 23.1 Myr mean life of ^{129}I is shorter than the expected interval between large-scale mixing events in the interstellar medium that we have discussed. Because both the mixing and the formation of new cloud complexes appear to be triggered by the formation of the same OB Association, it appears that the mixing event will sweep up the r -process products formed after the previous large-scale mixing event.

Again we use the spike method, but owing to the shortness of the mean life of ^{129}I , we need to consider only the ^{129}I made in the last spike. Because we take T to be 10^{10} yr with spike intervals of 10^8 yr, the last spike would produce 0.01 of all the ^{129}I ever made. Estimating the production ratio of $^{129}\text{I}/^{127}\text{I}$ to be

1.27 from observed r -process abundances, we obtain a $^{129}\text{I}/^{127}\text{I}$ ratio of 0.0127 after the last spike. This would decay to the early solar system observed level of 10^{-4} in 4.8 mean lives of ^{129}I , or 110 Myr. This is remarkably consistent with the decay interval for ^{244}Pu , which was independently estimated above.

Next consider ^{182}Hf . Here the mean life is 13 Myr. This radioactivity has only recently been discovered (Harper et al. 1991a), and with the abundance known only to be in the range 8 to 80×10^{-6} relative to ^{180}Hf (these numbers include an uncertain correction factor of 3), it might seem too uncertain to be of much use. However, despite this uncertainty, this nuclide can be used to make a decisive test of the r -process origin of both itself and of ^{129}I .

The r -process is comparable in abundance to the s -process at mass 182. Using the periodic spike method mentioned above, some 110 Myr prior to the solar system 0.01 of all the ^{182}Hf ever made was present, making the $^{182}\text{Hf}/^{180}\text{Hf}$ ratio at that time 2.1×10^{-3} (using the r -process abundance estimates of Käppeler et al. [1989]). If, in parallel to the considerations for ^{129}I , the ^{182}Hf is now allowed to decay for 110 Myr, the $^{182}\text{Hf}/^{180}\text{Hf}$ ratio is decreased to 4.4×10^{-7} . The lower limit on the $^{182}\text{Hf}/^{180}\text{Hf}$ is a factor of 20 higher. Therefore it appears that the r -process can only make a minor contribution to the ^{182}Hf in the early solar system.

It is clear from this calculation that the radioactivities which are shorter-lived than ^{182}Hf cannot have received significant contributions from the r -process.

As we have noted above, the r -process starts about 10 Myr after the formation of an OB Association and continues until about 25 Myr after the formation of the Association. ^{129}I decayed for an additional period of 110 Myr before formation of the solar system. This would then place the time interval between formation of the two OB Associations also to be 110 Myr, with the solar system being formed about 140 Myr after formation of the first OB Association.

The tentative conclusion to be reached at this point in the discussion is that ^{129}I may be formed primarily as an r -process product, but that the shorter-lived radioactivities can receive only a minor contribution from the r -process at best.

V. THE p -PROCESS RADIOACTIVITIES

There are two p -process nuclides among the extinct radioactivities, ^{146}Sm and ^{92}Nb , the latter newly discovered by Harper et al. (1991b). We consider these in turn.

The p -process products are formed by the photodisintegration of heavy elements that have previously been built up by neutron capture. The term “ p -process” was originally coined to denote an unspecified mechanism that would make nuclei on the proton-rich side of the valley of beta stability, but an alternative term “gamma-process” has recently been used to indicate the

photodisintegrations specifically as distinct from proton capture. However, throughout this chapter we use the original term.

Because of the extreme environmental conditions required for nuclear photodisintegrations, the *p*-process nuclei must be products of supernova explosions (Woosley and Howard 1978). The photodisintegrations take place on heavy nuclei that have been built up to substantial abundances by the prior operation of the *s*-process in the presupernova star. A heavy element like samarium (the same would be marginally true of niobium) will only be built up significantly in an *s*-process using a ^{13}C neutron source in an asymptotic giant branch star (AGB star, to be described in more detail in Secs. VI and VII) (Hollowell and Iben 1989). These stars have relatively low masses (up to $2 M_{\odot}$ or perhaps a little more) which do not ordinarily undergo supernova explosions unless (in some cases) they are in binary stellar systems.

The mean lives of the *p*-process nuclides are long enough so that we can use an averaging method to estimate their abundances in the interstellar medium. As long as the medium has not been isolated from the mixing currents in the interstellar medium (as in a molecular cloud complex), the average amount present in the medium relative to the total amount ever made is the ratio of the mean life τ to the total period T in which the radionuclide has been manufactured (roughly the age of the Galaxy) (Cameron 1962). Such an estimate assumes continuous nucleosynthesis at a constant rate, whereas it is evident that nucleosynthesis occurred at a more rapid rate near the birth of the Galaxy than at the time of formation of the solar system. To compensate for this, we take T to be a little too high, about 10 Gyr at the formation of the solar system. Because a supernova explosion would disrupt a molecular cloud, we must consider *p*-process products to be injected into the general interstellar medium and later introduced into a molecular cloud when it is formed.

Howard et al. (1991) have suggested that the *p*-process products in the vicinity of mass number 90 may also be built up by proton-capture reactions using protons released by carbon-burning at temperatures of about 3×10^9 K in Type Ia supernovae. These reactions would compete comparably with photodisintegrations under such conditions in Type Ia supernovae.

^{146}Sm is the longest lived of the extinct radioactivities discussed here, with a mean life of 149 Myr. Its reference isotope is ^{144}Sm , and Prinzhofer et al. (1989) have estimated the $^{146}\text{Sm}/^{144}\text{Sm}$ ratio at the time of formation of the solar system as about 0.015; Swindle (see his Chapter) estimates that this could be as much as a factor of three smaller. The latter estimate is in agreement with that of G. Lugmair (personal communication), who gives the ratio as 0.006 to 0.007 with an error of ± 0.0015 . Woosley and Howard (1990) have estimated the production ratio of $^{146}\text{Sm}/^{144}\text{Sm}$ to lie in the range 0.01 to 0.4. F.-K. Thielemann (personal communication) has also made a preliminary estimate of this ratio which is about 20 times as large as that obtained by Woosley and Howard with the same range of uncertainties.

If we adopt the continuous nucleosynthesis procedure of estimating the abundance of ^{146}Sm in the interstellar medium, with the Woosley and Howard

production ratio, we obtain a value in the range 1.5×10^{-4} to 0.006 relative to ^{144}Sm , which slightly overlaps the observed value range of 0.005 to 0.015. If we apply Thielemann's correction, the range becomes 3×10^{-3} to 0.12. The observed values lie entirely within this range. The uncertainties emphasize the need for further work to clarify the nuclear physics involved as well as the need for more experimental measurements.

For ^{92}Nb the mean life is about 50 Myr. The continuous nucleosynthesis model predicts that 0.005 of all the ^{92}Nb ever made would be present at the time of formation of the solar system. However, we can only guess at the $^{92}\text{Nb}/^{93}\text{Nb}$ production ratio. An extremely crude estimate can be made from systematics of *p*-process abundances. In the neighborhood of mass 92, the normal *p*-process abundances (of nuclei having even numbers of protons and neutrons) lie near 10 % of the even-even *s*-process products (however, they are considerably higher than this very close to ^{92}Nb because of the vicinity to the closed shell at 50 neutrons). In the heavier mass number range, the *p*-process abundances are roughly 3% of the *s*-process even-even products. There are only two stable odd-odd *p*-process nuclei, ^{138}La (very near a closed neutron shell) and ^{180}Ta , and these have abundances of 10% and 1 %, respectively, of neighboring even-even *p*-process nuclides. However, the observed long-lived ^{180}Ta is only an isomeric state and its abundance would be abnormally low. Therefore we take the abundances of odd-odd *p*-process nuclei to be about 10% of the even-even ones. Thus from systematics alone, with very large errors, we estimate that $^{92}\text{Nb}/^{93}\text{Nb}$ production ratio would be about 0.01.

The continuous nucleosynthesis model predicts that the observed $^{92}\text{Nb}/^{93}\text{Nb}$ ratio should be about 5×10^{-5} , compared to the observed value of 2×10^{-5} . In view of the large errors involved, and the tendency of the continuous nucleosynthesis model to predict somewhat high abundances, these two numbers are in essential agreement.

VI. THE MOLECULAR CLOUD ENVIRONMENT

To set the stage for the following discussion, it is useful to write down a few numbers characteristic of the molecular cloud environment. As noted previously, the average density of particles in the interstellar medium is about one particle per cubic centimeter. The average density in a molecular cloud is about 10^2 to 10^3 cm^{-3} . Cores form inside the cloud complex and have characteristic densities of in the range 10^4 to 10^5 cm^{-3} (Myers 1990). Small cores in massive clouds can have densities in the range 10^6 to 10^7 cm^{-3} . It is difficult to define the mass of a core because there is a smooth transition from the background density of the cloud to that in the interior of the core. The cores themselves have a fairly large range of masses, although there seems to be a smaller range within a given part of a cloud complex than the total range in general. We shall consider a nominal core mass of about $1 M_{\odot}$ for the central part of a core. The temperature within the cloud complex appears to be

a surprisingly uniform 10 K. The Doppler broadening of spectral lines emitted from core material corresponds to about Mach 0.7, or about 0.2 km s^{-1} .

Nevertheless, Doppler shifts from material outside the cores typically reveal radial velocities of about 0.5 to 1 km s^{-1} and therefore the velocities are characteristically supersonic (Myers 1990; Myers et al. 1991*b*). Such supersonic motions are strongly dissipative through shocks, and therefore they cannot persist for very long without being frequently and strongly driven by disturbances in the gas which effectively act like supersonic pistons. Because the effect is so widespread, the source of the supersonic turbulence must also be widespread, and in order for the turbulence to be persistent, very large amounts of mass must be set into motion. Possible sources for this include large-scale generation of hydromagnetic waves by gas motions in the cloud complex which are rapidly dissipated into the sub-Alfvénic velocity range, and the motion of the background stars that are embedded in the cloud and move with random velocities of 10 to 20 km s^{-1} relative to it. The accelerations impulsively given to the cloud gas by the passages of these stars (like the stellar acceleration of comets in the Oort Cloud) appear to be of the right order. The nonthermal behavior is some superposition of supersonic turbulence from these and other pervasive and widespread sources. We shall discuss several potential sources of much larger disturbances in the following paragraphs.

A major question of great relevance to us is the mechanism of formation of the cores. One possibility, discussed extensively by Shu (1983), is that the cores arise from density fluctuations within the cloud that attract surrounding material, which flows very slowly inwards to form the core by ambipolar diffusion, in which the matter slowly diffuses across the magnetic field lines. This generally requires the conditions to be rather quiescent. The characteristic radius of a core is about 0.1 pc . Thus the ambipolar diffusion needs to concentrate the gas from a sphere of radius about 1 pc . The ambipolar diffusion time is probably a few Myr (Shu 1983).

Cores can be formed much faster if the motion of the gas can be primarily along the field lines rather than across them. This would require the action of some disturbing event within the cloud that would accelerate the gas to a substantial velocity, followed by a channeling effect due to the surrounding magnetic pressure perpendicular to the field lines in the local flux tube. The radius of the affected part of the flux tube would be larger than 0.1 pc and smaller than 1 pc . As mass moves along the flux tube away from the point of the disturbance, the mass it encounters becomes swept up into a density enhancement traveling along the tube, but progressively more slowly as the amount of mass increases. Also, as the mass increases, some gravitational compression of it becomes likely, leading to a pinching together of the local field lines. In this picture there may well be two cores formed, one in each of the two directions along the flux tube from the point of the disturbance. The time taken for this longitudinal compression may typically be $< 1 \text{ Myr}$ (Cameron 1984).

These two pictures may well be extremes, with the truth most likely lying in between them. Thus, longitudinal compression may produce a substantial density enhancement, followed by ambipolar diffusion in the final stage of the core formation. Certainly, when a core becomes sufficiently concentrated to go into gravitational collapse, the field lines will be diffusing out all the time, although the net effect of the collapse will be a substantial enhancement in the magnetic field strength.

There can be a variety of disturbing events within the interior of a cloud complex. A star may come to the end of its active lifetime and eject material. Such events depend upon the accidental presence of a star within the cloud complex when its eruption takes place. But because star formation is an intrinsic process of the cloud complex itself, by far the most abundant disturbing events are likely to be those associated with star formation.

A typical star in the galactic plane moves relative to a molecular cloud with a velocity of 10 to 20 km s⁻¹. A typical path through such a cloud has a length of order 15 pc. Therefore the typical star takes about 4 to 8 × 10⁴ yr to traverse the cloud. However, stars formed within the cloud will normally have only a small velocity relative to it, and their residence time within it will be much longer.

Ordinary main-sequence stars have rather little effect on a molecular cloud when they pass through, unless they have a high mass. A star like the Sun emits sufficiently little ultraviolet radiation that only that part of the cloud within a small fraction of a parsec becomes ionized, too little to produce a significant perturbation to the cloud parameters. The most massive stars will destroy the cloud, as noted previously. Stars of intermediate mass may not destroy the cloud, but they are certainly likely to disrupt it locally, probably interfering with star-formation processes close to the intermediate mass star, but possibly enhancing it farther away due to induced compression within the cloud gas. Most observations of star formation in molecular clouds are associated with environments not containing these intermediate and massive stars, so we shall concentrate our discussion on them.

Stars of one up to a few solar masses produce the most interesting effects within a molecular cloud when they approach the ends of their post-main-sequence lifetimes. These stars are called asymptotic giant branch (AGB) stars. They have evolved through their hydrogen and helium burning stages, they have ascended the giant branch in their color-magnitude diagrams for the second time, and they end their active lifetimes near the tip of the giant branch where they eject typically a few tenths of a solar mass of envelope material as a planetary nebula, leaving a white dwarf remnant (Hollowell and Iben 1989). Prior to this, they will be the sources of strong stellar winds.

Thus the AGB star creates quite a disturbance within the molecular cloud during the final stage of its evolutionary lifetime. Consider only the final episode in which 0.1 or 0.2 M_⊙ is expelled to form a planetary nebula. This material is typically ejected with a velocity of several tens of km s⁻¹. This acts like a point explosion within the molecular cloud. An oversimplified

picture of the resulting events is the following one. The ejected material can move freely along the direction of the lines of force of the local magnetic field, but the motion perpendicular to the field lines compresses the field, which rebounds to redirect the ejecta along the field lines. In this way, the point explosion generates two pistons moving in opposite directions along the field lines, sweeping mass before them as they slow down. By the time the pistons have slowed to local sound speed, they will have swept up roughly 100 times their original mass, or of order 5 to 10 M_{\odot} for each piston (considering only momentum conservation). This is precisely the picture described above as required to form molecular cloud cores that will become unstable to gravitational collapse. Thus the final eruption of the AGB star is expected to act as a trigger for star formation within the cloud (Cameron 1984). With magnetic field entanglements and other variations in the field structure, a more realistic picture of what happens may differ significantly from this description.

Now consider the disturbances that originate from newly formed stars. These are observed to be of two kinds. Such newly formed stars are known by a variety of names; we shall call them young stellar objects (YSO) when they are very new and usually at least partly obscured, and at a later stage we shall call them T Tauri stars. The YSO are observed to emit very strong stellar winds. They are also observed to emit jets of material in opposite directions, a process called bipolar ejection. Within broad observational uncertainties, the amount of momentum in these jets is comparable to the amount of momentum in the ejection of a planetary nebula from an AGB star. Similar considerations apply, and thus it appears probable that newly formed stars can act as triggers to form yet another pair of new stars. If conditions were ideal, a cascade would develop from the original AGB trigger that would double the rate of star formation in each generation (Cameron 1984). Conditions are unlikely to be sufficiently ideal for that, but nevertheless a great deal of star formation can ensue.

Self-propagating star formation has been suggested before in a variety of contexts (see Elmegreen [1987*b*] for a list of these proposals). Most of the proposals involve considerably more energetic events than those discussed here, and the effects are expected to act over greater distances than the rather local processes with which we are concerned.

Let us make a crude estimate of the mixing induced by star formation within the molecular cloud. There is of order $10^9 M_{\odot}$ of gas in molecular clouds in the Galaxy, and in this gas about one star is formed per year, or about 10^{-9} stars per solar mass of gas per year. Because the mass outflow from a young star has an ejection velocity of order 100 km s^{-1} , then it follows that this ejecta will mix with about 100 times as much material in the cloud when the material is slowed to typical turbulent velocities of order 1 km s^{-1} in the cloud, again considering only momentum conservation. Thus something like 10^{-7} of the gas is mixed per year, for an interval between mixings of 10 Myr. However, since there are regions in which the star-formation activity

is concentrated, clearly the deduced mixing interval has a large dispersion. The turbulent velocities themselves will produce a diffusive mixing, but this will not rapidly spread the boundaries of a region that has been seeded with some radioactivity.

Another form of cloud disruption can occur because of a nova eruption. In this case hydrogen accretes onto a white dwarf component of a binary system. Thermonuclear ignition occurs in a thin shell near the surface of the white dwarf, heating and greatly expanding the upper layers of the envelope, which then initiates a substantial blowoff of mass. However, only a small fraction of the total stellar mass is ejected in the eruption, of order 10^{-4} to 10^{-5} of a solar mass. However, these eruptions are observed to repeat for the less energetic novae, and it is likely that all novae repeat as long as the material transferred onto them from their binary companions remains available. In a given eruption, the fraction of the ejected mass containing ^{26}Al is likely to be small. According to Weiss and Truran (1990), a nova in which hydrogen burning occurs only in solar composition material should eject material with a contaminated mass fraction of 10^{-6} to 10^{-4} , as is also true of a star with carbon and oxygen mixed into the burning material, but a star whose burning layer is contaminated with underlying oxygen-neon-magnesium may eject a mass fraction of 10^{-4} to 5×10^{-3} . This last amount probably occurs in about 25% of all novae.

When the nova eruption occurs, about 10^{45} erg of ultraviolet radiation is produced, a fair fraction of it above the hydrogen ionization threshold, so that something approaching 10^{56} hydrogen atoms will be ionized within roughly a parsec. At molecular cloud densities this hydrogen will recombine in about 100 yr. The speed of sound in the ionized hydrogen (at 10^4 K) is 10 km s^{-1} , and a sound wave will traverse 10^{-3} pc during the recombination time. Thus an organized spherical expansion does not have time to become established during the recombination time. Following recombination, hydrogen molecules can form again on grain surfaces. The time to do this is roughly the same as the time for a random hydrogen atom to collide with a grain, or 3×10^4 yr. In this time, ordinary gas cooling processes will bring the temperature down to 100 K or somewhat less. But some hydrogen molecules will form relatively quickly and provide a more efficient cooling. Thus the net effect of the nova explosion is to heat a region of order 1 pc in radius which will undergo significant expansion in a time of order 10^5 yr.

As the nova eruptions recur, a series of these heating episodes will take place along the track of the binary system in which the nova episodes are taking place. If the random velocity of the binary relative to the cloud is 10 km s^{-1} , then a cylindrical length of order 10 pc will be heated and will expand. This is substantially disruptive to the molecular cloud, and it is not consistent with the conditions observed in which the core collapses take place. Whether it can lead to star formation by a different mechanism is a separate question that will not be considered here.

VII. ^{26}Al

The mean life of ^{26}Al is 1.07 Myr, the shortest lived of the extinct radioactivities. We therefore expect that we should look for a stellar source within a cloud complex. There are a number of ways in which ^{26}Al can be made in stars, all of them involving the capture of a proton on ^{25}Mg , in the reaction $^{25}\text{Mg}(p,\gamma)^{26}\text{Al}$. This reaction occurs at slow stellar evolution rates at a temperature of 5×10^7 K, and it occurs very rapidly at temperatures higher by a factor of 4 or more (Champagne et al. 1984).

A supernova is expected to produce a $^{26}\text{Al}/^{27}\text{Al}$ ratio of order 10^{-3} (Truran and Cameron 1978; Arnett and Wefel 1978; Woosley and Weaver 1980; Arnould et al. 1980). This ratio will be reduced to the observed meteoritic value in not more than 5 mean lives, or about 5 Myr. Because a supernova explosion will eject a good fraction of $1 M_{\odot}$ (or more) of material at velocities of several thousand km s^{-1} , it would be highly destructive to a molecular cloud environment, and only a different scenario which utilizes the violence of the explosion, such as the supernova trigger hypothesis (Cameron and Truran 1977), might be consistent with solar system ^{26}Al . However, this scenario does not quantitatively support the production of the other extinct radioactivities.

^{26}Al is also expected to be formed in a nova eruption (Truran 1982). As is discussed above, relatively little material is ejected in such an eruption, and this material is not mixed efficiently into the surrounding mass that is briefly ionized following the eruption. Thus novae are not expected to be important sources of any extinct radioactivity in the solar system. Yet another class of objects in which ^{26}Al can be produced is that of the AGB stars. In the giant phase of their evolution they will have (periodically) a hydrogen-burning shell in which the temperature is at least 5×10^7 K, so that ^{26}Al will be produced in this shell region (Cameron 1984). In such giant stars, the outer convective region extends down from the surface to great depths. As the star approaches the planetary nebula ejection stage, it is expected that the outer convection zone will extend all the way down to the hydrogen-burning shell (Norgaard 1980), at which point it has been called a "hot bottom" configuration. Then the ^{26}Al produced in the shell can be mixed efficiently to the surface and hence expelled in a stellar wind. Important new insights are developing from the examination of meteoritic graphite and silicon carbide grains which are believed to have been formed in AGB stars (Zinner et al. 1991a). Large numbers of these grains show evidence for the one-time presence of ^{26}Al with $^{26}\text{Al}/^{27}\text{Al}$ ratios of order 10^{-3} or 10^{-4} . However, a few of the grains show much larger amounts of ^{26}Al ; in one SiC grain the $^{26}\text{Al}/^{27}\text{Al}$ ratio is 0.2; this same grain is depleted in ^{13}C relative to ^{12}C , enriched in ^{15}N relative to ^{14}N , and depleted in ^{29}Si and ^{30}Si relative to ^{28}Si . In a second, larger, grain the $^{26}\text{Al}/^{27}\text{Al}$ ratio is 0.23 (Zinner et al. 1991b), and the other depletion and enhancement patterns are similar. In addition, the isotope ^{44}Ca is anomalously large. In the following paragraph, the suggestion is made that

these are signatures of the hot bottom stage of the AGB star.

Before the hot bottom stage, there will have been a number of small mass exchanges between the hydrogen envelope and the helium layer; in the course of these, the hydrogen envelope will have been mixed with the products formed in the hydrogen-burning shell, including ^{26}Al , and most grains formed and expelled at this time will have small $^{26}\text{Al}/^{27}\text{Al}$ ratios. In the hot bottom stage, the entire hydrogen envelope circulates through the hydrogen-burning shell, so that much of the ^{25}Mg will be converted to ^{26}Al by proton capture. Because this shell is relatively close to the surface in the late evolutionary stage, its temperature will be quite high, probably about 7×10^7 K or more. ^{29}Si and ^{30}Si are much more rapidly destroyed by proton capture than ^{28}Si (Woosley and Hoffman 1986). Also at such a high temperature ^{15}N is destroyed less rapidly relative to ^{14}N than is true at lower temperatures, and so ^{15}N will become enriched. From time to time, material will be mixed in from below as the hydrogen-burning shell is shut down, and if the grains are ejected at such times, then, as discussed later, ^{12}C formed in the helium layer will be enriched, and it is possible that enough neutron-produced ^{44}Ca can be brought up from below to become visible as an anomaly (this is further discussed in the following section). The $^{26}\text{Al}/^{27}\text{Al}$ ratio may become significantly higher than 0.23, but we must await more experimental evidence to be sure of this. Zinner's two highly anomalous grains are unusually large, and they are thus candidates to have been made during the final AGB star stage in which the planetary nebula was expelled; under such circumstances the relative gas expansion rate is smaller than in a wind, and grains would have an opportunity to grow for a longer period of time after nucleation.

The winds are strong in high-luminosity red giant stars. A rough estimate is that $0.5 M_{\odot}$ will be expelled in the 1 Myr prior to the planetary nebula ejection from an average star operating with a ^{13}C neutron source (discussed below), which assumes that the average such star has an initial mass of order $1.5 M_{\odot}$. In the planetary nebula itself, another 0.1 or $0.2 M_{\odot}$ is expelled which will also contain ^{26}Al . If such a star also has a velocity relative to the cloud of about 10 km s^{-1} , then it will travel 10 pc in this last 1 Myr, a good fraction of typical cloud dimensions. If the wind has a velocity of order 100 km s^{-1} , then the $0.5 M_{\odot}$ of material ejected in the wind will mix into about $50 M_{\odot}$ of material (considering only momentum conservation) before being slowed down to typical cloud turbulent velocities. If the ^{26}Al abundance is about equal to 0.25 of the abundance of ^{27}Al (from Zinner's measurements), then the $^{26}\text{Al}/^{27}\text{Al}$ ratio in this mixed material will probably be about 2.5×10^{-3} . This is a factor of 50 higher than the ratio observed in the solar system. Thus some 3.9 mean lives of ^{26}Al would be necessary to bring the ^{26}Al abundance down to the solar system level. This AGB source of ^{26}Al seems the most plausible of the possible sources of this radionuclide in the early solar system. We now consider the frequency of such contamination in a molecular cloud.

Under steady-state conditions in the Galaxy, about one star is formed per year, primarily in molecular clouds, and therefore one star comes to the end

of its life every year, most of these being AGB stars in the lower-mass range. The end points of stellar evolution can be reached at arbitrary points in space. If we assume that one-quarter of the galactic mass is in molecular clouds, then the fractional volume within the galactic disk occupied by molecular clouds is about 2.5×10^{-4} , and this number is also the number of AGB stars that end their lives within a molecular cloud per year. If the ejecta from the terminal stage of an AGB star contaminates $50 M_{\odot}$ of material in its vicinity, as discussed above, then $0.012 M_{\odot}$ of molecular gas is contaminated per year in the Galaxy. In a mean life of ^{26}Al , $1.3 \times 10^4 M_{\odot}$ of material will be directly contaminated by AGB ejecta. This is small compared to the amount of mass that goes into new stars.

The net effect is that only a small part of the material within molecular clouds would be contaminated with ^{26}Al . If this were the entire story, then one would conclude that the probability of having the solar system emerge from average star formation within a molecular cloud complex is very small. But there is an escape clause. The possibility was mentioned above that events like the AGB stars and the bipolar ejecta from young stars can themselves trigger the formation of additional stars, leading to the formation of the close groups commonly seen in these clouds (Myers and Benson 1983). For purposes of illustration consider an oversimplified and ideal model. If the star formation events triggered by AGB stars should go through 12 generations, each generation doubling the number of star formation sites, then 4096 stars would be formed. Because the average stellar mass is considerably less than one M_{\odot} , these 4096 stars would have something like $10^3 M_{\odot}$ of material in them, which is an order of magnitude larger than the estimated amount of material that would be contaminated by a single AGB star event. The postulated chain of star formation would clearly induce some further mixing in the cloud. With this additional geometric dilution, the ^{26}Al abundance in the contaminated material would start out up to an order of magnitude higher than the solar system level, but this can be in error by a substantial factor. In Cameron (1984) it was estimated that the time required to complete a step in the above ideal star-formation chain would be about 5×10^5 yr. The full chain would thus take about 6 Myr. The early steps in the chain would produce stars with an ^{26}Al abundance higher than that in the solar system, but in the majority of them the ^{26}Al abundance level would be lower than in the solar system by a modest factor.

In summary, it appears that the local molecular cloud in the vicinity of the path of the AGB star would become contaminated with the $^{26}\text{Al}/^{27}\text{Al}$ ratio initially at a level about 1 order of magnitude above that found in the early solar system. Some combination of mixing and decay would reduce this ratio to the solar system level. If the reduction were entirely due to decay, then about 1 or 2 Myr would pass between the time the material was ejected from the AGB star and the formation of the solar system.

It is necessary to caution that many quite isolated new stars appear in molecular clouds, and these may have been formed by some other kind of

triggering process or even by a spontaneous core formation and collapse, so that they need not have any contamination by ejecta from an AGB star in its final phases. For the solar system, the evidence is that this contamination occurred.

VIII. *s*-PROCESS RADIOACTIVITIES

Previously (Sec. IV) we considered whether the observed abundances of the nuclides ^{107}Pd , ^{129}I , ^{135}Cs and ^{182}Hf could have been produced by the galactic *r*-process, and we concluded that only ^{129}I could have been obtained in this way. The other nuclides have shorter mean lives and hence would have decayed to too low a level to fit the solar system abundances. The ^{129}I identification was only tentative, however, and it remains to be determined whether all four of these nuclides can have been provided to the solar system as a result of the *s*-process taking place in the helium layer of the AGB star which provided the ^{26}Al from the hydrogen envelope.

It appears that the main contributions to the *s*-process in nature are made in an AGB star of 1 to 2 M_{\odot} (Hollowell and Iben 1989). Such a star has been through both hydrogen and helium burning in its central regions, and it therefore possesses hydrogen and helium shell burning sources. However, these shell sources are not active simultaneously, owing to the high-temperature sensitivity of the helium burning shell. After a period of hydrogen shell burning, the helium shell will undergo a thermonuclear runaway, leading to an extensive convection zone in the helium region that extends for a time to the lower boundary of the hydrogen envelope. After this outburst, the helium shell burning gradually dies away and the helium shell becomes dormant. Shortly thereafter the hydrogen burning shell is regenerated; the outer convection zone extends all the way down to the hydrogen burning shell, and some penetrative mixing into the top of the underlying helium zone occurs. This has two important effects: it mixes the products of the neutron capture in the helium layer out to the surface of the star, and it provides via the admixed hydrogen additional fuel for neutron production. The mixing brings together ^{12}C made in helium burning with the hydrogen, and the sequence $^{12}\text{C}(p,\gamma)^{13}\text{N}(\beta^+\nu)^{13}\text{C}(\alpha,n)^{16}\text{O}$ then creates the neutrons as the mixture of hydrogen and carbon is swept down to the base of the helium layer during the next helium flash. The optimum mixing ratio is 1 proton to 10 carbons, so that very little ^{14}N neutron absorbing poison is produced by the proton capture, and this mixing ratio appears close to that achieved in the AGB star.

The AGB star evolves through a series of these helium shell flashes, during which time carbon and oxygen formed in the helium region are deposited on the core below the helium-carbon boundary, and fresh helium is added to the helium region at the top as a result of the hydrogen burning. Thus in each flash, the helium region has been somewhat diluted by fresh material that has not been exposed to neutrons before, and which thus maintains a supply of seed nuclei in the vicinity of the iron abundance peak. It has been found that

this type of behavior is required so that the material in the helium zone can have been exposed to a roughly exponential distribution of neutron fluences, in accord with the observational inference.

More massive AGB stars can produce neutrons by purely helium reactions: as in $^{14}\text{N}(\alpha, \gamma)^{18}\text{F}(\beta^+ \nu)^{18}\text{O}(\alpha, \gamma)^{22}\text{Ne}(\alpha, n)^{25}\text{Mg}$. However, the total number of neutrons generated per iron seed nucleus in this way is smaller than in the lower-mass AGB star case, because the neutron source material is not renewable. Thus it is unlikely that the more massive stars can be as effective in producing ^{107}Pd as the lower-mass ones.

Analyses of the *s*-process abundance yields have shown that a neutron number density of $3 \times 10^8 \text{ cm}^{-3}$ characterizes the final abundances produced by the process (Käppeler et al. 1990). It should be noted that this conclusion is particularly sensitive to the lower neutron densities in a distribution of such densities, because lower densities allow the formation of nuclides in "protected" positions close to the valley of beta stability, whereas the neutron capture path does not traverse such nuclei if the neutron density is high. Bazan (1991) has concluded that this "freezing neutron density" is $3 \times 10^7 \text{ cm}^{-3}$. Bazan has also found that in the course of a helium shell flash, under a wide range of conditions, the neutron number density reaches a peak value close to $1 \times 10^{10} \text{ cm}^{-3}$. Also, during the course of a flash, the amount of material in the helium region convective zone increases while the neutron density is increasing, but it reaches its maximum extent after the neutron number density has abruptly dropped to a very low value. While the convection zone is near its maximum extent, the low neutron number density can regenerate nuclear abundances in protected positions near the valley of beta stability, but there is no substantial destruction of the abundance patterns established at maximum neutron number density. This means that the material left closest to the hydrogen boundary, which will be dredged up later, will be that characteristic of the highest neutron densities, or 3×10^9 to $1 \times 10^{10} \text{ cm}^{-3}$, even though an analysis of the Käppeler et al. (1990) type would indicate a much lower density (Hollowell and Iben 1990; Iben, personal communication).

The importance of this consideration may be seen from the following. I have calculated a steady-flow *s*-process through nuclei near the valley of beta stability, using an *r*-process network in which these nuclei were included (a similar *r*-process steady-flow calculation was reported by Cameron et al. [1983]). These calculations used nuclear data assembled by F.-K. Thielemann and J. J. Cowan (unpublished). The ratios of the four potential *s*-process extinct radioactivities relative to their reference nuclei are shown for several values of the neutron number density in Table II. Also shown in Table II are the effective production ratios in which the reference nuclide abundances are multiplied by the normal *s*-process abundance and divided by the sum of the *s*- and *r*-process abundances. This correction factor used the separation of nuclide abundances into *s*- and *r*-process components by Käppeler et al. (1989). Finally, Table II also shows the ratios of the corrected production ratios to the observed ones.

TABLE II
s-Process Ratios as a Function of Neutron Number Density^a

Nuc. Ratio	3×10^8	3×10^9	1×10^{10}	1×10^{11}
$^{107}\text{Pd}/^{108}\text{Pd}$	0.15	0.15	0.15	0.15
$^{129}\text{I}/^{127}\text{I}$	0.0037	0.033	0.102	0.55
$^{135}\text{Cs}/^{133}\text{Cs}$	0.095	0.72	1.38	1.72
$^{182}\text{Hf}/^{180}\text{Hf}$	0.0040	0.043	0.131	0.60
$^{107}\text{Pd}/^{108}\text{Pd}$	0.086	0.086	0.086	0.086
$^{129}\text{I}/^{127}\text{I}$	0.00020	0.0018	0.0057	0.031
$^{135}\text{Cs}/^{133}\text{Cs}$	0.014	0.11	0.21	0.26
$^{182}\text{Hf}/^{180}\text{Hf}$	0.0026	0.027	0.084	0.38
$^{107}\text{Pd}/^{108}\text{Pd}$	4, 300	4, 300	4, 300	4, 300
$^{129}\text{I}/^{127}\text{I}$	2.0	18	57	310
$^{182}\text{Hf}/^{180}\text{Hf}$	< 325	< 3, 400	< 10, 500	< 47, 500
$^{182}\text{Hf}/^{180}\text{Hf}$	> 32.5	> 340	> 1, 050	> 4, 750

^a Nuc. ratio is the ratio of abundances of indicated isotopes. Neutron number densities are in cm^{-3} . The first set of four rows shows the relative production ratios in the *s*-process. The second set of four rows shows the production ratios after multiplying the reference *s*-process abundance by the normal fractional production of the reference nucleus in the combined *s*- and *r*-processes. The third set of five rows shows the corrected production ratios relative to the observed ratios; the last two of these rows correspond to the lower and upper limits on the $^{182}\text{Hf}/^{180}\text{Hf}$ observed ratio.

It should be noted that we had concluded from the ^{26}Al discussion that the interval between ejection of material from this unique AGB star, that has contributed very short-lived radioactivities to the solar system, and the formation of the primitive solar nebula, is very short, probably not more than 2 Myr. Hence the correction to the abundances in Table II for decay during this interval is small and no correction is made here. Therefore the production ratios shown in the last set of rows of Table II should be proportional to the abundances of the three extinct radioactivities, all other factors being the same.

The numbers obtained in the last set of rows of Table II should correspond to a common factor which is the geometric dilution needed to bring the production ratios of the extinct radioactivities down to the level observed in the early solar system, provided that the assumption is correct that these four nuclides are products of the *s*-process in the AGB star. Another hidden assumption here is that the shape of the *s*-process abundance curve for the AGB star is the same as that in the solar system abundance distribution generally, which is probably a quite good assumption. From the earlier discussion of the AGB star neutron production environment, it should be expected that the best fit to a common geometric dilution factor should be for a neutron number density of 3×10^9 to 10^{10} cm^{-3} .

First, it should be noted that the *s*-process production of ^{129}I is much too small relative to the other nuclides. This confirms the previous tentative assignment of this nuclide to the galactic *r*-process.

Considering the substantial errors in making all of these estimates, the other three nuclides are consistent with a common production by the *s*-process with a neutron number density in the expected range. They could not be made at the lowest or highest neutron number densities shown in Table II. The common geometric dilution factor is roughly 4000. This favors an abundance of ^{182}Hf near the upper end of its range of uncertainty.

In the preceding section, it was estimated that the geometric dilution that occurred after ^{26}Al was ejected from the AGB star was about a factor of 100. If this is correct, the total geometric dilution of a factor 4,000 implies that the material from the helium region of the AGB star is geometrically diluted by a factor of 40 by mixing into the hydrogen envelope as a result of dredge-up toward the end of the AGB active lifetime. This 2.5% percent admixture from the helium layer is consistent with estimates that have been made from other considerations (Bazan 1991).

Thus we confirm that ^{107}Pd , ^{135}Cs and ^{182}Hf are primarily the products of the *s*-process operating in the AGB star that we postulate to have triggered a chain of star formation that included formation of the solar system.

Although ^{60}Fe has been listed in Table I as an extinct radionuclide, it should be kept in mind that the reality of its existence in the early solar system is not firmly established. With its mean life of 2.2 Myr, it is the second shortest lived of the extinct radioactivities. It can be made by both *s*- and *r*-processes, but from our earlier discussions it is evident that any *r*-process component of

the abundance would long since have decayed before the solar system was formed. However, it can be formed by the *s*-process in the same AGB star that we have been discussing here.

The abundance of ^{60}Fe relative to ^{56}Fe cannot be estimated by the method of steady-flow neutron capture in the manner done above. ^{56}Fe is the principal seed nucleus for the *s*-process, and in any one pulse of neutron capture in the AGB star, the ^{56}Fe will capture enough neutrons to become quite depleted; when hydrogen burns to helium and deposits material on the top of the helium layer, the ^{56}Fe that accompanies the converted hydrogen provides a fresh source of seed nuclei for the next pulse. Thus the amount of ^{60}Fe remaining after a pulse depends upon the detailed history of the pulse. In the steady-flow calculations for neutron capture that were described above, the neutron capture path is centered at ^{60}Fe for neutron number densities of 3×10^9 and 10^{10} cm^{-3} . Thus neutron capture on ^{56}Fe can be expected to lead straight to ^{60}Fe . As the neutrons are captured, the material initially present as ^{56}Fe forms an abundance peak that moves upward in mass number and spreads out as it goes. An initial guess is that the $^{60}\text{Fe}/^{56}\text{Fe}$ abundance ratio is roughly of order 10^{-2} during the neutron capture phases. If the material is now subjected to a geometric dilution by a factor of 4000, as indicated above, the order of magnitude of the $^{60}\text{Fe}/^{56}\text{Fe}$ ratio at the time of formation of the solar system is about 2.5×10^{-6} . This will be further diminished by a little less than a mean life of radioactive decay of the ^{60}Fe , making the abundance ratio compatible with the observed value of 1.6×10^{-6} , within large uncertainties.

Let us return briefly to the question of the abundances in the two large SiC grains analyzed by Zinner and his colleagues, described in the preceding section. The excesses of ^{12}C and ^{44}Ca were postulated to be introduced into the hydrogen envelope by mixing from the helium layer. Of course, the ^{12}C is a main product of the helium burning that takes place at the base of the helium layer. In the author's steady-flow neutron capture calculations at neutron number densities of 3×10^9 and 10^{10} cm^{-3} , the neutron capture path is centered on the calcium isotopes with mass numbers 42 through 46, including 44. The calculated cross section for capture on ^{44}Ca is lower than those for the other calcium isotopes, but not by a large enough factor to account for the ^{44}Ca peak observed by Zinner and his colleagues. However, the level spacing at the neutron binding energy in the ^{45}Ca compound nucleus is comparable to the mean thermal energy at which the capture takes place, indicating that the usual calculational method of estimating neutron capture cross sections, which averages over the expected resonances, is highly unreliable here; therefore the cross section for capture on ^{44}Ca could be very much less than estimated. It will be so postulated here. Then the situation would be similar to that of ^{60}Fe discussed above; the highly abundant seed nucleus ^{40}Ca would feed into the neutron capture path at ^{42}Ca , and its abundance would be periodically refreshed as hydrogen is converted into helium and added to the helium layer.

IX. UNOBSERVED EXTINCT RADIOACTIVITIES

The above analyses provide a crude basis for making some predictions about the expected abundance levels in the early solar system for several extinct radionuclides with reasonably long mean lives, some of which have been looked for in meteorites. In the above analyses, an estimate has been made of the production and dilution of the radionuclide into the surrounding medium, followed by a period of decay which would be required in order to bring the estimated diluted abundance down to observed solar system levels. There can be substantial errors in these estimates. In applying the resulting methods to make predictions of early solar system abundances for additional radionuclides, one can get led astray by these errors, and so the derived numbers for the abundances given below should be taken as just crude indications of the order of magnitude to be expected. The radionuclides are discussed in order of increasing mean life.

^{41}Ca : $\tau \approx 1.9 \times 10^5$ yr. This nuclide is normally made as part of the oxygen or silicon burning processes, so it is primarily a product of supernova explosions. The closest supernova events would be those producing ^{53}Mn , with a decay time of roughly 25 Myr. After this decay time, the ^{41}Ca abundance would be completely unobservable. It can also be made by neutron capture in ^{40}Ca in the neutron production stage of an AGB star; here the above discussion concerning ^{44}Ca is relevant. If we estimate the abundance of ^{41}Ca to be very roughly maintained at 0.01 of the ^{40}Ca , then the helium layer $^{41}\text{Ca}/^{41}\text{K}$ abundance ratio would become about 2.5. After dilution by a factor of 4000, this ratio becomes 6×10^{-4} . For every million years of subsequent decay, the abundance ratio decreases by a factor of 200. The observed upper limit is 8×10^{-9} (Hutcheon et al. 1984). The estimated abundance would decay to the observed upper limit in 2.1 Myr. As the initial abundance was just a guess, this seems roughly compatible with the decay period found for ^{26}Al , and it would appear that searching for this extinct nuclide remains a worthwhile goal.

^{247}Cm : $\tau \approx 22.5$ Myr. This is an r -process product which decays to ^{235}U , which should thus be regarded as the reference isotope. The fraction of all ^{247}Cm ever made that was present at the time of origin of the solar system was about 7×10^{-5} , making this estimate by the method of periodic spikes and allowing 110 Myr of decay after the last spike. The ^{235}U has a mean life of 1 Gyr, so the fraction of it that was ever made at the time of origin of the solar system is 0.1, with negligible subsequent decay. This gives a prediction for $^{247}\text{Cm}/^{235}\text{U}$ of about 7×10^{-4} , to be multiplied by a relative production factor. If the r -process yields peak around mass number 250, then the production factor is nearly unity, but if it peaks around mass number 235 or is fairly flat, then the production factor found in the author's could be as low as 0.1. The production factor that I find in my r -process calculations varies in the range between 0.4 and 0.7. Thus is estimated the probable solar

system $^{247}\text{Cm}/^{235}\text{U}$ abundance ratio to be about 4×10^{-4} . The measured upper limit to $^{247}\text{Cm}/^{235}\text{U}$ is 4×10^{-3} (Chen and Wasserburg 1981*a, b*).

X. DISCUSSION

In this survey of the ten extinct radionuclides, we have found a variety of responsible nucleosynthesis mechanisms. These include high temperature hydrogen-burning, the *s*-process (four times), the equilibrium process, the *r*-process (twice), and the *p*-process (twice). We concluded that five of the radioactivities were likely to be due to an AGB star reaching the final stages of its active evolutionary lifetime within the molecular cloud in which the solar system would form, and that the other five were due to supernova explosions taking place in the interstellar medium prior to the formation of the molecular cloud complex (in some cases, long before).

We also concluded that the probability was low of inheriting nucleosynthesis products from an AGB star contaminating a rather small part of the molecular cloud complex unless that star also triggered a chain of star formation that would be propagated by energetic events accompanying the star formation process itself. We cited some physical reasons for expecting that such triggering should occur.

The great majority of star formation currently observed to occur in the Galaxy takes place in molecular cloud complexes. One of the major objectives of this survey has been to see whether the extinct radioactivities found to have been present in primitive solar system matter could have been introduced in a timely manner into a core within such a molecular cloud complex. Our analyses were necessarily very crude due to some poorly known numbers, but we did conclude that the observed solar system extinct radionuclides were consistent with the formation of the Sun in such a molecular cloud environment.

The discussion given here of the abundances of now-extinct radioactivities in the early solar system was developed with the following postulated local history of the Galaxy, with which the abundances appear to be consistent. We consider the times to be relative to the time of formation of the solar system, and all of them will be before the solar system (BSS).

1. 130 or 140 Myr BSS. An OB Association formed in a local "great grandparent" molecular cloud. The cloud was destroyed and a large-scale mixing event took place in nearby space, leading to the formation of a new local "grandparent" cloud.
2. 110 to 120 Myr BSS. The OB Association stars in the range 8 to 10 M_{\odot} produced *r*-process nuclides. These remained rather localized to the sites of production. We obtained ^{129}I and ^{244}Pu from this event.
3. Prior to about 25 Myr BSS. There was a continuing production of *p*-process nuclides from imploding supernovae in suitable binary systems. These nuclides were also rather localized to the sites of production. We

obtained ^{92}Nb and ^{146}Sm from these events.

4. 25 Myr BSS. An OB Association formed in the grandparent cloud. This was destroyed with large-scale mixing and a new "parent" cloud was formed. The mixing brought in all locally produced r -process and p -process nuclides. ^{53}Mn produced in the highest mass O stars in the OB Association was also mixed into the parent cloud.
5. About 2 Myr BSS. A relatively low-mass AGB star, accidentally located in the parent cloud, came to the end of its active lifetime and triggered a chain of star formation that led to the formation of the solar system. We obtained ^{26}Al , ^{60}Fe , ^{107}Pd , ^{135}Cs and ^{182}Hf from this event.

There is rather little redundancy in this set of interpretations. It has been necessary to draw extensively on information from the fields of nucleosynthesis, stellar evolution and supernova explosions, and the theory of the interstellar medium and its structure, as well as meteoritics and planetary sciences. Further work can and should test several aspects of this set of scenarios.

Acknowledgment. I am especially indebted to my colleague F. Thielemann, who has been a patient and helpful source of information on quantities needed for nucleosynthesis estimates. I am also indebted to J. Wasserburg, T. Lee, J. Truran, J. Cowan, P. Myers, G. Lugmair, C. Harper, I. Iben, B. Elmegreen and T. Swindle for helpful discussions of some of these issues.

CLASSICAL NOVAE: CONTRIBUTIONS TO THE INTERSTELLAR MEDIUM

ROBERT D. GEHRZ

JAMES W. TRURAN

University of Illinois

and

ROBERT E. WILLIAMS

Cerro Tololo Inter-American Observatory

Classical novae, explosions that result from thermonuclear runaways on the surfaces of white dwarfs accreting matter in close binary systems, are sporadically injecting material processed by explosive nucleosynthesis into the interstellar medium. Although novae probably have processed less than $\sim 0.3\%$ of the interstellar matter in the Galaxy, there is theoretical and observational evidence suggesting that they may be important sources of the nuclides ${}^7\text{Li}$, ${}^{13}\text{C}$, ${}^{15}\text{N}$, ${}^{17}\text{O}$, as well as of ${}^{22}\text{Na}$ and ${}^{26}\text{Al}$. The latter nuclides are astrophysically important radioactive isotopes that could have been involved in the production of the ${}^{22}\text{Ne}$ (Ne-E) and ${}^{26}\text{Mg}$ enrichments in meteoritic inclusions believed to contain important clues about the chemical and mineral contents of the primitive solar nebula. These inclusions may be partially composed of dust condensed in nova outbursts. We review theoretical results predicting yields of these various isotopes in nova outbursts, and conclude that most of the heavy isotope anomalies are produced by the approximately 25% of novae that occur in systems containing massive ($\geq 1.2 M_{\odot}$) O-Ne-Mg white dwarfs. Ultraviolet, optical and infrared emission line spectra of classical novae reveal the abundances of some of the gas-phase elements present in the ejecta. Recent studies show that the ejecta in some novae can be strongly cooled by near- and mid-infrared radiation from forbidden-line radiation from highly ionized atomic states. We compare the abundances deduced from observations with the theoretical predictions, and suggest that future studies of infrared coronal emission lines may provide additional key information. Novae produce only $\sim 0.1\%$ of the galactic "stardust" (dust condensed in stellar outflows), but it may be some of the most interesting dust. Novae appear capable of producing astrophysical dust of every known chemical and mineral composition. We summarize the dust-production scenario for novae, and argue that explosions on O-Ne-Mg white dwarfs may lead to the formation of dust grains that carry the Ne-E and ${}^{26}\text{Mg}$ anomalies. Finally, we attempt to place quantitative constraints on the degree to which classical novae participate in the production of chemical anomalies, both in the primitive solar system and on a galactic scale. Diffuse galactic gamma-ray fluxes are especially useful for assessing the ${}^{22}\text{Na}$ and ${}^{26}\text{Al}$ yields from novae.

I. INTRODUCTION

Infrared observations support a picture of galactic chemical evolution in which grains condensed in the ejecta of stars may be a significant reservoir for the transportation of metals in the galactic ecosystem. Metals produced during the advanced stages of nucleosynthesis can be condensed into grains in circumstellar shells during late stages of stellar evolution, and injected into the interstellar medium (ISM) where they are processed and eventually incorporated into new stellar and planetary systems. Once in the ISM, these grains may be further processed by supernova shocks and in molecular clouds, before being incorporated into young stars and planetary systems during star formation in the clouds. Solids that may be remnants of the formation phase are found in our own solar system and around some other main sequence stars. Wolf-Rayet stars, novae and supernovae may also be capable of injecting copious amounts of gas-phase condensibles into the ISM, where they are later processed onto grains in the cores of dense molecular clouds.

Grains in circumstellar shells, the ISM and the solar system are similar in general mineral content. The same four basic mineral types—amorphous carbon (iron?), silicates, silicon carbide and hydrocarbons—are present in all three environments. There are important differences between the grains in these diverse environments (see Gehrz 1989*b*). ISM grains appear to be smaller than their circumstellar counterparts, and grains in some comets were apparently annealed at high temperature. Nonetheless, several properties of cometary dust and meteorite inclusions suggest that dust made in circumstellar shells (stardust) was incorporated directly into solid bodies in the primitive solar nebula. For example, some meteorites contain small dust inclusions with chemical abundance anomalies that strongly suggest that these grains condensed in the immediate ejecta of nova and supernova eruptions. This would imply that some grains may have survived from the circumstellar to the solar environments relatively unchanged. On the other hand, it has been argued that it is difficult for stardust to survive destruction by supernova shocks in the ISM and by high temperatures during the early evolution of young stellar objects.

Nucleation and growth of stardust in a circumstellar environment has been confirmed by infrared studies of classical novae. Although they contribute only a small amount of stardust to the ISM of a galaxy, classical novae are the only objects in which it has been possible to observe the process of circumstellar dust formation directly. Observations have shown that the infrared development of a nova outburst is governed by the evolution of the grains in the outflow, and have defined the conditions under which grains nucleate and grow as they are expelled into the ISM.

In this review, we concentrate specifically on the stardust and gas-phase chemical anomalies that may be contributed to the galactic ISM by classical novae. Novae are concentrated toward the center of the Galaxy, where they suffer obscuration. Therefore, some of their global properties have only

recently been estimated from studies of nearby galaxies. It is clear that they are associated with the old stellar population in galaxies, in that both the spatial distribution and the relative frequency of novae are well correlated with the infrared *K*-band luminosity (Ciardullo et al. 1990). Although the distribution of novae near the Sun suggests a concentration toward the disk of the Galaxy, the majority of novae belong to the halo or at least to a thick disk population (Warner 1989). The influence of nova ejecta on the ISM is therefore global. Roughly 30 novae per year occur in the Galaxy (Arp 1956; Capaccioli et al. 1989), and they all have in common the fact that they eject material at high velocities during outburst, with this material usually enriched in elements heavier than He.

II. NATURE OF THE OUTBURST

The theory of classical nova outbursts has advanced at a significant pace over the past two decades. Two factors contributing to these rapid developments are progress in theoretical modeling of the outbursts and, particularly, a growing body of observational data describing novae in outburst. Indeed, observations of novae are now available in virtually all interesting wavelength ranges (Starrfield 1989*a*). Recent observations have served both to constrain the theoretical models and to provide a quantitative measure of the influence of classical nova explosions on the surrounding ISM.

It is now commonly understood that a nova outburst results from a thermonuclear runaway on the surface of a white dwarf accreting matter in a close binary system. The companion stars in these "cataclysmic variable" systems are observed to be late-type stars that are filling their Roche lobes and passing matter through the inner Lagrangian point, via a disk, onto the surface of the white dwarf. Accumulation of a hydrogen-rich envelope on the white dwarf continues until a critical pressure is achieved at the base of the accreted envelope, and a thermonuclear runaway ensues. There follows: (1) a rapid rise of the luminosity to a maximum value that approaches (and sometimes exceeds) the Eddington limit; (2) a period over which the rekindled hydrogen burning shell powers the system at approximately constant bolometric luminosity; and (3) a gradual return of the system to its pre-outburst state. The detailed features of such outbursts have been reviewed by a number of authors (Truran 1982; Gehrz 1988; Starrfield 1989*b*).

Hot gas expelled in the explosion is initially seen as an expanding pseudophotosphere, but free-free and line emission are observed when the expanding fireball becomes optically thin. A dust condensation phase, characterized by rising infrared emission and sudden visible absorption occurs in many novae within 30 to 80 days following the eruption. Novae produce silicates, silicon carbide, carbon and hydrocarbons. Several have condensed all four types of grains in a single eruption, suggesting that novae may have a complex temperature, density and abundance structure in their ejecta.

Spectroscopy of infrared coronal emission lines in classical novae has provided new insight into the physics of the nova phenomenon. Abundance information implies that some novae may condense anomalous grains similar to those found in meteorite inclusions and has provided constraints on models of the progenitor stars of nova systems. One recent suggestion to explain these observations is that a substantial fraction of observed nova binary systems may contain O-Ne-Mg white dwarfs that are the predicted end product of the evolution of some intermediate-mass stars.

We are specifically concerned in these proceedings with the contributions of novae to the ISM. These contributions can be examined by considering the nature of the contributions from an individual "average" nova event. The critical parameter is the white-dwarf mass. Truran and Livio (1986, 1989) recently pointed out that the typical masses of the white dwarfs in nova systems observed in outburst are significantly higher than the 0.6 to 0.7 M_{\odot} range characteristic of single white dwarfs. This is understood to be a consequence of selection effects, favoring massive white dwarfs that require significantly less accreted matter to trigger a thermonuclear runaway and therefore experience recurring outbursts on much shorter time scales. Truran and Livio estimate the average white dwarf mass in observed classical nova systems to be approximately 1.1 to 1.2 M_{\odot} ; a comparable value has recently been determined by Politano et al. (1990). The relative frequencies of occurrence of white-dwarf masses $f(WD)$ from these two references are presented in Table I, together with an estimate of the (accreted) envelope mass required to initiate runaway (column 3), and an approximate determination of the recurrence time scale (column 4) based on the assumption that all systems have an accretion rate of $\sim 10^{-9} M_{\odot} \text{ yr}^{-1}$ (King 1989).

The mean envelope mass required to initiate a runaway that follows from the frequency estimates is approximately $2 \times 10^{-4} M_{\odot}$ (note that this is slightly larger than the envelope mass of $5 \times 10^{-5} M_{\odot}$ required for a white dwarf of the mean mass 1.1 to 1.2 M_{\odot}). The theoretical models and general energy considerations indicate that most of the accreted matter is ultimately ejected in the outburst and thus returned to the ISM. The mean mass returned by a nova outburst to the ISM is thus of the order of $2 \times 10^{-4} M_{\odot}$. If we assume that the nova rate of ~ 30 per year for M31 in Andromeda (Arp 1956; Capaccioli et al. 1989) can be applied to our Galaxy, it follows that novae introduce approximately $6 \times 10^{-3} M_{\odot} \text{ yr}^{-1}$ of processed matter into the ISM. Supernovae, occurring at a rate of 1 per 50 yr and ejecting approximately 3 M_{\odot} per event, introduce roughly $0.06 M_{\odot} \text{ yr}^{-1}$ of processed matter into the ISM. Therefore, if novae are to contribute significantly to nucleosynthesis, the levels of overproduction of heavy elements in novae must be on the order of 10 times the levels characteristic of supernova ejecta. This crucial question of the global contribution of novae will be emphasized several times in the discussions that follow.

The mass estimate provided here also allows us to determine the energy contributions of individual nova events to the ISM. Velocity determinations

for the principal ejecta of novae lie in the range 400 to 2000 km s⁻¹, although some of the material appears to be ejected at velocities as high as 10⁴ km s⁻¹. This implies that the typical output kinetic energies will fall in the range 10⁴³ to 10⁴⁵ erg, well below values typical of supernovae, and that novae do not constitute a significant source of energy for the heating of the ISM. Spectroscopic studies of classical novae have revealed two very important features:

- (1) The presence of extremely large concentrations of C, N and O nuclei and, more recently, of O, Ne and Mg nuclei in the ejecta;
- (2) The formation of grains in a substantial number of the slower novae.

The issue of grain formation and its implications is addressed in Sec. V. It is appropriate at this stage, however, to examine briefly the theoretical implications of the heavy-element enrichments.

III THERMONUCLEAR PRODUCTION OF HEAVY NUCLIDES

Nucleosynthesis associated with nova events is limited to the effects of the proton-induced reactions that can proceed at the temperatures of 1.8×10^8 to 3×10^8 K typically achieved in their hydrogen burning shells. CNO cycle hydrogen burning will, of course, act to redistribute these nuclei and thereby alter the concentrations of the isotopes of carbon, nitrogen and oxygen. The observational situation regarding the abundances of these and heavier nuclei in nova ejecta is reviewed in the next section, and the implications of the observed enrichments of heavy elements is addressed. In this section, we

review the possible role of novae in the synthesis of ${}^7\text{Li}$ and in the generation of significant abundances of the radioactive nuclei ${}^{26}\text{Al}$ and ${}^{22}\text{Na}$.

It is important to recognize in advance that the relative contribution of novae to nucleosynthesis is small, and that detailed predictions regarding their contributions are quite uncertain. We do not know with confidence either the rate of nova outbursts as a function of time over the history of our Galaxy or the average mass ejected per outburst. Nonetheless, the total amount of processed matter contributed by novae to the ISM may be roughly estimated by assuming that (1) the current rate of nova events is 30 yr^{-1} (Arp 1956; Capaccioli et al. 1989); (2) the rate has remained constant over the lifetime $\sim 10^{10}$ yr of the galactic disk; and (3) the average mass ejected per nova event is $\sim 2 \times 10^{-4} M_{\odot}$. This implies a total mass processed by novae of $\sim 6 \times 10^7 M_{\odot}$. By comparison, supernovae occurring at a rate of 1 per 50 yr and ejecting $\sim 3 M_{\odot}$ per event would have processed $6 \times 10^8 M_{\odot}$ during the same period. As the mass processed through novae represents only a fraction $< 1/150$ of the mass of interstellar matter ($\sim 10^{10} M_{\odot}$) in our Galaxy, it follows that significant contributions require enrichments, relative to solar system abundances, in nova ejecta of factors of > 150 . This would apparently rule out the possibility that novae are important contributors to galactic abundances of the dominant isotopes of carbon and oxygen, and probably of nitrogen as well. Novae may, however, produce important amounts of the rarer isotopes ${}^{13}\text{C}$, ${}^{15}\text{N}$ and ${}^{17}\text{O}$.

We have seen that classical nova outbursts provide an environment in which hydrogen-burning reactions proceed on carbon, nitrogen and oxygen (CNO) nuclei, and heavier nuclei, at high temperatures and densities on a dynamic time scale. For such conditions, the production of potentially interesting and detectable abundance levels of the radioactive isotopes ${}^{22}\text{Na}$ and ${}^{26}\text{Al}$ can also occur, and novae are believed by many to be potentially important nucleosynthesis sites for these elements. Weiss and Truran (1990) recently modeled the nucleosynthesis accompanying nova explosions for representative temperature histories extracted from hydrodynamic models, utilizing a significantly expanded nuclear reaction network (see Nofar et al. 1991). Their results confirm the earlier findings of Hillebrandt and Thielemann (1982) and Wiescher et al. (1986) that extremely low levels of both ${}^{22}\text{Na}$ and ${}^{26}\text{Al}$ are expected to form in nova envelopes of initial heavy-element composition comparable to that of solar system matter. This implies both that we should not expect to find detectable levels of ${}^{22}\text{Na}$ in the ejecta of slow novae (e.g., novae with relatively low heavy-element concentrations) and that such novae do not contribute significantly to the abundance of ${}^{26}\text{Al}$ in the Galaxy. Moreover, enriched CNO concentrations alone do not guarantee any significantly increased ${}^{22}\text{Na}$ and ${}^{26}\text{Al}$ production. The calculations by Weiss and Truran (1990) predict low concentrations of ${}^{22}\text{Na}$ and ${}^{26}\text{Al}$ even with the assumption of matter enriched to a level $Z_{\text{CNO}} = 0.25$. The conclusions drawn above to the effect that these systems characterized by solar abundances of CNO elements can neither produce detectable levels of ${}^{22}\text{Na}$ nor contribute significantly to the abundance of ${}^{26}\text{Al}$ in galactic matter are equally appropriate to

the case of novae with moderate CNO enrichments.

As anticipated, greatly increased ^{22}Na and ^{26}Al production results for envelopes characterized by substantial initial enrichments of elements in the range from neon to aluminum. Because these abundance enrichments are presumed to arise as a consequence of the dredge-up of core matter (see, e.g., Livio and Truran 1990), it follows that such systems involve more massive O-Ne-Mg white dwarfs. Theoretical estimates (Truran and Livio 1986; Truran 1990) and spectroscopic analyses of the ejecta of recent novae (Table I) indicate that such neon rich novae comprise approximately 1/4 to 1/3 of all observed classical nova outbursts. For these cases, burning by means of the neon-sodium and magnesium-aluminum hydrogen burning sequences can yield substantial concentrations of ^{22}Na and ^{26}Al . Specifically, for the choice of an initial composition consisting of matter enriched to a level $Z = 0.25$ in the products of stellar carbon burning (Arnett and Truran 1969), the calculations of Weiss and Truran (1990) predict that the abundance levels of ^{22}Na and ^{26}Al formed can be 1 to 2 orders of magnitude larger than for the case of matter of initial solar composition. They conclude that such neon-rich novae may represent an important source of ^{26}Al in our Milky Way Galaxy. Future observations of the distribution of ^{26}Al in the Galaxy may provide constraints upon the progenitors and, perhaps, indicate whether red giants, novae, or supernovae represent the dominant source.

The concentrations of ^{22}Na predicted for the ejecta of novae involving O-Ne-Mg white dwarfs are sufficiently high that we may also expect relatively nearby novae to produce detectable flux levels of ^{22}Na decay gamma rays. Weiss and Truran (1990) estimated that a nova known to be both enriched in neon and magnesium and at a distance of 500 pc may yield a gamma ray flux at a level of $\sim 6 \times 10^{-5} \text{ cm}^{-2} \text{ s}^{-1}$. Such novae should be considered as promising targets for the Gamma Ray Observatory. (Note that, in contrast, neither slow novae nor fast novae enriched only in carbon, nitrogen and oxygen are likely to produce detectable fluxes.) Livio et al. (1990) also argued that the Compton degraded gamma rays from ^{22}Na decay might contribute to the observed X-ray fluxes from several recent novae (Ögelman et al. 1987).

We have emphasized the importance of the detection of ^{22}Na gamma rays from novae as a means of imposing important constraints on theoretical models of nova outbursts and their role in galactic nucleosynthesis. In this context, however, it is important to recognize that the ^{22}Na concentrations produced in novae are quite generally insufficient to account for the observed abundance of its decay product ^{22}Ne in the Galaxy. Truran and Hillebrandt (1986) showed that the observational upper limit on the gamma-ray flux (Mahoney et al. 1982, 1984) is such that the total amount of ^{22}Na ever formed constitutes less than $\sim 1\%$ of the mass of ^{22}Ne in the Galaxy today. While novae and other astrophysical events may make interesting amounts of ^{22}Na with respect, for example, to the generation of Ne-E anomalies in meteorites, most of the mass of ^{22}Ne in the Galaxy is actually incorporated into the ISM directly as ^{22}Ne . The relative levels of overproduction of ^{22}Na and ^{26}Al in

novae, as predicted by recent calculations, are consistent with the conclusion that novae may contribute to galactic nucleosynthesis of ^{26}Al but not to that of ^{22}Ne .

Significant production of ^7Li can also occur in the thermonuclear runaways that define the outbursts of classical novae (Arnould and Norgaard 1975; Starrfield et al. 1978). The mode of ^7Li production here is similar to that in red giants: ^7Be is carried outward by convection to cooler regions of the envelope on a sufficiently rapid time scale to ensure that it will not be destroyed via $^7\text{Be}(p,\gamma)^8\text{B}$. The total mass of ^7Li ejected is a sensitive function of the conditions achieved in the outburst and may therefore be expected to vary from event to event. Model calculations (Starrfield et al. 1978) predict that ^7Li enrichments of factors of up to $\sim 10^2$ to 10^3 may characterize the ejecta of novae under some circumstances. The critical dependencies with regard to ^7Li production are on the temperature history of the matter and the convective character of the envelope over the course of the runaway (both of which may be a function of the speed class of the nova); the initial ^3He concentration of the envelope matter is also of interest, as much of the ^3He may be converted readily to ^7Be .

The integrated contributions of classical novae to the abundance of ^7Li in galactic matter cannot be estimated very reliably because of uncertainties in our knowledge of the properties of the progenitors of classical nova systems and of their rate of formation over the past history of the Galaxy. Nevertheless, a statement regarding production of ^7Li in novae is possible. The theoretical models by Starrfield et al. (1978) predict average enrichment factors for the rare isotopes ^{13}C and ^{15}N that are ~ 10 times that of ^7Li . If these relative production ratios are representative of classical nova systems, it must follow that novae can account at best for only $\sim 10\%$ of the ^7Li in the Galaxy (when one assumes that ^{13}C and ^{15}N have their origin entirely in nova events). Further detailed calculations of nucleosynthesis coupled to hydrodynamic models of novae are required to clarify the situation for ^7Li .

IV. ULTRAVIOLET/INFRARED SPECTRA OBSERVATIONS OF HEAVY NUCLIDES

A. Gas-Phase Abundances

The study of nova ejecta is central to the understanding of the nature of the outburst. Gaseous shells having a range of mass from $M_{\text{ej}} \sim 10^{-7}$ to $10^{-3} M_{\odot}$ are ejected with velocities of 4×10^2 to 10^4 km s^{-1} from each outburst, and this material may be an important nucleosynthesis source for certain elements and/or isotopes in the ISM. The fact that some novae form considerable quantities of dust soon after outburst may also have consequences for star formation in the galactic disk. The relative fraction of the ejected mass that precipitates out of the gas into grains is difficult to ascertain but, judging from the sudden decrease in the line emission from certain elements at the time that dust condensation occurs, it is substantial for some novae.

Elemental abundances in nova ejecta can, in principal, be determined by two entirely different procedures. For several days following the outburst, some nova envelopes exhibit an absorption spectrum from an expanding pseudophotosphere, that can be analyzed in the same manner as a stellar atmosphere. Because of the high lack of equilibrium and rapidly changing environment of the envelope, most of the normal atmospheric techniques are not valid, and they have produced inconsistent results (Williams 1977). Consequently, few such studies were attempted in the last decade.

A more effective approach to determining element abundances is to analyze the emission spectrum of the ejecta that typically appears within a week of the outburst. This spectrum shows many similarities to the spectra of nebulae and emission line galaxies. Although the conditions giving rise to the emission lines are very complicated immediately after outburst, in a short time a statistical equilibrium is established and the lines become optically thin, greatly simplifying the radiative transfer.

All emission line fluxes depend directly on the ion abundance and another parameter: either N_e , T_e , or the continuum radiation intensity, depending upon the particular excitation mechanism. Relatively few lines are excited by radiative excitation, especially when the radiation field weakens more than a few weeks after outburst, and if one considers the relative strengths of other lines; i.e., for those formed by collisional excitation and recombination, the dependence on N_e cancels, leaving T_e as the only remaining parameter. Thus, the line ratios of most lines will directly yield ion abundances if the electron temperature is known. One can even avoid a dependence of line ratios on T_e if one selects lines originating from similar ionization potentials. Fairly reliable abundances can therefore be determined for some ions. Reliable element abundance determinations require that one account for all of the ions of each element, even though many of the ions do not have observable lines in accessible regions of the spectrum. One is therefore forced to compare relative abundances of ions having similar ionization potentials, and to assume that these ion ratios reflect the relative element abundances. An alternative to this is to try to build a complete ionization model for the ejecta and to make theoretical corrections for unobserved ionization stages. As the post-outburst geometry of the ejecta is poorly known, but obviously complicated, reliance on models for these corrections is inadvisable. Thus, the operative procedure has been to take several ionization stages in elements in which the ionization potentials are similar and to equate the element abundances to those of the ions, i.e., to assume that $N/O = (N \text{ III} + N \text{ IV})/(O \text{ III} + O \text{ IV})$, for example. If the above procedure can be applied to collisionally excited lines with similar excitation potentials, there is little dependence on T_e , and the resulting abundances are less uncertain.

B. Infrared Fine-Structure Lines

Many novae develop infrared emission lines from transitions among the fine-structure levels of the ground states of ions of the heavy elements. Although

lines such as [Ne II] $\lambda 12.8 \mu\text{m}$ do occur, and can be dominant sources of cooling of the ejecta in some novae (see Gehrz et al. 1985, 1986), it is more common that higher ionization stages predominate in the infrared spectra, e.g., [Mg VIII] $\lambda 3.02 \mu\text{m}$ and [Si IX] $\lambda 3.92 \mu\text{m}$ (Grasdalen and Joyce 1976; Greenhouse et al. 1988, 1990).

Because of the very low excitation potentials of the infrared lines, $kT_e > \chi_{12}$ for all such transitions, and therefore the line intensities do not have a dependence upon T_e . Relative strengths of the infrared lines yield reliable ion abundances, since they are probably all collisionally dominated, leading to the same dependence upon density. Intercomparison of these lines produces relative abundances of Mg, Na, Al and Si.

C. Physics of the Infrared Coronal Phase

Infrared spectroscopic observations of infrared forbidden-line-structure lines were identified in the six recent novae V1500 Cyg 1975, Cyg 1986, QU Vul 1984, OS And 1986, V827 Her 1987 and V2214 Oph (Grasdalen and Joyce 1976; Gehrz et al. 1985; Greenhouse et al. 1988, 1990; Benjamin and Dinerstein 1990) confirming a theoretical prediction by Ferland and Shields (1978*a, b*) that such emission could be an important source of cooling in nova shells. The strongest of these lines was $12.8 \mu\text{m}$ [Ne II] emission from QU Vul (Gehrz et al. 1985). These data showed that infrared spectroscopic information can be important for the identification of, and the estimation of abundances of atomic species in nova ejecta. Greenhouse et al. (1988, 1990) established the importance of the infrared coronal emission phase in classical novae for estimating physical conditions in the ejecta, and for determining important chemical abundances related both to nucleosynthesis associated with the nova progenitor and to nucleosynthesis occurring in the thermonuclear runaway during the nova eruption. While the infrared transitions themselves are collisionally excited, the ionization states responsible for the transitions must be largely radiatively excited (Benjamin and Dinerstein 1990; Williams 1991). In some cases, it seems possible that a collisional excitation component may be required to explain the ionization structure (see Greenhouse et al. 1990). Temperature conditions associated with the coronal emission are not fully understood. On one hand, excitation temperatures inferred for the photoionization of the coronal states are as high as 5×10^5 to 10^6 K. On the other hand, the absence of certain lines that would be expected to occur suggests temperatures well below this. Infrared speckle interferometric measurements show that the coronal emission occurs in the principal ejecta rather than close to the central engine. High-resolution near-infrared spectroscopy shows that the velocity widths of coronal lines are likewise consistent with their production in the principal ejecta.

Analyses of the abundances of the coronal species show that the ejecta of many novae are rich in O, Ne and Mg. For example, the infrared coronal emission lines in QU Vul (Gehrz et al. 1985; Greenhouse et al. 1988) lead to the conclusion that some novae may be overabundant in neon and silicon

(Gehrz et al. 1984,1986; Gehrz et al. 1985; Williams et al. 1985; Gehrz et al. 1988). Starrfield et al. (1985*b*) and Truran and Livio (1986) argued that these novae result from accretion of matter onto O-Ne-Mg white dwarfs that are the evolutionary endproduct of intermediate-mass (8 to 12 M_{\odot}) stars. The nucleosynthesis associated with such nova explosions can produce significant quantities of the radioactive isotopes ^{22}Na and ^{26}Al that positron decay to ^{22}Ne (2.7 yr) and ^{26}Mg (3×10^5 yr). These materials could be trapped in grains during the dust formation phase of novae. Grain inclusions with significant overabundances of ^{22}Ne and ^{26}Mg have been discovered in solar system meteorites. The inference is that these meteoritic inclusions could have been produced by the condensation of grain materials in the immediate vicinity of sources of explosive nucleosynthesis, such as novae or supernovae (see Clayton 1982; Truran 1985,1990; Gehrz 1988; Weiss and Truran 1990). Theoretical studies suggest that these abundances may reveal important information about nucleosynthesis during both the outburst and or the evolution of the progenitor.

D. Gas Abundances in Nova Ejecta

There are now a number of novae that have experienced outbursts in the last decade, for which post-outburst abundances were determined by the methods described above (Snijders et al. 1987; Williams 1985; Snijders 1990). Because such studies are based on emission-line fluxes, they sample only the gas, and not the dust. The relative dust/gas ratio is difficult to determine, and therefore the gaseous depletion of certain elements from the gas phase by condensation into dust is unknown. In some novae that form optically thick dust shells, the evolution of the emission spectra of certain elements suggests that a substantial fraction of some elements may precipitate into dust in the months after outburst. The gas-phase abundances may therefore not reflect the actual distribution produced by the outburst and injected into the ISM. It is usually the case, however, that thermal emission from dust is absent from the infrared spectra of novae when infrared forbidden-line emission is important, so that one can presume that the emission line phase refers to an epoch when the condensable elements are still mainly in the gas phase. Nonetheless, because evidence for extensive dust formation occurs in only $\sim 1/3$ of all novae, the gaseous abundances of a sample of many novae should, in fact, characterize the true ejecta abundances rather well. A compilation is given in Tables II and III of gas-phase abundances for those novae whose emission spectra were analyzed in the past 15 yr. In spite of the uncertainties associated with the results for individual objects, certain features are clear that may be taken to be general characteristics of nova outbursts:

1. He is generally enhanced with respect to H in the ejecta; i.e., H is depleted.
2. The CNO nuclei are highly enriched, with N typically being the most abundant of these elements.

^a 1: Williams and Gallagher 1979; 2: Tylenda 1978; 3: Gallagher et al. 1980; 4: Salzar et al. 1990; 5: Stickland et al. 1981; 6: Williams et al. 1985; 7: Williams et al. 1978; 8: Snijders et al. 1987.

3. Perhaps as many as 33% of the novae show a strong enrichment of neon. These "neon" novae usually also show enhancements of elements with $Z > 10$, e.g., Mg and Si.

The first two of these characteristics can, in principle, derive in part (e.g., H depletion and high N) from the outburst phenomenon, as these features can follow naturally from the proton-capture reactions that occur in the thermonuclear runaway. The high-neon abundance is difficult to produce in normal outburst models on CO white dwarfs, and is believed to result from material mixed from O-Ne-Mg white dwarfs in those novae (Starrfield et al. 1986; Truran and Livio 1986). Moreover, the high-CNO abundance enrichments also demand outward mixing of core matter (Truran 1990; Livio and Truran 1990).

Spectroscopy of the emission lines from ions does not enable isotopic abundances to be determined; the isotope shifts are too small to be detected. Thus, the neon could be ^{20}Ne or ^{22}Ne , and the aluminum could be ^{26}Al or ^{27}Al . Any isotopic information must be deduced from theory or, perhaps, as in the case of ^{22}Na , from gamma-ray observations of novae after outburst. The direct evidence for the gaseous contribution of novae to the element abundances of the ISM is limited to the information in Tables II and III. Gas of this composition is ejected into the Galaxy by roughly 30 novae per year, each of which contributes about $2 \times 10^{-5} M_{\odot}$ of gas at velocities (see Table IV) usually exceeding the escape velocity of the Galaxy ($\sim 300 \text{ km s}^{-1}$ for a galactocentric distance of 10 kpc). Thus, the ejecta must interact with a greater mass of ambient gas if they are to be confined to the Galaxy, eventually settling into the ISM.

V. INFRARED OBSERVATIONS OF DUST FORMED FROM HEAVY NUCLIDES

The most convincing cases for transient circumstellar dust formation are those based upon infrared observations of the temporal development of classical nova systems; see Bode 1988,1989; Bode and Evans 1989; Gehrz 1988; Starrfield 1989*a* for reviews of these observations. Their infrared temporal development progresses in several identifiable stages (Gehrz 1988). The initial eruption results from a thermonuclear runaway on the surface of a white dwarf that has been accreting matter from a companion star through the inner Lagrangian point in a close binary system. The hot gas expelled in the explosion is initially seen as an expanding pseudophotosphere, or "fireball." Free-free and line emission are observed when the expanding fireball becomes optically thin. A dust condensation phase, characterized by declining visual light and rising infrared emission, occurs in many novae within 50 to 200 days following the eruption. The infrared emission continues to rise as the grains grow to a maximum radius of 0.2 to 0.3 μm within a few hundred days after their condensation, and then falls as the mature grains are dispersed by the

outflow into the ISM (Gehrz et al. 1980*a, b*). Thus, nova grains initially grow much larger than interstellar grains, which typically have radii in the range from 0.01 to 0.12 μm (see Greenberg 1989*a*). However, the rate of decline of the infrared radiation and the relatively slow cooling rate of the grains in the outflow suggest that the grains begin to decrease in radius again shortly after having grown to their maximum size. The observations are consistent

with the hypothesis that the nova grains could be processed to interstellar grain sizes by evaporation or sputtering before they eventually reach the ISM. About 10^{-8} to $10^{-6} M_{\odot}$ of dust forms in each episode.

Although most novae produce carbon (possibly iron?) dust, recent observations suggest that nova explosions can produce every other type of astrophysical grain, including silicates, silicon carbide (SiC), and hydrocarbons (see Gehrz 1988, 1989*a, b*; Hyland and MacGregor 1989). Recently, it has been shown that nova shells can be strongly cooled by infrared fine structure forbidden-line emission (Gehrz et. al. 1985).

A. Abundances from Observations of Dust

Table IV summarizes our knowledge of outburst and shell parameters for 21 recent novae from optical/infrared observations. The mass of gas in the ejecta can be measured using the energy distribution, as determined by infrared techniques. As the pseudophotosphere begins to become optically thin, the energy distribution deviates slightly from that of a blackbody, but the ejecta are still hot enough that the Thomson (electron) scattering opacity κ_t dominates radiative transfer in the shell. In this case, the shell mass is given by $M = \pi R^2 \kappa_t^{-1}$ where the shell radius $R = tV_o$ and t is the time since outburst. Later, when the ejecta cool sufficiently that thermal Bremsstrahlung dominates the shell opacity, the shell mass of a shell of depth ℓ pc and electron density $n_e \text{ cm}^{-3}$ can be determined through the relationships $n_e^2 \lambda_c^2 \ell = 10^{18}$ and $M \sim \pi R^2 \ln_e H$ where λ_c is the cutoff wavelength in μm at which free-free self-absorption becomes important, and H is the mass of the nucleon. The mass of dust can be inferred from the dust shell opacity required to produce the observed visual extinction for novae that produce optically thick shells. Opacities for carbon, SiC, silicates and iron are given by Gilman (1974*a, b*) and Draine (1985*b*). The gas to dust ratios calculated in this way imply overabundances of carbon and silicate materials in a few cases.

B. Mineral Composition of the Grains

Although most novae condense carbon or iron dust, there is evidence that astrophysical dust of every known chemical and mineral composition can condense in nova ejecta. QU Vul 1984, V842 Cen 1986 and QV Vul 1987 (Gehrz 1990) formed silicate grains; V1301 Aql 1975 may have formed SiC or a combination of SiC and silicates (Gehrz et al. 1984), and V842 Cen 1986 (Hyland and Macgregor 1989) and QV Vul 1987 (Greenhouse et al. 1988, 1990) apparently formed hydrocarbons. The hard radiation from the nova remnant may provide the ultraviolet radiation that is believed to be important in creating hydrocarbons from amorphous carbon (Allamandola 1984; Allamandola et al. 1987).

The formation of more than one type of grain has now been recorded for at least three novae (Gehrz 1990). Both V842 Cen 1986 and QV Vul 1987 apparently formed carbon and silicates dust, and hydrocarbons. It is difficult to understand how both silicate grains and carbon grains can form co-spatially

in the ejecta if silicate grain condensation requires an environment where $C < O$ and carbon grain condensation requires an environment with $C > O$ (Hackwell 1971, 1972). One possibility is that there are significant abundance, temperature and density gradients within the ejecta. Perhaps the polar plumes and equatorial ring that are believed to be produced in the explosion (Gallagher and Starrfield 1978) have different properties.

C. Continuum Emission from Dust

Most dust-producing novae condense dust that emits a gray or black, smooth 1 to 25 μm continuum that is devoid of emission features. Both carbon and iron grains can produce this spectral signature (Gilman 1974*a, b*). Because a similar continuum is characteristic of the circumstellar emission from carbon rich stars (see, e.g., Gehrz and Hackwell 1976), it has generally been assumed that this continuum in classical nova systems is produced by amorphous carbon grains (see Gehrz 1989*a*). The genesis of the argument that smooth infrared continua result from circumstellar carbon dust in carbon stars is an equilibrium condensation calculation showing that carbon grains condense if $C > O$ and silicate grains condense if $O > C$ (Gaustad 1963, Hackwell 1971, 1972). A fundamental problem with the carbon grain hypothesis for novae is that it is unlikely that $C > O$ can occur in nova ejecta that result from thermonuclear reactions on CO and O-NE-Mg white dwarfs (Truran 1990); theoretical models generally predict that $C < O$ for runaways on both CO and O-Ne-Mg white dwarfs. If this is the case, the formation of carbon grains seems improbable, unless the condensation of carbon proceeds in a rather different manner than is predicted by the equilibrium calculation.

An alternative explanation for the continuum dust emission in novae is that the grains are iron. We can use the opacities and Planck mean cross sections given by Gilman (1974*a, b*) to estimate the mass of iron dust that would be required to produce the observed visual extinction in a typical optically thick nova shell. As an example, we consider NQ Vul 1976, a nova that formed a shell with a visual optical depth of $\tau_v = 4.6$ about 80 days after the eruption; the shell involved $10^{-4} M_\odot$ of gas expanding at 750 km s^{-1} . In this case, the observational parameters require a dust mass of $10^{-6} M_\odot$ of iron or $1.4 \times 10^{-7} M_\odot$ of carbon, leading to gas-to-dust ratios of 100 and 700 for iron and carbon, respectively. The gas-to-dust ratios for iron and carbon in solar material are 670 and 250, respectively. We conclude that NQ Vul's ejecta would have had to have been enhanced in iron by at least a factor of 7, if the dust were all iron grains. The ejecta of one dust forming nova, V1370 Aql 1982, may have been enhanced in iron by a factor of 4 (see Tables II and III), although there is no obvious way to account for such an iron enrichment in the context of the standard thermonuclear runaway model. No enhancement of carbon is implied by the visual extinction in NQ Vul, but at least one dust forming nova, LW Ser 1978, would require a carbon enhancement of a factor of ≥ 5 over solar. We conclude that the existing

evidence suggests that the dust responsible for the continuum radiation in novae is most likely carbon.

D. THE CONDENSATION PROCESS

A significant question is how can grains nucleate and grow in the hard radiation field of the central engine. It is generally accepted that the dust must form in clumps of material that shield the grains from extreme-ultraviolet radiation (see Rawlings 1988; Martin 1989; Bode and Evans 1989). The visual lightcurve of V842 Cen 1986 provided some interesting circumstantial evidence for clumps in the ejecta. The very deep and short-lived minimum during the transition phase of that nova could have been caused by a dense dust knot that obscured the line of sight for a very short time (Gehrz 1990). If clumps are the major sites of dust production, the abundances derived above may be significantly in error. Albinson and Evans (1987) argued that carbide whiskers can form under some conditions. Perhaps iron is at least an important factor in producing seed nuclei, as suggested by Lewis and Ney (1979).

A novel suggestion by Matese et al. (1989) is that the outburst can release a significant amount of pre-existing dust from comet nuclei in a cometary disk and that this material provides seed nuclei that then accrete material in the ejecta. Stern and Shull (1990) determined that up to $10^{-3} M_{\odot}$ of dust may return to the ISM per year from this source. Dust released from planetesimals in sufficient quantities could cause a sudden obscuration of the visible light from the remnant; it can be shown that the opacity of a given circumstellar mass of solid planetesimals increases as a^{-1} where a is the radius of the average planetesimal (Gehrz 1989*b*).

VI. ABUNDANCES OF HEAVY NUCLIDES AND COMPARISON WITH THEORY

Theoretical studies show that Li, CNO and Ne-Na-Mg-Al are expected to be enhanced by substantial factors over solar abundances in runaways on CNO and O-Mg-Ne white dwarfs, as discussed in Sec. III. Elemental abundance data are now becoming increasingly available for a number of classical nova systems (for reviews, see Truran 1985; Truran and Livio 1986; Williams 1985; Truran 1990). The abundance data concerning hydrogen, helium and some heavy elements are summarized in Tables II and III. Table II presents, specifically, the mass fractions (where known) in the form of the elements hydrogen, helium, carbon, nitrogen, oxygen, neon, sodium, magnesium, aluminum, silicon, sulphur and iron, adapted from the indicated references. Table III provides helium-to-hydrogen ratios for a somewhat larger sample of novae. Here again, where known, the total mass fractions Z in the form of heavy elements are also tabulated. For purposes of comparison, we note that solar system matter is characterized by a helium-to-hydrogen ratio by number $\text{He}/\text{H} = 0.08$ and a heavy-element mass fraction $Z_{\text{solar}} = 0.019$ (see

Cameron 1982,1992). The column labeled enriched fraction in Table III gives the total mass fraction of enriched matter in the form of both helium and heavy elements.

It is apparent that all classical novae with relatively reliable abundance determinations show enrichments relative to solar composition in helium and/or heavy elements. This statement is fairly secure even when the large uncertainties in the abundance determinations are taken into account. We conclude that envelope enrichment in classical novae is a very general phenomenon. Truran and Livio (1986) argued that it is extremely unlikely that the source of these enrichments is either the mass transfer from the secondary star or nuclear transformations accompanying the outburst, and concluded that the abundance patterns suggest that some fraction of the envelope is dredged up from the underlying white dwarf. Given the presence of large concentrations of neon and heavier elements in the ejecta of several recent novae (e.g., V693 CrA 1981 and V1370 Aql 1982), it is interesting to note that this conclusion has the consequence that massive O-Ne-Mg white dwarfs (as opposed to CO white dwarfs) occur quite frequently in classical nova systems.

The important question that immediately arises is what is the mechanism that is responsible for the mixing between the accreted envelope and the white dwarf core? This was addressed in the recent paper by Livio and Truran (1990). Four possible mechanisms were suggested: (1) diffusion induced convection; (2) shear mixing; (3) convective overshoot-induced flame propagation; and (4) convection-induced shear mixing. Livio and Truran (1990) discuss each of these mechanisms, pointing out their strengths and weaknesses, and attempt to identify critical observations that will help to determine which mixing mechanism is most likely to dominate.

VII. INTEGRATED CONTRIBUTIONS ON LOCAL AND GALACTIC SCALES

Estimates of the enrichment of ISM material by classical nova ejecta are important for understanding possible inputs to the primitive solar nebula. We discuss below the general concept of ISM enhancement by ejections from novae, and review specific theoretical predictions for the capability of novae to produce enhancements of specific nuclides.

A. Global Processing of ISM Material by Classical Novae

Recent optical/infrared spectral observations and theoretical studies support the proposition that thermonuclear runaways on massive (1.1 to $1.3 M_{\odot}$) O-Ne-Mg white dwarfs accreting matter in close binary systems account for $\sim 25\%$ of the 30 classical novae that occur each year in our Galaxy. Assuming that each of these novae ejects $\sim 3 \times 10^{-5} M_{\odot}$ per eruption, and that the Galaxy has an age of $\sim 10^{10}$ yr, we find that $\sim 10^7 M_{\odot}$ has been processed through nova eruptions of these massive novae during the lifetime of the Galaxy which is only $\sim 0.3\%$ of the $3 \times 10^9 M_{\odot}$ of gas estimated to be in the present ISM.

We conclude that nova eruptions must give a yield of 100 to 300 times solar abundance of any given nuclide if they are to be a significant source of that nuclide on a galactic scale. It is, of course, possible that nova eruptions could be significant sources of overabundances of certain nuclides associated with star formation on a local scale where the ejecta could be concentrated into a molecular cloud shortly before a star formation event within the cloud (see, e.g., Cameron 1984). We show below that theoretical predictions suggest that novae can produce significant abundance anomalies if the eruptions occur on O-Ne-Mg white dwarfs.

B. Contributions to Specific Anomalies

The Ne-E and ^{26}Mg anomalies found in meteorites are especially interesting in the context of classical novae in view of the large amounts of ^{22}Na , and ^{26}Al that can be produced in runaways on O-Ne-Mg white dwarfs (Weiss and Truran 1990). 1. *Ne-E*. ^{22}Na positron decays to ^{22}Ne via the reaction $^{22}\text{Na} \rightarrow ^{22}\text{Ne} + e^+ + \gamma + \nu$, leading to the emission of 1275 KeV gamma rays that can be detected from Earth. The mean life of the reaction is only 3.9 yr, so that novae will be short-lived sources of gamma rays from ^{22}Na decay, and the galactic background should be very anisotropic, with strong peaks in the direction of the most recent novae. This short mean life also implies that ^{22}Ne trapped in grains probably requires that the parent ^{22}Na was trapped in the grains very shortly after their formation, probably at the site of formation. No detections of 1275 KeV gamma rays have been made to this date, but several upper limits were placed on the diffuse galactic emission and specific nova events. Leventhal et al. (1977) found that V1500 Cyg 1975 must have produced $<10^{-6} M_{\odot}$ of ^{22}Na . Truran and Hillebrandt (1986) argued that the observational upper limit on the gamma-ray flux (Mahoney et al. 1982, 1984) is such that the total amount of ^{22}Na ever formed constitutes less than approximately 1 % of the mass of ^{22}Ne in the Galaxy today. Higdon and Fowler (1987) concluded that limits to the diffuse galactic 1275 KeV flux suggested a production of less than $6 \times 10^{-7} M_{\odot}$ of ^{22}Na per nova event. The calculations of Weiss and Truran (1990) discussed in Sec. III predict that the average yield of ^{22}Na per O-Ne-Mg outburst should be between 10^{-8} and $10^{-7} M_{\odot}$. Under these conditions, the galactic background will be difficult to detect with current technologies, but NASA's Gamma Ray Observatory may be able to detect individual novae within 0.5 to 1 kpc of Earth.

2. *^{26}Al* . Classical novae appear to be a promising source of ^{26}Al , at least on local scales. There is chemical evidence that the ^{26}Al that produced the ^{26}Mg anomaly in meteorites was alive in the primitive solar system, implying that the parent nova (if a nova and not a red giant was, indeed, the source) was relatively nearby (see, e.g., the discussion by Cameron [1984]). Gamma radiation at 1809 KeV will be produced via the decay of ^{26}Al to ^{26}Mg by the reaction $^{26}\text{Al} \rightarrow ^{26}\text{Mg} + e^+ + \gamma + \nu$ that has a mean life of 10^6 yr. This long mean life would enable ejecta from many eruptions of a single nova system to inject live ^{26}Al into the primitive solar system during its formation. The

long mean life also implies that the galactic background at 1809 KeV from novae should be fairly isotropic, with components from disk and halo nova populations. Assuming that approximately 10 novae per year are O-Ne-Mg novae capable of injecting into the ISM $3 \times 10^{-5} M_{\odot}$ of material with a fraction by mass of ^{22}Al of 2×10^{-3} , the steady-state galactic mass of ^{26}Al from novae is about $0.4 M_{\odot}$. The measured 1809 KeV background implies that there is $\sim 3.3 M_{\odot}$ of ^{26}Al in the galactic ISM (see Higdon and Fowler 1989). Although novae therefore do not appear to be a dominant source of ^{26}Al on a galactic scale, they may contribute significantly to the ^{26}Al concentration on a local scale in the ISM.

FORMATION OF INTERSTELLAR CLOUDS AND STRUCTURE

BRUCE G. ELMEGREEN
T. J. Watson Research Center

Cloud formation is discussed for an interstellar medium that is clumpy, supersonic and magnetic. Two types of clouds, diffuse and self-gravitating, are distinguished by a dimensionless ratio of pressure to self-gravity. Diffuse clouds probably form by thermal instabilities and pressurized accumulation of low-density gas, and self-gravitating clouds probably form by condensation in dense regions, such as shells and spiral arms. Unbound clouds are a third structural type. Superclouds and cloud associations are the largest part of the hierarchy of cloud structures. They apparently form by coalescence, condensation and fragmentation in spiral arms, and then follow a standard sequence of events in which dissipation and collapse lead to star formation, disruption forms shells and giant bubbles, and then shell collapse forms more molecular clouds and stars. Eventually the gas disperses somewhere in the interarm region, after ~ 100 Myr of activity. The generally supersonic and superviral velocities between clouds imply that most collisions are shattering if they occur at the full random speed. In this case the coagulation of small clouds into large complexes will be driven by collision-induced cooling instabilities and self-gravity in the cloud fluid rather than sticky collisions. If the mean collision speed scales with cloud mass, then random coalescence could be more important. Magnetic fields affect cloud formation by limiting the random motions of individual clouds, by transferring linear momentum between clouds without physical contact, by removing angular momentum from growing condensations, and by directly pushing, shocking and twisting the gas in nonlinear waves. Differences between astrophysical and laboratory turbulence are summarized.

I. DEFINING THE PROBLEM OF CLOUD FORMATION

Theories of interstellar cloud formation generally follow the available observations. When optical absorption lines in the 1930s to 1950s showed an average of eight interstellar features per kiloparsec (Blaauw 1952), the gas that caused this absorption was described as originating in well-separated clouds, sometimes assumed to be spherical, moving in a more or less ballistic fashion until they collided with other clouds (see, e.g., Oort 1954). Cloud formation was then viewed as a random coagulation process, with star formation disrupting the largest clouds to reform the smallest clouds. When the highest velocity features were found to have anomalous metallicities (Routley and Spitzer 1952), and to exceed in abundance the extrapolation from a gaussian velocity distribution (Munch 1957), as well as the extrapolation to

large heights above the galactic plane based on an isotropic velocity distribution (Munch and Zirin 1961), a second model for their origin was proposed, involving expansion and shock fronts around early-type stars and supernova remnants (Spitzer 1968*b*; Siluk and Silk 1974).

These early theories became increasingly refined as the observations grew more detailed, first with the discovery of a warm, neutral intercloud medium (Clark 1965) leading to two-phase models based on thermal instabilities (Field et al. 1969) and cloud coagulation (Field and Saslaw 1965), and then with the discovery of the ionized (Reynolds et al. 1974) and hot (Jenkins and Meloy 1974; Burstein et al. 1976) intercloud phases, leading to frothy models (Brand and Zealey 1975) in which clouds form in swept-up shells around H II regions (Hills 1972; Bania and Lyon 1980) and supernovae (Cox and Smith 1974; Salpeter 1976; McKee and Ostriker 1977). At the same time, various large-scale instabilities in the interstellar gas (Goldreich and Lynden Bell 1965*a*; Parker 1966) were offered as explanations for the largest clouds and spiral-like features observed locally and in other galaxies. Similar formation theories involving random coagulation (Kwan 1979; Norman and Silk 1980*b*), pressurized shells (Tenorio-Tagle 1981; Olano 1982; Elmegreen 1982*a*; Franco et al. 1988*a*), and various instabilities (Elmegreen 1979; Blitz and Shu 1980; Cowie 1981) followed the discovery of giant molecular clouds in the mid-1970s. Reviews of the history of these theories, and of the many observations that stimulated them, can be found in Elmegreen (1987*a*, 1990*a*), Kwan (1988), Larson (1988), Tenorio-Tagle and Bodenheimer (1989), Balbus (1990), and Franco (1990).

Observations of the interstellar gas now present a very different problem to solve. We see that the gas is highly textured (Low et al. 1984; Perault et al. 1985; Bally et al. 1987; Loren 1989*a, b*; Stutzki and Gusten 1990; Dickman et al. 1990; Falgarone et al. 1991) and although most of the mass is in the form of amorphous density concentrations that can still be named clouds or clumps, the geometries and juxtapositions of these concentrations defy mathematical description. According to Scalo (1990), the gas is not just a collection of isolated spheres, filaments and shells, as we formerly thought, but an interconnected network that has only been made to look like spheres, filaments and shells by inadequate resolution, undersampling, and line-of-sight overlaps (see also Deul and Burton 1990). This revision implies that the coagulation theories no longer have their isolated objects to coagulate, the shell theories have lost their uniform preshock media to compress, and the instability theories have been using an oversimplified equation of state.

We also know now that thermal motions are usually negligible compared to cloud line widths and the cloud-to-cloud dispersion (Blaauw 1952; Barrett et al. 1964; Radhakrishnan and Goss 1972; Myers and Benson 1983; Stark 1984), in which case the thermal instability, which requires thermal pressures to be important, may be relevant on small scales only in cold gas (Yoshii and Sabano 1980; Gilden 1984) and in the cooling regions behind shock fronts (Avedisova 1974; Mufson 1975; McCray and Stein 1975), and perhaps on large scales in

the tenuous warm (Parravano 1987; Heiles 1989; Lioure and Chieze 1990) and hot (Bregman 1980; Lepp et al. 1985) phases of the intercloud medium (see review in Begelman 1990). Modifications of the thermal instability may have other applications, however, if stirring from supernovae and other sources is considered as a type of heating mechanism for bulk cloud motions, and if cloud collisions, shocks and other nonlinear magnetohydrodynamic processes are considered as macroscopic cooling mechanisms for these motions (Struck-Marcell and Scalo 1984; Tomisaka 1987; Elmegreen 1989*d*).

Evidently the first problems to solve, before detailed studies can be devoted to cloud formation, are to find mathematical descriptions for the distribution and motion of the interstellar gas, and to assess the relative importance of the various forces that regulate these motions, such as magnetic, gravitational, thermal pressure and inertial forces (i.e. the ram pressure from supersonic collisions or the $\mathbf{v} \cdot \nabla \mathbf{v}$ term in turbulence theory). Then models using the proper balance of forces can be tuned to match the descriptions of gas in various environments. Unfortunately, finding a description for the structure does not appear to be very simple, and finding an explanation for the origin of what is eventually described may be more difficult than describing it.

This chapter takes the point of view that the study of cloud formation can be divided into two parts, and that we have made progress in only one of these parts. These two parts are (1) the identification of physical processes that cause rarefied, generally clumpy gas to condense into big cloudy objects, and (2) the mathematical description of the structure of the condensations that form by these processes. The first of these parts has several reasonable solutions, but the second has hardly been approached.

A good example of how cloud formation can be understood in terms of a condensation theory but not in terms of a theory for the origin of structure arises for terrestrial clouds. There the formation process is known to involve the condensation of water droplets in convection cells that rise to where the temperature falls below the dew point. But the origin of the structure inside these clouds, the convoluted boundaries and wisps, is not understood in detail, and may be more a result of droplet segregation in a turbulent medium than droplet formation (Lovejoy 1982). Similarly, in the interstellar medium, the growth of various instabilities and other condensation processes can be described using reasonable assumptions about heating, cooling and magnetic effects, but these theories alone do not predict the structures of the resulting density enhancements, even if the statistical mass distribution function for the condensations and their idealized shapes (e.g., clumps, filaments, etc.) can be determined from first principles. Understanding the structure and dynamics together seems to require computer models in which the instabilities are followed in time with a resolution comparable to that of the observations. Such models are in progress for cosmological studies (see, e.g., Park 1990), but not yet for interstellar theory.

The purpose of this review is to summarize the condensation and coagulation theories for interstellar cloud formation, which is the first part of the

division suggested above, and, for the second part of the division, to discuss briefly the connection between interstellar structure and laboratory turbulence. One hopes that these two parts are eventually made indistinguishable by one comprehensive theory.

Section II begins by highlighting the physical differences between diffuse and self-gravitating interstellar clouds, based on the dimensionless ratio of external pressure to internal gravitational binding-energy density, and suggests a difference in their formation routes. This section also notes that diffuse clouds are not always atomic and self-gravitating clouds are not always molecular, even though this correspondence usually appears in the solar neighborhood.

The subsequent sections summarize various implications for cloud formation theories that follow from three observed features: the apparent hierarchical structure of the gas (Sec. III), the prevalence of supersonic motions (Sec. IV), and the ubiquitous magnetic field (Sec. V). Section VI then discusses scenarios for cloud and star formation. All of these scenarios are made very uncertain by the supersonic and magnetic nature of the interstellar gas and by the role of spiral density waves.

The exact nature of the random motions, or "astrophysical" turbulence, that is observed, is also unknown, as discussed in Sec. VII. It seems likely that the bulk of the interstellar medium is turbulent, but not in the same way as a laboratory fluid because strong magnetic fields limit vorticity and the random diffusion of clumps, because there are no hard boundaries as in a laboratory, and because the kinetic energy is applied and dissipated on all scales, without a clear cascade from large to small scales as in Kolmogorov turbulence. Gravity and embedded energy sources such as stars are also much more influential in astrophysical turbulence than in the laboratory.

II. DEFINING THE STRUCTURE OF CLOUDS

A. Three Structural Types

For the purposes of this discussion, interstellar clouds will be categorized into three structural types: diffuse, self-gravitating and unbound. The difference between the first two depends on the relative importance of pressure and self-gravity for confinement. Unbound clouds are not confined by either pressure or gravity, and are presumably in the process of dispersing. This distinction between structural types is convenient for studies of cloud formation because the diffuse and self-gravitating types probably have different formation mechanisms. Structurally diffuse clouds should form by processes in which pressure is important, such as shock accumulation and thermal instabilities. Self-gravitating clouds should form where gravity is important, as in galactic spiral arms, dense shells and diffuse regions that have become cold or quiescent as a result of dissipation. Unbound clouds may form in the same way as diffuse clouds, by the pressurized accumulation of gas, for example, but the high pressure that formed them must have disappeared very recently. All

of these cloud types can presumably grow by coagulation of other clouds too (Sec. IV).

A single dimensionless parameter is used to distinguish between diffuse and self-gravitating clouds. This parameter involves the pressure P external to the cloud, and the average mass column density inside the cloud σ_c . The origin of the external pressure is unknown, but it is probably a combination of thermal pressure and ram pressure from external flows; it may be highly variable with time and position. The column density is also poorly defined because it depends on an arbitrary choice of cloud boundaries. Even with these uncertainties, the dimensionless ratio $P/G\sigma_c^2$ is a convenient measure of the relative importance of gravity and external pressure in binding a cloud together. If $P/G\sigma_c^2$ is much larger than 1, then self-gravity is relatively unimportant for a cloud and the shape and size should be governed primarily by external flows and pressure gradients. Such clouds should also have a more or less uniform average density inside their boundaries (although with clumps and filaments), and a structureless, or diffuse shape. A "standard cloud" for example (Spitzer 1978) has a value of $P/G\sigma_c^2 \sim 30$. Interstellar condensations with small values of $P/G\sigma_c^2$ may be significantly self-gravitating (if they are not unbound), and consequently stratified by internal pressure and average-density gradients. Most molecular clouds in our Galaxy are probably of this latter type, having values of $P/G\sigma_c^2$ between 0.01 and 0.1. Because of the importance of self-gravity, these are the clouds where stars form. We refer to them here as self-gravitating clouds (not molecular clouds) to emphasize their physical (not chemical) state.

Most likely, real clouds span a wide range of $P/G\sigma_c^2$ with no bimodal separation between diffuse and self-gravitating types. Indeed, Dickey and Garwood (1989) find a continuous mass spectrum for clouds, with only a slight change in slope to indicate the transition from diffuse to self-gravitating types.

Our definition of diffuse clouds differs from the operational one in which they are taken to be any cool objects observed in absorption. For example, the CS absorbing clouds on the line of sight to W49A were labeled diffuse by Miyawaki et al. 1988, even though these clouds are rather dense (100 cm^{-3}) and may be self-gravitating. Similar dense clouds were studied in absorption by Cardelli et al. (1990). Diffuse clouds that are more opaque than those commonly observed at 21 cm and in the ultraviolet are sometimes called translucent (van Dishoeck and Black 1989). If these clouds are also influenced more by external pressures than internal gravity, then our structural classification system still places them in the diffuse category, although they may be transition cases ($P/G\sigma_c^2 \sim 1$). The distinction between diffuse and dark molecular clouds made by Myers (1989) is analogous to our distinction between diffuse and self-gravitating clouds, although Myers considers only low-mass clouds ($< 10^4 M_\odot$), which generally look dark when they are self-gravitating. Extremely high mass clouds ($10^7 M_\odot$) can be self-gravitating too, but virtually invisible in extinction studies and also primarily atomic

(Sec. II.B). Thus the structural distinction based on $P/G\sigma_c^2$ is more useful for clouds in general, and also more illustrative of possible formation routes, than distinctions based on opacity or molecular abundance alone.

Unbound clouds are difficult to recognize unless the recent history of external pressure is known. This pressure includes both the uniform thermal pressure from surrounding gases and the nonuniform, time-averaged pressure from external flows, cloud collisions, magnetic waves and other variable sources. The cloud is unbound if two conditions are satisfied: $P_{\text{int}}/G\sigma_c^2 \gg 1$ and $P_{\text{int}} \gg P$ for internal pressure P_{int} . Note that a non-self-gravitating cloud with a low external pressure at the present time can still be pressure bound if the time-averaged external pressure, including pressure fluctuations in the past and future, is large enough to bind it on average. Such stochastic binding requires that the frequency of pressure fluctuations exceed the cloud expansion rate. Stochastic pressure binding may be applicable to most diffuse clouds because the external pressure environment of all clouds is likely to be highly variable with random supernovae, passing bright stars, and magnetic and physical cloud collisions. Clumpy regions that are swept up by a shock front should also have a variable post-shock pressure (including clump motions) that satisfies the global shock conditions only on average; large transients should occur as each new clump joins the front (Elmegreen 1988a).

The dimensionless pressure $P/G\sigma_c^2$ may also be useful as a tracer for diffuse and self-gravitating regions in large maps of interstellar gas. The boundaries of these regions are usually ambiguous if only the molecular emission line contours are used to delineate them, but if contours of $P/G\sigma_c^2$ are used instead, then some of the complicated structures that are likely to be present could become more clear. For example, it is possible that a cloud is structurally diffuse on one scale, where P and σ_c locally satisfy $P/G\sigma_c^2 \gg 1$, but that it contains self-gravitating pieces where $P/G\sigma_c^2 < 1$ on a smaller scale, and at the same time is part of a larger cloud that is also self-gravitating ($P/G\sigma_c^2 < 1$) at a larger boundary. This would be the case for a giant self-gravitating cloud complex that has diffuse cloud pieces on its periphery (see, e.g., Federman and Willson 1982), where the pressure may be high because of a history of supernova explosions, and which also has dense, self-gravitating clumps inside of the diffuse pieces, as observed, for example, by Stacy et al. (1989). Other combinations are possible too. In practice, one might try to measure the density ρ , density gradient $k\rho$ and velocity dispersion c everywhere in a three-dimensional region, and then determine the local value of $P/G\sigma_c^2 \sim k^2c^2/G\rho$ as an indicator of the relative importance of pressure and self-gravity at each location. A contour map of this quantity should distinguish between self-gravitating "objects," which have some structural integrity, and diffuse material, which is amorphous and poorly defined by other means. In such a map, the contours enclosing low values of $k^2c^2/G\rho$ would designate the self-gravitating objects. The actual threshold for "strong" self-gravity could be adjusted, but once chosen, the mapping procedure becomes objective and potentially informative.

B. Two Chemical Subtypes

The distinction between molecular and atomic clouds is based on a different combination of cloud properties than the distinction between diffuse and self-gravitating clouds. This difference took a while to recognize. The first decade of CO observations taught us that most dark clouds are also molecular, and that most molecular clouds are strongly self-gravitating. We also learned that most atomic clouds, like the diffuse clouds studied with optical and ultraviolet absorption, are not strongly self-gravitating. A change occurred when giant dust complexes and star-forming regions in irregular galaxies were found to emit very little CO radiation (Elmegreen et al. 1980; see review in Thronson 1988), when giant HI clouds in our Galaxy and other galaxies were discovered to be virialized (Elmegreen and Elmegreen 1987), and when diffuse-looking, non-self-gravitating, possibly unbound clouds at high galactic latitude were observed to emit CO (Magnani et al. 1985). We also have examples now of clouds that are primarily composed of H₂ molecules but which have very low column densities of CO (Blitz et al. 1990); this may also be the case for some of the giant cloud complexes in irregular (Israel et al. 1986) and other galaxies (Israel et al. 1990).

Evidently both diffuse and self-gravitating clouds can be either atomic or molecular. We refer here to four basic types of bound clouds: molecular self-gravitating, molecular diffuse, atomic self-gravitating, and atomic diffuse, and give below the expected conditions for each type and observed examples. The molecular nature of a cloud is assumed for this discussion to be based on the relative fraction of H₂, but the discussion could refer to CO instead if the CO formation criterion were used (see, e.g., van Dishoeck and Black 1988*b*; Federman et al. 1990).

Molecular hydrogen begins to appear in great abundance when the H₂ formation rate on dust balances the photodissociation rate from line absorption of background starlight. Jura (1974) and Federman et al. (1979) calibrated this condition from ultraviolet observations. Their results for diffuse clouds can be approximated by the criterion that molecular hydrogen appears when the path integral of the hydrogen-grain collision rate, which is proportional to $n^2 D Z \sim n N Z$, exceeds the absorbed incident ultraviolet flux, which is proportional to $\sim \phi N^{1/3}$. Here, n is the rms density of H nucleons, D is the cloud size, $N = \langle n^2 \rangle D / \langle n \rangle$ is the effective column density through the cloud, considering clumpiness, Z is the grain surface area per atom, which is written here as a metallicity, and ϕ is the radiation field. The factor $N^{1/3}$ is an approximation (Elmegreen 1989*a*) to the column density dependence in Federman et al. (1979), which arises because clouds with higher column densities absorb more dissociative radiation in the line wings; one could also use a Voigt function. Under most conditions, the absorption of photodissociative radiation arises in the molecular line transitions, not in dust, although extinction is still important in the ultraviolet. This implies that the molecular fraction depends on ambient pressure (through n) and not just

extinction (through N), i.e., that clouds with low extinction can be molecular if the pressure is high enough.

The numerical calibration suggested by Federman et al. (1979) gives a condition for a high H_2 fraction in diffuse clouds:

$$S \equiv \left(\frac{n}{60 \text{cm}^{-3}} \right) \left(\frac{N}{5 \times 10^{20} \text{cm}^{-2}} \right)^{2/3} \left(\frac{Z/Z_\odot}{\phi/\phi_\odot} \right) > 1 \quad (1)$$

where S is a shielding function and Z_\odot and ϕ_\odot are values in the solar neighborhood. Small values of S presumably correspond to predominantly atomic clouds. If we also write the dimensionless pressure $P/G\sigma_c^2$ in terms of the same parameter values, using, for convenience, the cloud-averaged (instead of surface) pressure $P = \rho c^2$ and the column density $\sigma_c = m(H)N$, then

$$\frac{P}{G\sigma_c^2} = 15 \left(\frac{n}{60 \text{cm}^{-3}} \right) \left(\frac{c}{1 \text{km s}^{-1}} \right)^2 \left(\frac{N}{5 \times 10^{20} \text{cm}^{-2}} \right)^{-2}. \quad (2)$$

Now the conditions for each of the four cloud types can be determined. Generally, when N is low and all of the other parameters are typical for the solar neighborhood, S will be small and $P/G\sigma_c^2$ will be large, so the cloud is an atomic diffuse cloud. When N is large and the other parameters are typical, S will be large and $P/G\sigma_c^2$ will be small, so the cloud is molecular and strongly self-gravitating. These two cases include most of the clouds in the solar neighborhood, which span the range from atomic to molecular as the column density increases. A less typical case arises when n is large and N is small, as in a small region or thin shell that is exposed to a high pressure. Then both S and $P/G\sigma_c^2$ can be large and the cloud can be both molecular and diffuse (with the exception of some shock fronts and other regions too hot or young to form molecules). The other unusual case is when n is small and N is large, which implies that the radius and mass are large ($10^7 M_\odot$). Then S and $P/G\sigma_c^2$ are both small and the cloud can be mostly atomic but still self-gravitating (with the exception of extremely low-density objects, which can become unbound by galactic tidal forces). Variations in ϕ and Z give odd cases too. Regions with large ϕ or low Z , for example, can have mostly atomic self-gravitating clouds, even with a relatively large N . This latter situation presumably occurs in irregular galaxies (see, e.g., Skillman 1987).

Real clouds are more complicated than this four-part classification scheme would suggest because they can have subparts that are a different type than the main clouds, all depending on local values of n , c , N , ϕ and Z . For example, atomic self-gravitating clouds often have molecular self-gravitating cores (Sec. III), and molecular self-gravitating clouds can have molecular diffuse wisps and clumps inside of them (see, e.g., Falgarone and Perault 1988). Molecular self-gravitating clouds can also have atomic clumps (diffuse or self-gravitating) inside if ϕ is large there from an embedded star (van der Werf and Goss 1990).

Specific examples of diffuse molecular clouds, some of which may be unbound, include (1) local high latitude clouds and their pieces (Magnani et al. 1985, 1989, 1990a; Lada and Blitz 1988; Mebold 1989), which may have a large $P / G\sigma_c^2$ because of high pressures from the Sco-Cen OB association; (2) uniform-density molecular clouds in various stages of disruption around star clusters (Leisawitz et al. 1989, 1990), which may have large P from the clusters, and (3) non-self-gravitating molecular clumps along the peripheries of dense H II regions, such as NGC 7538 (Pratap et al. 1990), which are presumably pressurized by the nebulae. Maloney (1990b) suggests that essentially all molecular clouds are of this type, i.e., bound more by external pressure than self-gravity, and Issa et al. (1990) suggest that the largest molecular clouds are not virialized but defined instead by artificial boundaries in crowded regions. Evidently, it is difficult to know if some clouds are virialized or not, but in general one expects true diffuse clouds to contain very little star formation (see, e.g., Magnani et al. 1990b).

Diffuse molecular emission is also evident on a galactic scale. Parts of the molecular dust lanes in galaxies (Kaufman et al. 1989) could be non-self-gravitating because of the high ram pressure from the convergent flow. Diffuse molecular clouds in the inner part of our Galaxy were discussed by Polk et al. (1988), in the interarm regions of M83 by Wiklind et al. (1990), and in NGC 6946 by Casoli et al. (1990). Warm CO emission from optically thin gas in IC 342 (Eckart et al. 1990; Wall and Jaffee 1990) may be diffuse also.

Examples of atomic self-gravitating clouds are the giant HI emission features in star-forming regions of irregular galaxies, where the metallicity is low (Skillman 1987; Viallefond 1988), and the largest self-gravitating clouds in our Galaxy (Elmegreen and Elmegreen 1987). Some of the atomic gas downstream from the dust lanes in M83 (Allen et al. 1986) and M51 (Tilanus and Allen 1989) could be in this category too, because of the high radiation fields.

Examples of truly unbound clouds are difficult to recognize because of the possibility that continuous pressure fluctuations occur, and that current pressures are only temporarily low. Nevertheless, high-latitude clouds that appear to be unbound have been studied by Pound et al. (1990) and Meyerdierks et al. (1990), who suggest that supernovae shocks compressed them recently and then cooled, bringing their environments to a low pressure. Support for this idea comes from Verschuur (1990), who suggests that two intermediate velocity HI clouds were recently stripped and displaced from their former molecular cores (which are still observed) by passing supernova shocks. The entire Ophiuchus cloud complex could be unbound as well, as a result of disruptive pressures from the nearby Sco-Cen OB association (de Geus et al. 1990), although many of the cores and clumps could still be bound internally.

In addition to this simple distinction between clouds that are primarily atomic or primarily molecular, all molecular clouds should also have photodissociated surfaces that are largely atomic. Examples of atomic surface

layers were discussed by Chromey et al. (1989), Anderson et al. (1990) and Pound et al. (1990). Such atomic shielding layers may, in some cases, be difficult to distinguish, both morphologically and physically, from self-gravitating atomic cloud entities that happen to have dense molecular cores. Presumably the difference between these two types of atomic regions can be determined from the self-gravitational binding of the atomic part alone. A simple shielding layer should be bound to the whole cloud but not to itself, unlike a giant HI cloud complex. Thus the line width of the HI envelope in the case of simple shielding should not satisfy the virial theorem given the total HI mass and the radius of the cloud, but the line width of a giant HI complex should satisfy the virial theorem. Using this criterion, the HI around the Orion cloud, which is bound to the whole complex but not to itself (Chromey et al. 1989), is a simple shielding layer for the enclosed molecular gas, and the giant HI complexes in the inner Galaxy, which are wholly virialized (Elmegreen and Elmegreen 1987), are distinct entities that happen to have dense molecular cores (e.g., M17).

III. CLOUD FORMATION AND HIERARCHICAL STRUCTURE

Numerous observations suggest that most of the gas in the interstellar medium is a combination of clumps, filaments, holes, tunnels and various other structures in a more or less connected magnetic network. This structure is evident in projection against the sky on maps that have a sufficiently large ratio of survey area to resolution size (Low et al. 1984; Bally et al. 1987; Scalo 1990). What is remarkable about the structure is that in some regions, it appears to extend in an approximately self-similar fashion, with no obvious break in structural properties, from giant spiral arm clouds and shells, hundreds of parsecs in size, to tiny clouds, clumps, filaments and holes that are less than 0.1 pc in size (Scalo 1985; Falgarone and Perault 1987, 1988; Efremov 1989). Such self-similarity is very uncertain, however, and it may not be ubiquitous. For example, Perault et al. (1985) suggested that the substructure in one particular cloud has a lower length scale of ~ 1 pc, below which the gas is more uniform. Also, on a larger scale, many of the giant clouds and holes seen in high-resolution maps of other galaxies (Casoli et al. 1990; Brinks and Bajaja 1986) have a structure distinctly different than the clumps, wisps and holes observed in nearby clouds, presumably because of the influence of stellar density waves and galactic shear on the large scale.

The origin of the apparent hierarchy is an important unsolved problem, not unrelated to cloud formation. Observations on the largest scale may offer a partial solution. The largest clouds in our Galaxy appear in the spiral arms as HI emission regions containing $10^7 M_{\odot}$ of neutral hydrogen at an average density of $\sim 10 \text{ cm}^{-3}$ (McGee and Milton 1964). These clouds, along with similar clouds in other galaxies (Viallefond et al. 1982), are apparently dense enough to be bound against galactic tidal forces (Elmegreen 1987*b*; Waller and Hodge 1991), which are particularly low in the arms (Elmegreen 1987*d*),

and their internal 21-cm velocity dispersions make them appear virialized (Elmegreen and Elmegreen 1987). Thus, many are well-defined objects, sometimes referred to as "superclouds," in analogy with the "superassociations" of Ambartsumian et al. (1963). Lo et al. (1987) and Rand and Kulkarni (1990) find similar clouds in the spiral arms of M51, but because M51 is generally more molecular than other galaxies (perhaps it has a higher pressure; see Sec. II), these largest clouds are mostly molecular. Rand and Kulkarni (1990) refer to them as "giant molecular associations." The common appearance of such giant clouds in the main spiral arms of our Galaxy and other galaxies makes it likely that they were formed by processes related to compression in a density wave. They may be the first generation of clouds that form in a region after such a wave passes by. Detailed studies of their properties may elucidate the mechanisms by which spiral arms trigger cloud and star formation.

The denser regions of superclouds, which contribute to the impression that there is hierarchical structure in the interstellar medium (Scalo 1985; Efremov 1989), often show up as giant molecular clouds. Such a hierarchy is illustrated for the Carina arm by Grabelsky et al. (1987), for the Sagittarius arm by Elmegreen and Elmegreen (1987), and for a 3-kpc region around the solar neighborhood by Efremov and Sitnik (1988). Similar structures have been resolved in other galaxies too, including spiral arm complexes in M31 (Lada et al. 1988a) and NGC 6946 (Casoli et al. 1990). In fact, many of the star-forming clouds in spiral arms could be the cores of much larger, low-density complexes. In the Carina arm, for example, nearly every observed molecular cloud (Grabelsky et al. 1987) is associated with one of the $10^7 M_{\odot}$ HI clouds found by McGee and Milton (1964). In M101 (Viallefond et al. 1982) and M33 (Viallefond et al. 1986) the bright H II regions also tend to be associated with giant HI clouds. It follows that most giant molecular clouds in the main spiral arms of galaxies could be the dense, strongly self-gravitating fragments of larger cloud complexes that were directly triggered by the stellar wave (Elmegreen and Elmegreen 1983).

Not all giant molecular clouds are parts of obvious superclouds, however, and this may be an important clue to the mechanisms of cloud formation. Several other well-studied molecular clouds in our Galaxy, such as those associated with giant shells or those in the interarm regions (Solomon et al. 1985) apparently have no well-defined superclouds associated with them. For example, the local clouds in Orion, Sco-Cen, Monoceros and Perseus are relatively bare molecular clouds. They all have HI envelopes (Chromey et al. 1989; Strauss et al. 1979; Puchalsky et al., in preparation; Sancisi et al. 1974), but unlike the main spiral arm clouds that are inside superclouds (e.g., M17), the envelopes of the local clouds are relatively small, having an HI mass only comparable to or less than the molecular mass (see, e.g., Efremov and Sitnik 1988). Thus the HI around bare molecular clouds is probably only a photodissociated surface layer and not a distinct self-bound entity (although it is probably bound to the molecular cloud; cf. Sec. II.B).

A second clue along these lines is that several of the local bare molecular

clouds appear to be part of Lindblad's expanding ring (Olano 1982; Elmegreen 1982a), in which case they probably formed in a giant pressurized shell (e.g., see also Franco et al. 1988). Moreover, the region is not young, as if it were a first generation of star formation, because most of the star formation in the solar neighborhood, which is in Gould's Belt, began its present activity some 60 Myr ago (Stothers and Frogel 1974; Palous 1986). In addition, the local clouds are not in a main spiral arm (they appear to be in only a spur; Blaauw 1985), but if we extrapolate the position of the solar neighborhood back for this 60 Myr, using the spiral pattern speed for our Galaxy given by Yuan (1969), then the gas would be at the position of the Carina arm, which is a main arm. The Sirius supercluster of stars in the solar neighborhood has also been traced back to an origin in the Carina arm (Palous and Houck 1986).

These observations suggest a scenario for cloud and star formation in the solar neighborhood that may be representative of other regions too. The local star-forming activity began 60 Myr ago when the Carina arm passed through the local gas. The triggering process was probably one of collection of this local gas into one or more superclouds, which fragmented into a first generation of molecular clouds and star formation. One of the associations that formed at that time, the now dispersed Cas-Tau association (Blaauw 1984), blew a giant bubble that made Lindblad's ring today (this association is in the center of the ring and it has the right age; for an even larger-scale expansion, see Palous [1987]). When the ring fragmented some 20 Myr ago, the nearest giant molecular clouds in Orion, Sco-Cen and Perseus formed as a second generation, and more recently, the Ophiuchus and Taurus (Olano and Pöppel 1987) clouds may have formed or been compressed as a third generation. The original low-density supercloud probably was dispersed by this time.

This scenario is largely speculative, but it fits the observed distribution and ages of the nearest clouds and star clusters in the solar neighborhood, and it is consistent with cloud- and star-formation processes observed elsewhere (Elmegreen and Elmegreen 1983; Efremov 1989). If true, it suggests that the largest scales in the hierarchy of gas structure, the superclouds and the embedded giant molecular clouds, form by pressurization, condensation and fragmentation of gas in spiral density waves. The densest cores of the giant molecular clouds, where the stars actually form, and other smaller steps in the structural hierarchy, could be a continuation of this fragmentation process. But the scenario also suggests that not all molecular clouds form this way, that they are not all part of a self-similar hierarchical structure extending to larger scales. Some molecular clouds are parts of rings and shells, which are not structurally similar to superclouds, and other molecular clouds are probably bare, the largest objects in their hierarchies. In this latter case, the extended gas that was formerly involved in the formation of the molecular clouds, and which may have once connected them to other dense clouds, has been dispersed or ionized so that it is currently unrecognizable. The associated H I envelopes are then simple shielding layers.

Hierarchical structure on smaller scales, as in low-mass molecular clouds and diffuse clouds, could also result from fragmentation and cooling after the main cloud forms. This might involve thermal instabilities if gravity is not important. But there are alternative possibilities (which also apply to larger clouds although they were not discussed above). For example, the pieces of a cloud could have existed prior to the cloud's formation and been brought into the cloud during the mass accumulation process, which may include shock accumulation of the ambient clumpy medium, random coagulation of formerly independent clouds, or large-scale instabilities. Some of the substructure could also grow behind shocks inside the cloud, as a result of spontaneous steepening of magnetosonic waves (Zweibel and Josafatsson 1983; Elmegreen 1990*b*), or in shells around embedded stars (Norman and Silk 1980*a*). Hierarchical and fractal structures could also result from collisional fragmentation of clumps inside the cloud (see, e.g., Nozakura 1990). These processes are discussed in more detail in Sec. VI.

There is no reason to think that the hierarchy of density structures is not accompanied by an analogous hierarchy of clump and cloud formation processes, which structure the interiors of clouds in the same way as they structure the general interstellar medium, but scaled down in size. Bally (1989), for example, suggests that much of the substructure in molecular clouds results from agitation by local stars, which is a structuring process similar to that in the general interstellar medium.

IV. CLOUD FORMATION AND SUPERSONIC MOTIONS

The independent motions of individual clouds and clumps appear to be somewhat random, giving broad and nearly gaussian spectral lines whenever several clouds or clumps are unresolved in a telescope beam (Perault et al. 1985; Kwan and Sanders 1986; Tauber and Goldsmith 1990). This randomness may also persist on larger scales in the hierarchy of cloud structures, as in the correlated motions of clusters of clouds which may be random with respect to each other. Such random motions are the likely result of cloud or cloud-cluster interactions of a gravitational or magnetic nature, analogous to two-body scattering or turbulence, just as the random motions of atoms in a gas result from collisions.

Deviations from purely gaussian motions appear in the form of broad and faint-line wings. These line wings sometimes occur in regions that are far from obvious embedded stars, and so presumably originate with purely hydrodynamic processes. Proposed explanations are that the high-velocity gas is an unbound interclump medium (Blitz and Stark 1986), that the wings result from high-speed clump collisions (Keto and Lattanzio 1989) or turbulent intermittency (Falgarone and Phillips 1990), or that they arise in nonlinear Alfvén waves (a form of turbulence) on the periphery of the dense cores, where the Alfvén velocity is expected to exceed the cloud's virial velocity because of the lower average density (Elmegreen 1990*b*). Observations of the

distribution and average density of the wing-emitting regions could presumably determine the origin of this gas. Magnani et al. (1990a), for example, suggest that in some sources this emission comes from the periphery of the cores, where the gas has a density of ~ 0.1 times the peak value, and Falgarone et al. (1991) find that the excitation density of the wing-emitting gas is the same as the excitation density in the line-core. These observations can be mutually consistent if both the line-core and the line-wing emission come from equally dense clumps which have a filling factor 10 times higher for the line-core emission than for the wing emission. This contrast in average density is consistent with the predictions of the wave theory, and the observed relative positions of the core and wing-emitting regions are consistent with the collision theory (the cores are then the shocked gas that is at rest between the colliding clumps). Unfortunately, the line wings in interstellar clouds are very weak and at the present time can be observed only by adding together many spectra. Then, there is a possibility that some of the wing emission is associated with stellar winds and other forced motions instead of turbulence (see, e.g., Margulis et al. 1986, 1988).

The motion of interstellar gas also has a systematic component wherever gravity or magnetism exert significant long range forces, acting on many clumps simultaneously, or where the pressures from stars or cloud-cloud collisions sweep up large regions in a type of shock, or cloud-collision front. Such systematic motions occur on a variety of scales, ranging from contracting envelopes, rotating disks and bipolar expansions around protostars, to the formation, condensation and disruption of whole clouds, to the rotation, shear and spiral flows of a galaxy. The importance of systematic flows for cloud formation arises when large-scale shock fronts compress the gas in bulk, forming shells and other cloudy structures, and when Kelvin-Helmholtz instabilities form clouds in shearing regions. Hunter and Whitaker (1989), for example, suggest that some of the clumps and small-scale structures observed in clouds result from Kelvin-Helmholtz instabilities, and Fleck (1989) attributes cloud rotation to them. Other systematic motions, such as linear and torsional waves that are probably magnetic in nature were discussed by Shuter et al. (1987), Heiles (1988) and Uchida et al. (1990), and wave-like motions, in general, were fitted to molecular line profiles by Stenholm (1990).

One of the most important characteristics of the random motion of clumps is their high speed relative to both their internal thermal speed and their internal velocity dispersion. These high speeds imply that most clump collisions are supersonic, and if one identifies the internal velocity dispersion with an Alfvén velocity for magnetic waves, then the motions are probably also super-Alfvénic (see, e.g., Heiles 1989). In that case, clump collisions lead to shocks and significant energy dissipation. Such dissipation makes the large-scale properties of the interstellar gas, taken as an interconnected network of clumps or tiny shocks, for example, qualitatively different from the large-scale properties of a conventional fluid, taken as a system of atoms or molecules. Because of the dissipation, a better analogy may be with a molecular fluid

where the thermal energy greatly exceeds the binding energy of the molecules. Such a fluid is not in equilibrium, but will quickly dissociate its molecules and cool. Similarly, the interstellar fluid may rarely find a stable equilibrium, but may always be in a state of rapid dissipation following constant or sporadic agitation by stellar energy sources, gravitational interactions, inertial forces from collisions or ram pressure, and various types of sonic and magnetic waves and shocks.

It follows that the adiabatic equation of state, $P \propto \rho^\gamma$, which has often been used for interstellar gas dynamics, is largely irrelevant for the interstellar fluid, even if γ is taken to be much less than 1. In fact, the effective value of γ , if one is to be defined, should depend on the rate of change of the density, in addition to the density and the relevant cooling and heating rates. An effective value of γ was given by Elmegreen (1991a) for a particular model of large-scale cloud formation by combined instabilities:

$$\gamma_{\text{eff}} = \frac{\gamma\omega - \omega_c(2l + s - m - 2r)}{\omega + \omega_c(m - s)} \quad (3)$$

where $\gamma = 5/3$ for purely translational cloud motions, ω is the rate of condensation into a cloud, $\omega_c = (\gamma - 1)\Lambda_0/(2P)$ is the cooling rate, and l , s , m , r are powers in the cooling and heating rates, given by $\Lambda \propto \rho^l c^m$ and $\Gamma \propto \rho^r c^s$ for density ρ and interstellar velocity dispersion c ; Λ_0 is the value of Λ in equilibrium. For typical large-scale instabilities with cloud collisional cooling ($l = 2$, $m = 3$), $\gamma_{\text{eff}} \sim 0.3$, which is comparable to the average value of $\text{dln } P / \text{dln } \rho \sim 0.25$ obtained from Myers' (1978) compilation of cloud properties. If $r < 0.5(1 + s)$, then $\gamma_{\text{eff}} < 0$ for some values of ω and there is an instability analogous to the thermal instability at constant pressure.

Supersonic motions also imply that sticking collisions between separate clouds should be rare. The individual velocities of diffuse clouds, for example, are so large compared with their internal dispersions and temperatures that direct hits between them should be destructive or shredding (Hausman 1981). Self-gravitating clouds should also disperse upon collision, unless they are either very massive or the relative velocity decreases with decreasing mass. Calculations suggest that if the relative cloud velocity exceeds approximately 2 or 3 times the escape velocity of the largest cloud, then the nonoverlapping and overlapping pieces will not be gravitationally bound to each other after the collision ends, and the clouds will fragment or explode upon impact instead of coalesce (Vazquez and Scalo 1989; Elmegreen 1990a; Lattanzio and Elmegreen 1991). Such high velocities may be common, considering that the relative velocity between two clouds is, on average, $6^{0.5} = 2.4$ times the observed one-dimensional dispersion. This dispersion has a random component between 3 km s^{-1} (Clemens 1985; Alvarez et al. 1990) and $\sim 7 \text{ km s}^{-1}$ (Stark and Brand 1989), so the relative cloud velocity is between 7 km s^{-1} and 17 km s^{-1} , nearly independent of cloud mass for all but the largest clouds. If the coalescence limit is 2 times the escape speed for a typical collision, then only clouds larger than $0.1 \times 10^5 M_\odot$ to $4 \times 10^5 M_\odot$ can stick to each other

after a random collision, considering the two dispersions, respectively. These numbers assume that the escape velocity for a cloud of mass M in solar masses equals $0.34 M^{0.25} \text{ km s}^{-1}$, from the scaling relations in Solomon et al. (1987).

These limiting masses for coalescence allow giant molecular clouds such as the Orion cloud to coalesce after a low speed impact, and this includes at least half of the molecular mass in the Galaxy considering the $M^{-1.5}$ cloud spectrum, but the limiting mass is too large for a complete Oort cycle of cloud coalescence from the smallest to the largest molecular clouds. Coalescence is possible above these limits if the clouds are self-gravitating so they stick, but then the geometric cross section for collisions should scale with the cloud-mass, as observed for molecular clouds (Solomon et al. 1987), and the resulting cloud mass spectrum should vary as M^{-2} in the Oort model (Elmegreen 1989e) instead of the observed $M^{-1.5}$ (Dickey and Garwood 1989).

The coalescence model of cloud formation works better when the velocities, masses and separations between clouds are correlated in the sense that low-mass clouds move slower relative to each other than high-mass clouds. This might be the case in a turbulent, fractal fluid where small neighborhoods have small-scale structure and low relative velocities (see, e.g., Falgarone and Phillips 1991). Then both high and low-mass clouds can hit each other at low enough velocities relative to their escape speeds to allow coalescence as often as fragmentation. The turbulent nature of the interstellar fluid might even be based on this condition, that cloud masses and positions take on a distribution such that the fragmentation probability equals the coalescence probability for the given amount of kinetic energy density. Indeed, fractal structures have been shown to result from cloud interactions (Nozakura 1990).

Can magnetic fields make cloud collisions more sticky? A naive answer is no: during a collision between two clouds on different magnetic flux tubes, the magnetic field lines that connect each cloud to the ambient medium should be distorted by the other cloud, producing a magnetic force that is generally repulsive. But a more subtle answer to this question may be affirmative if the magnetic field diffuses or reconnects significantly during the interaction. The outcome of such a magnetic collision has never been modeled, but it seems possible that the field can diffuse or reconnect to a geometry that eventually helps bind the clouds together gravitationally in the direction parallel to the field. Obviously, if two clouds start on the same flux tube, their collision should be somewhat sticky, but such collisions probably represent only a small fraction of cloud interactions. However, diffusion or reconnection could mix parts of their flux tubes and have the same effect.

The sticking problem with the random coagulation model of cloud growth calls into question some of the assumptions made for computer simulations of cloud dynamics, which show substantial cloud coagulation in spiral arms even though the collision velocities in the spiral arm streams are large. Most of these simulations assume that the cloud particles live forever, drifting freely between collisions, but magnetic fields and internal star formation would

seem to prevent such prolonged drifting in real galaxies. Many models also assume that some of the clouds stick upon impact, or that they lose relative energy after a bounce but do not destroy each other. Then coagulation is more likely. But the real situation may be very different, with the interarm clouds getting shattered and destroyed after colliding with clouds in the arms, producing a more diffuse type of gas (dust lanes?) instead of discrete cloud complexes. The statistical nature of the cloud distribution can also give the appearance of groupings and complexes for those interarm clouds that do not disperse in the arms (Adler and Roberts 1988), but such random groupings are transient and do not generally produce virialized objects like the molecular clouds (Lee et al. 1990) or superclouds in our Galaxy. Computer models also do not indicate why the cloud particles coalesce into complexes. If the cloud particles bounce off of each other with a reduced velocity after the collision, as is sometimes assumed for cloud cooling, then the simulated condensation into giant complexes cannot result directly from sticky coagulation, but probably results instead from cooling instabilities, in which the internal pressure in an incipient complex decreases rapidly because the component clouds dissipate their relative energy, and then continued collisions with fast-moving external clouds compress the complex to a high density. Such a cloud-formation process may look like sticky coalescence in a computer simulation, but it is really an instability related to the classical thermal instability.

Supersonic motions also imply that the length scale at which random kinetic energy is dissipated spans the entire range over which these motions are observed, occurring at shock fronts between any two colliding eddies or clouds, and in pervasive nonlinear magnetic waves. This differs from subsonic turbulence in laboratory fluids, for which the dissipation is thought to occur at the end of a swirling energy cascade to small scales. The kinematic energy may also be put into the interstellar fluid on all scales, in the form of wind or radiation pressure-driven bubbles or explosions from stars with a variety of luminosities, or in gravitational scatterings between clumps that are magnetically or viscously tied to the rest of the gas.

V. CLOUD FORMATION AND MAGNETIC FIELDS

Another important characteristic of the interstellar gas is the pervasive magnetic field. In the general interstellar medium, this field has a uniform component of $\sim 1.6 \mu\text{gauss}$ and a seemingly random component of $\sim 5 \mu\text{gauss}$ (Rand and Kulkarni 1989; see also Beck et al. 1989; Beck 1991). The relatively large value of this random component suggests that the random and expansive motions of the gas push the field around significantly, with a short time scale, but the general uniformity of the average field direction (Mathewson and Ford 1970) implies that such pushing does not completely control the field line structure. The field should respond with a restoring force from $B \cdot \nabla B$ tension that ultimately controls the gas on large scales.

In dense regions, the field is often so strong that the magnetic pressure is comparable to or larger than the kinematic pressure from random motions (Heiles 1989; Myers and Goodman 1988*a*). This implies that the field should influence these motions, which is probably the case in many regions, especially at low densities (see, e.g., Heyer et al. 1987). However, the orientation of the field in general seems to be independent of detailed structural features (Goodman et al. 1990), as if the field has a relatively minor role in cloud formation.

How can this discrepancy be resolved? A simple explanation is that the field lines are helical (Bally 1989), in which case the lines on the near side have some angle with respect to the cloud axis. But then the average orientation of the field, for the front and back sides combined, should still be parallel to the filament, and polarization observations using background stars should show this parallel direction, on average.

Another explanation is that a dense cloud's orientation is influenced by pressure gradients on a small scale, as would be the case if the cloud were swept up by some pressure source, but the field's orientation is determined by larger-scale processes, such as the positions and motions of other more remote clouds to which the field is also attached. The consequences of this idea are easily imagined. For example, a parcel of gas in a magnetic field can be accumulated into a cloud by a neighboring high pressure event, and the cloud can have any orientation relative to the initial field if the pressure is high enough. The field lines inside the cloud should follow the gas at first, in which case the component parallel to the pressure front should increase linearly with density; this orients the internal field so that it is nearly parallel to the cloud axis. But after a diffusion time (and several oscillations), the field lines inside the cloud should return to their initial orientation without much of a change in the cloud's overall orientation. Then the internal field becomes parallel to the external field again, and it will, in general, have no relation to the final orientation of the cloud. A condition for such random orientations between magnetic fields and cloud structure in this model is that the diffusion or straightening time should be less than or comparable to the time scale for cloud accumulation.

Consideration of the magnetic field is essential for theories of cloud formation: (1) It limits the random motions of individual clouds by dragging along low-density gas. (2) It transfers linear momentum between clouds without physical contact. (3) It removes angular momentum from a cloud during condensation. (4) Nonlinear waves also act as a source of pressure for pushing, twisting and shocking the gas into dense cloudy regions.

The first of these four processes makes it unlikely that a dense molecular cloud will drift freely for a geometric mean free path (Elmegreen 1981*b*). The characteristic confinement length corresponds to a distorted volume of the cloud's magnetic flux tube that contains a mass of other clouds equal to the cloud's mass. For dense molecular clouds with virial equilibrium field strengths, this length implies a maximum excursion of only several hundred

(<500) parsecs from an equilibrium position, which is much less than the geometric mean free path (~ 2000 pc). Theories of cloud formation involving random linear drifts followed by physical coagulations are therefore oversimplified, as are N -body computer models of cloud fluids with no intercloud medium or interlinking magnetic field structure. The relatively uniform field structure in nearby clouds also implies that these clouds are not composed of numerous pieces which drifted from random directions carrying their field lines with them.

Strong magnetic confinement also implies that one of the characteristics of a terrestrial turbulent fluid, i.e., the random diffusion of every pair of points away from each other, may not apply to interstellar fluids. The clumps may just oscillate on their interconnecting field lines (see, e.g., Elmegreen 1988*b*; Zweibel 1990*a*), as if they were trapped in a net.

The second of the four magnetic processes mentioned above implies that both diffuse clouds and the small clumps inside dense molecular clouds are likely to interact more by purely magnetic linkages than by direct physical collisions (Clifford and Elmegreen 1983; Falgarone and Puget 1986). The relative importance of these two interactions depends on the ratio $(\rho_c v_A / \rho v)^{2/3}$ for average and clump densities ρ and ρ_c , clump Alfvén velocity v_A , and relative clump velocity v . Large values of this ratio make magnetic linking interactions more important than physical collisions as a means of momentum exchange. When the interclump mass is low, the ratio ρ / ρ_c is the clump filling factor f . For self-gravitating clumps inside a self-gravitating cloud, the ratio v_A / v is approximately $(R_c / R)^{1/2}$ for size-line width relation $v \propto R^{1/2}$ and cloud and clump sizes R and R_c (see, e.g., Perault et al. 1986). Then the quantity $(\rho_c v_A / \rho v)^{2/3}$ equals approximately $(f^5 N)^{-1/9}$ for number of clumps N . Clumps typically have $f < 0.1$ (Falgarone and Phillips 1991), so this ratio exceeds unity for $N < 10^5$; in that case, magnetic linking interactions should dominate the collisions. For non-self-gravitating pieces in a cloud, the magnetic field could be more uniform in the clump and interclump regions, and then $v_A / v \sim (\rho_c / \rho)^{-0.5}$ so that $(\rho_c v_A / \rho v)^{2/3} \sim f^{-1/3}$, which also exceeds 1. Magnetic linking interactions give the interstellar fluid a cohesion and resilience that is not possible with purely physical cloud interactions.

In the third process mentioned above, magnetic fields exchange angular momentum between clouds and their environment, with a spin-down time approximately equal to the time for an Alfvén wave to traverse an external mass having a moment of inertia equal to the cloud's moment of inertia (see Chapter by McKee et al.). This implies that clouds and cloud complexes should not be rotating significantly, and it removes some of the stability against self-gravitational collapse given to the interstellar fluid by galactic rotation (Elmegreen 1987*c*, 1991).

Angular momentum exchanges by a magnetic field should also limit the vorticity of the interstellar fluid, strongly in two dimensions and weakly along the field (see, e.g., Dorfi 1990). This could remove one of the primary mechanisms for kinetic energy cascade from large to small scales in a ter-

restrial turbulent fluid, i.e., vorticity stretching (cf. Sec. VII), although other mechanisms for energy cascade could replace it. The transfer of energy between different scales in the interstellar medium could be driven by magnetic stresses and torques, i.e., the nonlinear $B \cdot \nabla B$ term in addition to, or instead of, the nonlinear $v \cdot \nabla v$ term, which is more important for weakly magnetic turbulence. This energy transfer may proceed from small to large scales, as when a moving, spinning or expanding region magnetically drags along the surrounding gas (Uchida et al. 1990), as well as from large to small scales, as when two colliding clouds pump energy into internal Alfvén waves which steepen into shocks (see, e.g., Falgarone and Puget 1986).

Magnetic fields can also form clouds directly, by the parallel-pushing action of nonlinear waves, or by twisting the gas into ropes. In the first case, strong plane-polarized waves will couple the transverse and parallel motions of the field and gas, so that strong transverse field-line deformations, as might result from explosions or random field-line entanglements, can lead to magnetic shock fronts and other pulses of dense gas traveling along the field at or slightly below the Alfvén speed. Because such deformations should be common in the interstellar medium, collisions between these parallel-moving pulses can form very dense, transient clouds and small-scale structure. The shock fronts can also clear out much of the gas between the deformations, producing a low-density intercloud medium. Numerical simulations of such collisions are in Elmegreen (1990*b*), and an illustration of the long-time evolution of numerous interacting magnetic waves is in Elmegreen (1991*b*). These simulations suggest that some cloud clumps could be transient shock-like fronts between regions of converging flows; the clumps last for the convergence time, which is several internal wave-crossing times. In the second case, the angular momentum drain from one part of a cloud can cause another part to spin up, and then the field lines can become helical and exert a tension that compresses the gas into a dense filament (Fukui and Mizuno 1991). Evidence for such twisting compression in Orion is discussed by Uchida et al. (1991).

Magnetic fields influence almost every aspect of cloud formation and gas dynamics. In some situations, this influence is probably so large that models which do not consider magnetic effects may have limited application. Some cloud formation models are based entirely on magnetic effects, such as the Parker (1966) instability and nonlinear wave-pushing models. Other models are greatly helped by the fields, such as the gravitational instability model and the coagulation model where pre-existing clouds and their field lines link together in a nondestructive fashion behind moving pressure fronts. Still other models, such as the random coalescence model in which dense clouds move independently for over a mean free path, are probably oversimplified because they do not consider the confining influence of magnetic fields.

General models of interstellar gas dynamics may also need revision when the magnetic field is included. For example, the three-phase model by McKee and Ostriker (1977) proposes that random supernova explosions become so

large that they overlap in space. Their primary assumption is that a supernova shock front passes over individual clouds without imparting much momentum to them (McKee and Cowie 1975); then most of the shock goes around the cloud and grows to a large size. But this assumption may not be true if all of the clouds are strongly connected to each other and to the intercloud medium by magnetic fields. Then the clouds could move together with the intercloud medium, and most of the enclosed mass should stay with the front, especially at late times (Elmegreen 1981*a*, 1988*a*). As a result, a strongly magnetic front should slow down faster and stall in a shorter distance than a nonmagnetic front that sweeps up only the intercloud medium. One of the observational consequences of this effect is that large supernova shells should have low-density interiors because the clouds that were there before the explosion were removed and not evaporated in place. Of course, such magnetic clearing should occur primarily at late times when the supernova pressure is not so large that it severely distorts and then detaches (by reconnection) the field lines that emerge from an impacted cloud. Another magnetic effect is that the expansion of a supernova shock in even a homogeneous medium should be resisted by magnetic tension in the swept-up shell (Tomisaka 1990; Ferriere et al. 1991). Both of these magnetic effects, the added shell mass and the surface tension, should decrease the porosity of the hot intercloud phase by limiting the expansion of individual supernovae remnants (see also Cox 1990).

Another potentially important effect of magnetic fields is the cushioning of collisions between clouds. Magnetic linking collisions, for example, may allow small clumps to be gently collected into moving pressure fronts without disruptive collisions. This implies that some of the clumpy structure observed in clouds could have been present in the ambient gas before the cloud formed, and not been disrupted by the (supersonic) violence of the formation process. Whether such soft coalescence can preserve the observed fractal structure of the clumps is unknown. Perhaps many of these effects will be observed in computer simulations when magnetic fields are generally included.

VI. CLOUD FORMATION SCENARIOS

The various theories of cloud formation can be divided into three categories: cloud formation by spontaneous instabilities in the ambient interstellar gas, including gravitational, thermal, Kelvin-Helmholtz and Rayleigh-Taylor instabilities; cloud formation by pressurized accumulation of ambient gas into shells, sheets, cometary globules and chimney walls; and cloud formation by random coalescence of existing clouds. Most practical theories today are combinations of these. Many of these theories were mentioned in the preceding sections. More detailed and specific comments are given here.

Liou and Chieze (1990) suggest that cloud formation occurs in two steps, first with a thermal instability that condenses the warm H I phase into cool diffuse clouds, and then with a coagulation of the diffuse clouds into self-gravitating cloud complexes (see also Field and Saslaw 1965). Cloud

formation by thermal instabilities in the warm HI was also investigated by Parravano (1987,1989), who suggested that the interstellar pressure can regulate itself to remain close to the maximum value for two stable phases (Parravano et al. 1988,1990). Thermal instabilities in the warm HI phase seem very likely, in fact (Heiles 1989), but whether these instabilities lead to the observed diffuse clouds (of mass $10^2 M_\odot$ or larger) as assumed by these authors, or only to very small-scale (< 1 pc) cool structures inside the warm HI regions is uncertain. In fact, thermal instabilities tend to favor small scales (Field 1965; Smith 1989) and may even generate a fractal structure (Elphick et al. 1991), and the mobility of the small pieces that condense out of the warm gas may be limited by magnetic effects (cf. Sec. V). Moreover, alternate scenarios for the formation of the observed diffuse clouds, such as accretion in pervasive shocks from supernovae and other sources (see, e.g., McKee and Ostriker 1977; Chiang and Prendergast 1985), are difficult to rule out. Most likely, some diffuse clouds form by thermal instabilities and others form in shocks of various types (Sec. II.A), but whether these clouds move freely enough to collide and slowly enough to coalesce is difficult to know without further modeling.

The coalescence of small interarm clouds into giant spiral-arm cloud complexes was discussed and modeled by Casoli and Combes (1982), Kwan and Valdez (1983), Tomisaka (1984,1986), Combes and Gerin (1985), Johns and Nelson (1986), Roberts and Steward (1987) and others. Such coalescence seems inevitable, but the details of the coalescence process and of the gas flow in a density wave are not understood. Diffuse clouds may be destroyed when they enter a spiral arm, splattered by mutual collisions and strongly pushed around by pressures from stellar radiation and giant HII regions. Their remnants could then disperse, creating the somewhat uniform gas that is observed as a long and continuous dust lane. The dense, self-gravitating clouds that enter a spiral arm should move differently than the diffuse clouds, colliding infrequently with other self-gravitating clouds (because of their long mean free path) and responding more freely to the spiral potential—perhaps in a somewhat ballistic fashion (because external pressures are less important for these clouds than for diffuse clouds; see Sec. II). Whether or not they coalesce depends on their relative velocity (Sec. IV), and this depends on the strength of the arm and on viscous effects such as magnetic drag (Sec. V). Perhaps the largest interarm clouds coalesce upon impact in an arm, with the considerable amount of mutual destruction that is expected in such a collision leading to the formation of the high-dispersion HI component that is seen as a supercloud (Sec. III). Subsequent cooling then reforms the molecular cores and ultimately leads to star formation.

Models which emphasize the destructive power of cloud collisions but still produce coalescence and giant complexes utilize a different, indirect route for cloud assembly. Struck-Marcel and Scalo (1984), for example, suggest that collisions between pre-existing diffuse clouds can be largely destructive and shredding, rather than directly coalescing, but that these collisions are

still important as a coolant for the diffuse cloud fluid (i.e., they lower the velocity dispersion). This cooling may then lead to a thermal-like instability in which slightly overdense regions diminish their dispersions faster than they are increased by random supernovae and other discrete pressure sources. When combined with gravitational forces between the clouds, the resultant gravitational-thermal instability (Elmegreen 1989c) can form cloud complexes with a much wider mass range than the pure Jeans instability (for an adiabatic fluid), and at a rate comparable to both the diffuse-cloud collision rate and the Jeans rate, which is ~ 20 Myr, depending on density. Tomisaka (1987) considered this combined instability in the gas that flows through a spiral density wave, and Cowie (1981) considered cloud collisional cooling and gravitational instabilities too, but without the intermediate stage of a thermal-like instability.

The existence of such macroscopic cooling instabilities is uncertain because it depends on unknown details of the stirring and energy dissipation processes for the interstellar medium. Many of these processes depend on length scale, so the velocity dispersion should depend on scale also. This implies that the equilibrium or initial state could be turbulent, in which case the theory of gravitational instabilities should be revised (Chandrasekhar 1951a; Bonazzola et al. 1987; Leorat et al. 1990). Nevertheless, applications of the conventional Jeans analysis with cooling have been made to rotating and shearing galaxy disks that are infinitesimally thin (Elmegreen 1989c) or thick and also subject to the magnetic Rayleigh-Taylor (Parker 1966) instability in the third dimension (Elmegreen 1991a). In this latter study, the shearing wavelets that grow in the gas by the so-called swing amplifier were found to be gravitationally unstable to fragmentation along their length, producing discrete, self-gravitating clouds out of a continuous (clumpy, magnetic) fluid. Superclouds follow naturally from the instability model, because they have the expected characteristic mass (see Skillman 1987). Smaller clouds can form by the same mechanism also, but this depends on the rate of energy dissipation in the ambient gas. If the kinematic energy dissipates too slowly, then the smaller self-gravitating clouds would have to form inside the larger clouds, where the density is already high (or they form by other mechanisms).

A limitation to this instability model is that the collapse of gas into discrete clouds has never been followed for a realistic flow in a density wave, considering the simultaneous triggering of magnetic Rayleigh-Taylor, gravitational and thermal instabilities in three dimensions, with shear and density variations appropriate for the wave. Balbus and Cowie (1985) calculated a criterion for the collapse of whole spirals parallel to the flow direction, which is like the criterion for ring instabilities in a disk, but this collapse does not produce discrete clouds, and shear variations parallel to the spiral were not considered (nor were magnetic fields). Balbus (1988) considered such shear variations and got more realistic effects such as spurs, but again without magnetic fields. Elmegreen (1987c) considered shear instabilities in magnetic gas with various shear rates appropriate to spiral arms and interarms, but the time

dependence of this shear and of other flow properties in the arm were not considered, nor was the fragmentation of the shearing wavelets into discrete clouds. This latter effect was addressed in Elmegreen (1991*b*), but with no density wave variations at all. All of these analyses point to an increase in the instability rate in spiral arms because of the high density and low shear rates there, with the resultant formation of giant cloud complexes resembling the observed superclouds, but the conditions for when this should occur are vague (e.g., is there a minimum spiral arm strength and does the instability operate faster than the arm flow-through time?). The application of this instability model to the formation of low-mass self-gravitating clouds is also unknown, because of uncertainties involved with the thermal instability part of the model (i.e., with cloud stirring and various cooling effects). The Parker instability part of the model for cloud growth has been studied in more detail by Matsumoto et al. (1988), Shibata et al. (1989) and others.

Another complication is that spiral-arm cloud formation could differ in strong and weak spiral arms (Elmegreen 1987*b*, 1988*a*), with pervasive cloud destruction and the formation of a homogeneously dense compression front (dust lane) followed by large-scale instabilities and supercloud formation occurring only in the case of strong arms. Weak-arm galaxies may scatter the existing dense clouds without severe destruction and create a dust lane by the dispersal of only the diffuse clouds. Examples of these two cases seem to be M51 (Rand and Kulkarni 1990) and M83 (Lord and Kenney 1991), respectively.

Observational evidence for cloud formation in swept-up shells was reviewed by Elmegreen (1987*b*) for small scales, and by Tenorio-Tagle and Bodenheimer (1989) for large scales (see also Deul and Hartog 1990). Both diffuse and self-gravitating clouds can form this way, but in the latter case a second step is required, in which the ring or shell that forms directly by the high-pressure event collapses gravitationally along its perimeter. The theory for the expansion has been progressing steadily (see, e.g., Tenorio-Tagle and Palous 1987; Norman and Ikeuchi 1989; Palous et al. 1990), but the theory for the collapse is in a poor state. McCray and Kafatos (1987) suggest that the time scale for the collapse of a large shell is the gravitational free-fall time at the compressed density, but transverse flows behind the shock may destroy or modify incipient condensations on these short time scales (unless the geometry is special; Kimura and Tosa 1988) giving a longer time for monotonic collapse (Elmegreen 1989*b*). Transverse flows and magnetic forces also redistribute mass inside the shells (Ferriere et al. 1990; Tenorio-Tagle et al. 1990). Magnetic effects during the collapse are generally unknown, and the possibility of blow out perpendicular to the disk (MacLow et al. 1989; Igumenshchev et al. 1990; Tomisaka 1990; Tenorio-Tagle et al. 1990), which would limit the total accumulation of material in the midplane, is a concern (Cox 1990).

VII. CLOUD FORMATION AND TURBULENCE

The above discussion summarizes some of the constraints on theories of cloud formation that are imposed by the hierarchically clumpy, supersonic, and magnetic nature of the interstellar gas. Obviously there is no complete theory of cloud formation yet, but the various parts of a complete theory seem to be evident, and a quantitative understanding of them seems to require only more calculations. But is this the way to proceed?

Most of the theories assume that the various cloud formation processes can be studied separately, as if in isolation, and that they combine without much change into a complete theory for the whole interstellar medium. This is basically a microscopic point of view, in which the local physics is probed to whatever depth is desired. However, the microscopic view currently fails to explain the self-similar (fractal) structure of clouds, and it may also fail to explain, for the same reason, the power-law correlations between cloud properties and the observed power-law mass spectrum (in spite of several theories in the literature which contain microscopic-type explanations for these power laws). How does one derive a cloud mass spectrum when some of the clouds form as shells around high-pressure OB associations, some form by fragmentation or collisional fracturing of larger objects, and some form by coalescence of smaller objects—all equally plausible and likely scenarios for cloud formation?

A different point of view is to ignore the microscopic details of interstellar gas processes entirely and to concentrate instead on the macroscopic properties of the fluid, taken as a complete system. This would presumably involve various conservation laws, assumptions of detailed balancing, equilibrium states and so on, and all of the details such as supernovae explosions, instabilities, etc. could enter the system as stochastic noise with a scale-dependent power. This is the approach often applied to laboratory systems that exhibit fractal structures and power laws, such as systems with second-order phase transitions, which have infinite correlation lengths (see, e.g., Ma 1976). Indeed, many of the details of laboratory phase transitions, such as the power-law indices, are independent of the microscopic details of the interactions between atoms and molecules, but depend only on gross properties of the system, such as the number of dimensions. The macroscopic approach is also generally applied to laboratory turbulence as an explanation for the power index of the velocity-position correlation (Kolmogorov 1941), without detailed consideration of the exact fluid motions or viscous coefficient.

Perhaps a future generation of theories will combine these two points of view, or perhaps detailed computer simulations, with all of the microscopic physics included, will show the scale invariant properties of the macroscopic system whether or not it makes their origin transparent. A problem with combined theories, however, is that if the power law and fractal behavior of the macroscopic system is independent of microscopic details, then the detailed physics that is put into the theory could be wrong and still the right

general characteristics of the gas could be derived. This is often a problem with computer simulations, which can be made to look realistic with very simple, and in some cases, inappropriate assumptions about the detailed physics. Obviously both points of view, the microscopic and the macroscopic, should be investigated simultaneously.

The discussions in the preceding sections questioned the application of what we know about laboratory turbulence to interstellar gas processes. Such cautions are useful at this time, and should not be mistaken as an implication that the interstellar medium is not turbulent at all. Indeed, most of the interstellar gas is probably very turbulent: it has a random element, as does turbulence, nonlinearities in the fluid equations are important, and both laboratory and astronomical systems seem to have fractal structures (Beech 1987; Bazell and Desert 1988; Scalo 1990; Dickman et al 1990; Falgarone et al. 1991). Falgarone and Phillips (1990) suggest further that the broad line wings in interstellar clouds are another manifestation of turbulence; in their interpretation, the line profile is not a probability distribution for velocities, which would be nearly gaussian for turbulence (Batchelor 1967; Monin and Yaglom 1981), but a distribution of velocity differences inside a mapped region or telescope beam. Yet even with these similarities between astronomical and laboratory motions, the interstellar gas is still very different from a laboratory fluid. To emphasize this difference here, we use the terms "astrophysical turbulence" and "interstellar turbulence" (Scalo 1987) instead of just "turbulence." Indeed, it seems possible that some of the self-similar, nonlinear motion and structure currently ascribed to turbulence may later prove to be caused by other processes. An example might be the structure and velocities that result from overlapping wind-swept shells with a power-law distribution of stellar wind luminosities. Another example was given by Dickman et al. (1990), who noted that the area-perimeter correlation for molecular clouds, which suggests that the clouds have a fractal structure reminiscent of turbulence, could instead result from a random positioning of unresolved clumps with no required connection to turbulence. Fractal structures may arise from thermal instabilities also (Elphick et al. 1991).

How does the interstellar gas differ from turbulent fluids usually studied in the laboratory? There seem to be at least four characteristics of astrophysical gas dynamics that distinguish it from laboratory turbulence: highly supersonic motions, strong magnetism, strong self-gravity, and the presence of numerous embedded (stellar) energy sources.

Section IV suggested that the supersonic nature of the interstellar motions should cause much of the dissipation of energy to occur in shock fronts between colliding clumps or eddies. This shocking process short-circuits the usual cascade of energy from large to small scales and shunts the energy directly from every scale to the smallest scale (which is the shock thickness, equal to the molecular mean free path, or the ion-neutral collision scale in the case of a magnetic shock). Shocks also make the fluid highly compressible. Theory suggests that such compressibility makes the velocity-distance relation

steeper than in an incompressible fluid (Fleck 1983; Biglari and Diamond 1988), in which case the observed relation $v \propto l^{1/3}$ for astrophysical gas (Falgarone and Phillips 1990) may be uncomfortably close to the relation observed in the laboratory for incompressible fluids.

The shocks in supersonic turbulence might also be expected to take the form of thin layers that appear as sheets or filaments in projection (Passot et al. 1988). Such sheets and filaments, unless they are unresolved, appear different from most of the interstellar gas, which looks more clumpy. In addition, the observed fractal structure of interstellar clouds, which is a property of the distribution of mass, differs significantly from the fractal structure discussed for laboratory turbulence, which is a property of the space in which energy is dissipated, the density being uniform. The dissipating regions in subsonic laboratory turbulence seem to consist of layered vortex sheet-like structures (Schwarz 1990), which have not yet been observed in astronomical sources.

Magnetic fields should also limit the motion of interstellar gas much more than the gas in laboratory fluids (see, e.g., Chaboyer and Henriksen 1990; Kahn and Breitschwerdt 1990). It may prevent or severely constrain vortical motions altogether and prevent the random diffusion of eddies and subsequent vortex stretching, which helps drive the energy cascade in laboratory fluids. Nonlinear magnetic wave interactions could drive turbulence in very different ways, replacing the vortex stretching in laboratory fluids with other nonlinear processes that cause energy to cascade. Alternatively, the most massive parts of interstellar clouds may just oscillate regularly on their magnetic field lines, driven by a balance between gravitational forces and magnetic tension. Such oscillations could drive nonlinear magnetic waves and turbulence elsewhere, but not be turbulent themselves.

Self-gravity is also likely to be important in structuring the interstellar gas. Gravitational collapse can increase the eccentricity of prolate or oblate objects (Smith 1989), exaggerating an already filamentary or sheet-like structure, and it can change the flat shocked layer between two colliding eddies or clumps into a globular feature. Note that the collapse time is comparable to the crossing time for a virialized object, and this is the approximate duration of a shock between two large eddies or clumps.

Embedded stars should also give structure and motions to the gas. Both field stars and newborn stars in a cloud probably have a power-law distribution of luminosities and winds, and they should push the gas around into structures that have a power law distribution too (see, e.g., Norman and Silk 1980a). Whether this structure resembles interstellar clouds cannot be determined without detailed modeling.

These considerations imply that many of the characteristics of interstellar gas that are currently attributed to turbulence may not really be the exclusive result of nonlinear terms in the equation of motion for isolated parcels of gas, but could instead be the result of power-law energy sources, gravitationally induced motions and waves, and mutual interactions between mass elements that have a random but nonturbulent nature. The net result of all of these pro-

cesses could differ significantly from terrestrial turbulence, thereby limiting direct analogies, but the interstellar fluid could still be turbulent in a broader sense.

Perhaps something more analogous to laboratory turbulence is realized on very small scales in the interstellar medium (see, e.g., Spangler and Gwinn 1990), where thermal pressure is important, gravity is unimportant, magnetic diffusion is so fast that the field lines are relatively straight, and the nearest star is relatively far away. This smallest scale for astrophysical turbulence might be the largest scale for conventional turbulence, i.e., for nonlinear fluid processes that resemble those seen in the laboratory. Such small-scale turbulence may then cascade down in the usual fashion until it reaches the microscopic scale of the collision mean free path. As long as the nonlinear terms in the equations of motion dominate the dynamics, the interstellar fluid can presumably be self-similar over a wide range of scales, from 0.01 pc to 1000 pc for example, but if other terms are important too, such as the pressure from stars, self-gravity, galactic shear and so on, then such a wide range for self-similarity might be difficult to explain.

Acknowledgments. This review benefited from comments by J. Holliman and C. McKee, and from extensive discussions, particularly about turbulence, with E. Falgarone, J. Scalo and K. Schwarz.

GIANT MOLECULAR CLOUDS

LEO BLITZ

University of Maryland

The properties of galactic giant molecular clouds (GMCs) in the solar vicinity and in the inner Galaxy are reviewed. Special attention is given to the role of the clouds in forming stars. The question of whether all GMCs form stars is raised and it is shown that there is little evidence that GMCs anywhere in the Galaxy are devoid of star formation, even O star formation. The angular momentum of local GMCs is then discussed in relation to the angular momentum of the diffuse interstellar medium. At least three GMCs in the solar neighborhood have retrograde rotation in an inertial frame of reference if their large-scale velocity gradients are due to rotation. Three GMCs in different evolutionary states are identified, and some of the differences in their properties are identified. The internal structure of GMCs is then discussed in some detail. It is argued that clumps are the fundamental units in which the GMC mass is distributed. Clump properties are discussed quantitatively, and the mass spectrum of five GMCs are compared and shown to be remarkably similar. Although the majority of clumps do not appear to be gravitationally bound, the clumps can be confined by the pressure of an atomic intercloud medium. The observations presented in this review are used to suggest a tentative outline for the evolution of GMCs.

I. INTRODUCTION

The fundamental goal of the study of molecular clouds is to understand how they form stars. All present-day star formation takes place in molecular clouds, so we may think of them as providing the initial conditions for the process of star formation. Yet, while all stars may form in molecular clouds, there are at least some small molecular clouds that do not form stars. Furthermore, even within those clouds that do form stars, it appears that only a small fraction of the mass of a cloud actively takes part in the star-formation process. What controls both the presence and the absence of star formation in molecular clouds? There seems to be an inevitability to the star-formation process. Observational evidence from surveys of stars and gas indicates that almost all of the giant molecular clouds (GMCs) in the solar vicinity are currently forming stars. How is this inevitability to be reconciled with the absence of star formation in most of the molecular mass of the Galaxy?

We begin by asking a few broad questions about molecular clouds. (1) How do molecular clouds, especially the GMCs, form? (2) Once a molecular cloud forms, how does it evolve to generate the entities that eventually become stars? (3) What is the basic unit of a molecular cloud that produces stars,

and how does it evolve to form a star? None of these questions has been answered as yet, but partial answers are beginning to emerge. This chapter will review some of the observational material relevant to these questions and will concentrate on the larger-scale aspects of the structure and evolution of GMCs. It will be argued that an understanding of the evolution of the interstellar medium into stars requires a detailed knowledge of the clumpy structure of molecular clouds. It will be shown that it is possible to identify molecular clouds in different evolutionary states, and that evolutionary effects within a particular molecular cloud, the Rosette Molecular Cloud, are observable in the dispersion of relative velocities of the identifiable clumps. The observations of a number of star-forming molecular clouds are reviewed with the aim of providing generalizations that are useful for future work. Among the topics not covered is the energy balance within molecular clouds. A good review of this subject is given by Genzel (1991*b*). We begin with a review of the large-scale properties of GMCs.

II. GLOBAL PROPERTIES OF GMCs

It is rather amazing that 15 yr since the identification of giant molecular clouds, there is no generally accepted definition of what a GMC is. There seems to be little disagreement about the classification of the largest clouds as GMCs, but an all inclusive definition of what a GMC is has proven elusive. A large part of the problem is that the various studies of the mass spectrum of molecular clouds indicate that the spectrum is well fit by a power law (see below) and there is consequently no natural size or mass scale for molecular clouds. What we call a GMC is therefore largely a question of taste. For the purposes of this chapter, any molecular cloud that has a mass $\gtrsim 10^5 M_\odot$ will be defined to definitely be a GMC, a cloud with a mass $10^5 M_\odot \gtrsim M(\text{cloud}) \gtrsim 10^4 M_\odot$ probably to be a GMC, and a cloud with a mass $\lesssim 10^4 M_\odot$ probably not to be a GMC. In most cases, this fuzziness does not cause serious problems.

Giant molecular clouds have been studied as a whole largely through their CO emission in the radio portion of the spectrum. The studies have been mainly of two kinds. (1) Observations of individual objects, where a cloud is identified, often by its association with a visible H II region, and then mapped to its outer boundaries. (2) Surveys of the galactic plane in CO, where GMCs are identified through some objective criterion. In the second case, GMCs are generally defined down to some contour level because of the possibility of confusion with other gas along the line of sight. Surprisingly, the general properties of GMCs defined in this way are not significantly different from those identified by the first method. Table I gives the properties derived for clouds in the solar vicinity (see, e.g., Blitz 1987*b*). Inner Galaxy molecular clouds may be somewhat denser and more opaque (see McKee 1989; Solomon et al. 1987), but there is no evidence that they form a separate population from the local clouds. This important conclusion suggests that detailed studies of the molecular clouds near the Sun can tell us about the

ensemble properties of GMCs everywhere in the disk. An exception is likely to be in the innermost regions of the Galaxy such as the molecular disk within 400 pc of the center.

TABLE I
Global Properties of Solar Neighborhood
Giant Molecular Clouds

Mass	$1-2 \times 10^5 \text{ M}_{\odot}$
Mean diameter	45 pc
Projected surface area	$2.1 \times 10^3 \text{ pc}^2$
Volume	$9.6 \times 10^4 \text{ pc}^3$
Volume averaged $N(\text{H}_2)$	$\sim 50 \text{ cm}^{-3}$
Mean $N(\text{H}_2)$	$3-6 \times 10^{21} \text{ cm}^{-2}$
Local surface density	$\sim 4 \text{ kpc}^{-2}$
Mean separation	$\sim 500 \text{ pc}$

An example of a local GMC is shown in Fig. 1, the L1641 cloud in Orion, in which the Orion Nebula is located. The figure shows the emission from the $^{13}\text{CO } J=1-0$ transition in various velocity bins, and in the last panel, the emission integrated over the cloud as a whole is shown. The figure shows several important features that are common to many local GMCs. (a) The ridge line of the final panel closely parallels the galactic plane (it is located at $b = -19^\circ 4'$). Most local GMCs are similarly elongated (Blitz 1978; Stark and Blitz 1978). (b) The ^{13}CO emission shows a strong velocity gradient along the length of the cloud which is generally interpreted as rotation. The subject of angular momentum in GMCs is discussed in Sec. IV. (c) The ^{13}CO emission is seen to break up into discrete clumps. In the L1641 cloud, the clumpiness is apparently quite filamentary. The clumpiness of GMCs is discussed in detail in Secs. VII, VIII and IX.

From the study of local GMCs, the following general conclusions may be drawn:

1. GMCs are discrete objects with well defined boundaries (see, e.g., Blitz and Thaddeus [1980] for a quantitative discussion of this point—see especially their Appendix B). The well-defined boundaries suggest that there is a phase transition at the edges of a molecular cloud. This point is discussed in greater detail below.

2. GMCs are not uniform entities, but are always composed of numerous dense clumps and have small-volume filling fractions (see Sec. VII for a quantitative discussion). These clumps appear to have a range of geometries from spherical to highly filamentary (see the maps in the references to Table IV below as well as Bally et al. [1987]). Nevertheless, maps of the CO emission from the complexes suggest that the surface filling fraction of the clumps is almost always near unity, where unity is defined as one or more clumps along the line of sight (Blitz 1980, and references therein).

3. The CO and ^{13}CO line widths of the clumps are *always* wider than

Figure 1. A series of maps, each showing ^{13}CO emission integrated over a 1 km s^{-1} wide velocity range illustrating the internal structure of the Orion A cloud. The number in each subpanel is the LSR velocity range shown. Each panel shows a region roughly $2^\circ \times 5^\circ$ in extent with an angular resolution of about $100''$. The galactic plane closely parallels the ridge line in the final panel. Figure from Bally et al. (1987).

the thermal widths implied by the excitation temperature. The linewidths are usually interpreted as the result of bulk motions associated with turbulence and/or magnetic fields.

4. GMCs are gravitationally bound (see, e.g., Kutner et al. 1977; Elmegreen et al. 1979; Blitz 1980). GMC masses are orders of magnitude larger than the Jeans mass computed from the excitation temperature of the CO. An indirect argument for the boundedness of local GMCs comes from considerations of their internal pressures (see Sec. VII). Typical internal pressures, P/k , are $\sim 1 \times 10^5 \text{ K cm}^{-3}$, much larger than the mean local interstellar pressure of $\sim 1 \times 10^4 \text{ K cm}^{-3}$ (Bloemen 1987). Because these clouds are known to exist long enough to give rise to several generations of stars, or $\sim 20 \text{ Myr}$ (Blaauw 1964), the GMCs would have dispersed if they were not held together by gravity.

5. All OB associations form from GMCs; thus GMCs are the nucleation sites for nearly all star formation in the Milky Way (Zuckerman and Palmer 1974; Blitz 1978, 1980, and references therein).

6. Within the uncertainties, the cloud-to-cloud velocity dispersion of local GMCs (with typical masses of $\sim 2 \times 10^5 M_\odot$) is the same as that of the small molecular clouds (with typical masses of $\sim 50 M_\odot$) found at high galactic latitude (Blitz 1978; Stark 1984; Magnani et al. 1985). The velocity dispersion of local molecular clouds therefore appears to be independent of mass over 3 or 4 orders of magnitude. If clouds are formed by collisional agglomeration of smaller independently moving clouds, then cloud velocity dispersions would be proportional to $M^{-0.5}$, unless there were some way to selectively re-energize the more massive clouds, an unlikely prospect. Furthermore, the velocity dispersion of molecular clouds seems to vary only weakly with galactocentric distance (Liszt and Burton 1983; Stark 1984; Clemens 1985). The constancy of the velocity dispersion with radius can also be inferred from the radial variation of CO scale height (see, e.g., Sanders et al. 1984). The half thickness of the CO layer increases from 50 to 70 pc when R increases from 0.4 to 0.8 R_0 . The scale length for the stars in the disk of the Milky Way is about 5 kpc (van der Kruit 1987). Because $(v_g)^2 \propto (h_g)^2 \rho_*$, the increase in the scale height h_g just makes up for the decrease in the midplane stellar density ρ_* , and the velocity dispersion of the gas, v_g , is nearly constant.

For the most massive clouds, Stark (1983) has shown that the scale height, and by implication the vertical velocity dispersion of GMCs, is smallest for the largest clouds at a given radius. Cloud-cloud collisions may therefore be important for the largest, most massive clouds. All of these results taken together suggest that collisional processes are not important in the formation of GMCs except possibly in the inner Galaxy at the highest masses ($\sim 10^6 M_\odot$).

It is noteworthy, however, that within a GMC, collisional processes do seem to be important. This point is discussed in more detail in Sec. VII.

7. The survey of local molecular material within 1 kpc of the Sun (Dame et al. 1986) finds no GMCs without star formation. In fact, within 3 kpc of the

Sun, only one GMC is found without evidence of star formation (Maddalena and Thaddeus 1985). This cloud is discussed in more detail below. In the solar vicinity at least, molecular clouds without star formation are quite rare. It therefore appears that star formation is quite rapid after the formation of a GMC.

8. The above result, when combined with calculations of the destructive processes associated with the formation of massive stars, implies that the GMCs are quite young, ~ 30 Myr (Blitz and Shu 1980). That is, because all GMCs appear to be sites of star formation, especially massive star formation, the clouds do not appear to be able to survive the birth of more than a few generations of massive stars, an argument that is consistent with various other lines of reasoning (Blitz and Shu 1980). Direct observational evidence for lifetimes of this order was first presented by Bash et al. (1977), and subsequently by Leisawitz et al. (1986) from the association (or lack thereof) of molecular material with young clusters of varying ages. Cohen et al. (1980) have come to the same conclusion from the confinement of the molecular arms in the outer Galaxy to narrow velocity ranges.

The primary argument for long-lived clouds in the Milky Way had come from continuity arguments based on the ratio of atomic to molecular gas in the molecular ring of the Milky Way (see, e.g., Solomon and Sanders 1980). That is, if the mass in a ring at some radius R is overwhelmingly molecular, and if GMC formation is initiated primarily by compression of diffuse gas in spiral arms, then in a steady state the mean ages of molecular clouds should be much greater than the mean time between spiral arm passages, ~ 100 Myr at $0.5 R_0$. However, the Bloemen et al. (1986) COS-B gamma-ray analysis shows that at virtually all radii, the atomic gas dominates the surface density, and even at the peak of the molecular ring, the excess of molecular gas is small. Some authors (see, e.g., Wolfendale 1991) prefer even lower molecular abundances. The data therefore suggest that the primary argument for long-lived clouds in the disk of the Milky Way is not tenable. A corollary of this conclusion is that clouds found in the interarm regions may have formed there; throughout most of the Galaxy, there is sufficient atomic gas to condense into clouds, even between spiral arms. It should be pointed out, however, that in the molecular disk within 400 pc of the galactic center and in some extreme molecule-rich galaxies, the molecular gas may be so abundant, that clouds may be quite long lived, especially if star formation can be inhibited in them.

9. A large fraction of the stars formed in GMCs do not return their material to the interstellar medium in a Hubble time. Therefore, either the GMCs were more numerous in the past, or the interstellar medium is replenished by infall or inflow from the outer reaches of the Galaxy (see, e.g., Lacey and Fall 1985).

Studies of GMCs based on inner Galaxy CO surveys run into the problem of finding an objective way to identify the molecular clouds. The degree of blending of the spectral lines, the large amount of foreground and background emission, and the necessity of using kinematic criteria for identifying the clouds add a significant amount of uncertainty to the identification of

GMCs (see, e.g., Adler 1988; Blitz 1987a). Nevertheless, a number of important properties of GMCs are inferred from the galactic CO surveys, and the searches for molecular clouds in the outer Galaxy. Some of the more important of these are the following:

(a) There appears to be a linewidth-size relation for GMCs in the inner Galaxy. Larson (1981) was the first to point out the existence of a power-law relationship between the sizes of molecular clouds and their intrinsic velocity dispersions. From various recent studies, the results are given in Table II. In this table, the quantity on the left is either the full width at half maximum or the one-dimensional velocity dispersion in km s^{-1} , and the quantity on the right is some measure of the mean linear size of a GMC in pc. The scatter in all of the studies is not terribly large, but note that the second and the third determinations are obtained from the same data set. The close agreement between the various observers in the value of the power-law exponent of the linewidth-size relation is so striking, that unless there is a selection effect common to all of the studies (see, e.g., Blitz 1987a; Kegel 1989), it suggests that the relation underlies some fundamental property of GMCs.

TABLE II
Linewidth-Size Relation for GMCs

Relation ^a	References
$\Delta V = 1.20R^{0.50}$	Dame et al. (1986)
$\sigma_V = 1.0S^{0.50}$	Solomon et al. (1987)
$\sigma_V = 0.31D^{0.55}$	Scoville et al. (1987)
$\Delta V = 0.88D^{0.62}$	Sanders et al. (1985)
$\Delta V = 0.85D^{0.63}$	Leisawitz (1990)

^a ΔV = full-width at half maximum in km s^{-1} ; σ_V = one-dimensional velocity dispersion in km s^{-1} ; R , S and D are measures of the mean linear size of a GMC in parsecs.

Nevertheless, both the reality and the implications of the linewidth-size relation have been challenged by several observers. Adler and Roberts (1992) have argued on the basis of N -body simulations that many of the clouds identified in galactic surveys are likely to be chance superpositions of unrelated clouds. Nevertheless, these spurious clouds produce a linewidth-size relation with the observed slope. The reality of the relation has been questioned by Issa et al. (1990) from an analysis of published survey data. These authors showed that if the Solomon et al. (1987) method of analysis is used on their own survey data, but at (a) positions not centered on their clouds, and (b) at random locations in the survey, one obtains a linewidth-size relation similar to that of the original analysis. This result is puzzling unless the linewidth-size relation is an artifact of the dataset itself, rather than of the dynamical state of the clouds. In addition, Issa et al. also lowered the threshold of their analysis to a point where one expects clouds to be blended together into apparent clouds that are unrelated to one another. Again, Issa et al. obtained a linewidth-size

relation indistinguishable from that of Solomon et al. suggesting that there is no physical significance to the linewidth-size relation. Its application to clouds to obtain, for example, their distances, may be flawed. Analysis of the Bell Labs ^{13}CO galactic plane survey, should be able to resolve this issue because of the higher contrast in the ^{13}CO data compared to that of CO.

(b) Solomon et al. (1987) have shown that for GMCs in the inner Galaxy there is a correlation between CO line luminosities and virial masses, and thus that (1) the CO line is a good tracer of the mass of a GMC, and (2) GMCs are in approximate virial equilibrium. Maloney (1988, 1990a) has challenged this interpretation on two counts. First, he argues that the CO luminosity-virial mass correlation can be an artifact of the linewidth-size relation alone. Second, he argues that one obtains a linewidth-size relation indistinguishable from the data if one models an ensemble of *pressure* confined clouds. Because the CO luminosity-virial mass correlation may be the result of pressure confined clouds and not gravity, it need not imply that GMCs are virialized. However, it seems to this author that although pressure may confine the relatively small clouds, the evidence for gravitationally bound GMCs is overwhelming; see point (4) above.

(c) Independent estimates of GMC masses from gamma-ray observations (Bloemen et al. 1984, 1986) and from IRAS observations (see, e.g., Boulanger and Perault 1988), suggest values for the CO/H₂ conversion ratio which imply that GMCs are gravitationally bound. If the clouds are in virial equilibrium, then

$$(\Delta V)^2 = \alpha GM/R \quad (1)$$

where α is a constant near unity.

If $(\Delta V) \sim R^{0.5}$, then $M \sim R^2$ which in turn implies that the mean H₂ column density of GMCs is constant. This simple conclusion is presumably telling us something important about either how GMCs form or how they regulate themselves. McKee (1989) has assumed the latter in his recent theory of photo-regulated star formation in GMCs. Kegel (1989) however has criticized the constancy of the H₂ column density of GMCs as an artifact of observational selection. This issue can be resolved by aperture synthesis observations of GMCs in other galaxies.

(d) GMCs in the outer Galaxy appear to have lower excitation temperatures than GMCs in the inner Galaxy (Mead and Kutner 1988). It is unclear at present whether this is due to a lower external heating rate, decreased star-formation rate or both. In any event, the outer Galaxy GMCs have lower CO luminosities than those in the solar vicinity (Digel et al. 1990), which suggests that the CO/H₂ conversion ratio is a function of galactocentric distance.

(e) The distribution of masses for GMCs in the inner Galaxy is found to be (for masses in excess of $10^5 M_\odot$), $dN(M)/dM \propto M^{-1.5}$ (Solomon et al. 1987). The power-law exponent is the same as that found for the distribution of clump masses in a GMC (see Sec. VII). If one tries to determine at what cloud mass half of the H₂ mass in the Galaxy resides, the various analyses of

the inner Galaxy CO give results that fall within a factor of 2 of the range 1 to $2 \times 10^5 M_{\odot}$ when account is made of the different assumptions used and assuming that the power law doesn't steepen significantly at low masses. This is very close to the mean value in the solar vicinity (Stark and Blitz 1978).

One of the glaring deficiencies in galactic studies of GMCs is a quantitative study of how the properties of GMCs vary with galactic radius. For example, we might expect that to be stable against the larger tidal forces and the larger energy density of dissociating radiation, that inner Galaxy clouds would be denser than the clouds at larger galactocentric distance. Such a conclusion was reached from an indirect analysis of Liszt et al. (1981); however, no direct confirmation has been made. Such a study would be particularly useful in trying to understand how different galactic environments affect the formation and evolution of GMCs. It has been known since the Altenhoff et al. (1970,1978) 5 GHz surveys of the galactic plane, for example, that giant HII regions are much more common in what later became known as the molecular ring than they are at larger galactic radii. Surely the greater efficiency with which the inner Galaxy GMCs converts molecular gas into O stars must be a reflection of differing molecular cloud properties, but which properties? There have been a few studies of molecular clouds in the outer Galaxy that suggest that there are differences between them and the inner Galaxy clouds (see, e.g., Mead and Kutner 1988; Digel et al. 1990), but other than these, systematic studies of the gradients of the large-scale properties of GMCs as a function of galactic radius are almost totally lacking. It would seem imperative that even a rudimentary understanding of extragalactic CO emission would require an understanding of how GMC properties vary within the Milky Way.

III. DO ALL GMCs FORM STARS?

As mentioned above, various surveys of the molecular gas in the vicinity of the Sun have turned up only one GMC within 3 kpc that is devoid of star formation. On the other hand, Mooney and Solomon (1988) argue that at least 25% of the GMCs in the inner Galaxy are devoid of massive star formation. Therefore, on the basis of local observations, the answer to the question posed in the heading is essentially yes, and on the basis of inner Galaxy observations, the answer would be no. We must keep in mind that clouds without O star formation may still be forming stars of lower mass in great abundance, so strictly speaking, the solar vicinity and inner Galaxy observations are not necessarily incommensurate. Care must therefore be taken in defining the question so that answers are not biased by studies with different sensitivity limits.

Mooney and Solomon (1988) approach the question by looking at the 100 μm surface brightness of inner Galaxy molecular clouds and comparing the far-infrared luminosities, L_{IR} to the virial masses of the clouds, M_{VT} . They find that the ratio $L_{\text{IR}}/M_{\text{VT}}$ varies by 2 orders of magnitude for a given mass,

but the mean is independent of mass. Molecular clouds with masses greater than $10^4 M_{\odot}$ (i.e., all of which are probably GMCs) are equally efficient, on average, at forming stars. On the other hand, they find a number of GMCs with low infrared surface brightnesses. They argue that these clouds are not rare and that therefore, about 25% of GMCs have no massive stars forming within them. Let us examine this latter conclusion with reference to what we know about nearby molecular clouds with known stellar contents.

Consider, for example, the Taurus and Ophiuchus clouds. Each has a mass of about $10^4 M_{\odot}$ (Ungerechts and Thaddeus 1987; de Geus et al. 1990), and from the definitions given in Sec. II, these are probably not GMCs. Nevertheless, both clouds have substantial associated star formation, but no associated H II regions. The star-formation efficiency in the core of Ophiuchus, for example, may be as high as 25% (Lada and Wilking 1984). Although these cloud complexes both have stars as early as B associated with them, it would be very difficult to determine whether clouds in the inner part of the Milky Way that otherwise appear to be devoid of signs of star formation are like these clouds. Ophiuchus, for example, has a $100 \mu m$ infrared luminosity of about $7000 L_{\odot}$, and the infrared luminosity is consistent with it being reradiated starlight from embedded sources (Greene and Young 1989). The overall star-formation efficiency of the Ophiuchus complex (zero age main sequence and pre-main-sequence stellar mass divided by the mass of H_2) is about 2 to 3% (Wilking et al. 1989a; E. Lada, personal communication), equal to the mean in the plane of the Galaxy (Myers et al. 1986). This value must be typical of GMCs in the Milky Way if most star formation takes place in GMCs. The level of activity found in Ophiuchus, even if it were scaled up for clouds with masses which would here be considered definitely to be GMCs, that is, masses greater than $10^5 M_{\odot}$, would not be recognizable from studies such as those of Mooney and Solomon (1988).

However, we run into difficulties even if we attempt to determine whether all OB star formation would be detectable in galactic surveys, where we define OB stars as those that give rise to H II regions. To see this, it is useful to refer ahead to Fig. 3a which shows the $100 \mu m$ surface brightness of the cloud complex associated with the Rosette Nebula as observed by IRAS. The peak brightness of the map, which has had the background removed, is 720 MJy sr^{-1} , and the infrared luminosity of the cloud is $\sim 5 \times 10^5 L_{\odot}$.

Mooney and Solomon find that there is a class of infrared-quiet molecular clouds, many with masses $> 10^5 M_{\odot}$, which have peak $100 \mu m$ surface brightnesses only 1/20 that of the infrared-strong clouds. The infrared-strong clouds are defined by strong localized infrared emission which, in most cases, seems to result from the action of an H II region. If it were located in the inner Galaxy, the Rosette Molecular Cloud would probably be classified as infrared quiet based on the definition for infrared-strong clouds given by Mooney and Solomon. That is, an infrared-strong cloud must have a peak $100 \mu m$ surface brightness more than a factor of 2 above the local background. In the longitude range $40^\circ > l > 0^\circ$, the mean surface brightness of the galactic plane between

$0.75^\circ < b < -0.75^\circ$ is never less than 1000 MJy sr^{-1} (Sodrowski et al. 1987), thus in a typical location in the inner Galaxy, the Rosette Molecular Cloud would not meet the brightness criterion. Incidentally, the Rosette H II region itself is actually a minimum on the infrared maps. Furthermore, its peak $100 \mu\text{m}$ surface brightness is only 3.5 times that of the mean of the infrared-quiet clouds, $\sim 200 \text{ MJy sr}^{-1}$. Nevertheless, the Rosette Molecular Cloud is particularly rich in O stars even though its size and mass are typical of GMCs in the solar vicinity.

The nebula itself is illuminated by 7 stars of spectral type O4 to B0 stars (Pérez et al. 1987) and the stellar association has 13 stars of spectral type O9.5 or earlier (Morgan et al. 1965; Turner 1976). The association is about as rich as the Orion OB1 association, the most spectacular star-forming region within 1 kpc of the Sun. However, in spite of the richness of its OB star formation, the RMC would probably have been classified by Mooney and Solomon as being devoid of OB star formation on the basis of its surface brightness, probably because there are no *embedded* O or early B stars. Furthermore, if the Rosette OB association had fewer O and B stars, its far-infrared surface brightness and luminosity would likely be even smaller. It is quite possible, therefore, that all of the clouds classified as infrared-quiet are Rosette-like objects or similar sources with fewer O and B stars.

A similar problem exists if one tries to use H II regions to trace the star formation in inner Galaxy GMCs as was done by Myers et al. (1986). They used the Altenhoff et al. (1970, 1978) 5 GHz surveys to find H II regions associated with molecular clouds, and found a few GMCs (a smaller percentage than Mooney and Solomon) with very low star-formation efficiencies based on the absence of detectable 5 GHz flux. However, the Rosette Nebula is known to have an emission measure of about $3000 \text{ cm}^{-6} \text{ pc}$ (Bottinelli and Gouguenheim 1964), well below the detection limit at which H II regions are unambiguously identified in the Altenhoff survey. Other solar vicinity OB associations (e.g., the Mon OB1 association which contains the well known young cluster NGC 2264) have H II regions with even lower emission measures. Low-level infrared or radiocontinuum emission may simply signal that the conditions in inner Galaxy molecular clouds without giant H II regions are like those in the Rosette Nebula, and not due to the absence of O stars, or star formation in general. Such situations can arise when the action of O stars destroys the dust, when the angle subtended by the molecular cloud at the ionizing stars is small, or both.

Lockman (1990) has considered the detectability of the Rosette Nebula in the inner Galaxy in a recent review. He concludes that the Rosette Nebula would not have been detected in *any* discrete source survey of the inner Galaxy to date, including his own sensitive recombination line survey (1989). Consequently, the abundance of low surface brightness H II region/molecular cloud complexes in the inner Galaxy is unknown, and may account for the clouds identified by Mooney and Solomon and by Myers et al. that have little apparent star formation.

There may therefore be no discrepancy between the fraction of GMCs that form stars in the solar vicinity (virtually all) and that found in the inner Galaxy. The Mooney and Solomon clouds not only may have star-formation efficiencies similar to that of other GMCs in the Galaxy, but they could contain substantial OB star formation and still be infrared quiet according to their definition. On the other hand, some of the clouds in their sample may have low star-formation rates, but much more sensitive observations are necessary to determine this. The Maddalena-Thaddeus cloud remains the only known molecular cloud where the star-formation rate within the cloud is known to be a small fraction of the rate observed in local OB associations. It is possible with directed observations to set better limits on the stellar content of individual inner Galaxy molecular clouds than are currently available, and it may be possible to find clouds with star-formation rates significantly smaller than those found in local GMCs. On the other hand, if the inner Galaxy clouds form stars with the same efficiency as local GMCs (Mooney and Solomon 1988), we might expect that finding GMCs with significantly depressed star formation efficiencies inside the solar circle will prove difficult.

We conclude, on the basis of both local and Galaxy-wide studies, that the fraction of GMCs devoid of star formation is very small, probably less than 10%, but no more than 25%. This fraction suggests that the onset of star formation in a GMC is only a small fraction of its age, and that a GMC which is found to be truly without young stars must be very young, possibly 3 Myr, if the mean ages of GMCs are 3 Myr, as is the prevailing view. The alternative view requires that the small fraction of GMCs without star formation comprise a separate population of clouds in which the formation of stars is strongly inhibited for some reason. Detailed comparison of objects like the Maddalena-Thaddeus cloud with other GMCs should help to determine whether the latter viewpoint has any validity.

IV. ANGULAR MOMENTUM

The angular momentum of a GMC should reflect the angular momentum of the interstellar medium from which the cloud formed, thus the specific angular momentum of a GMC (that is, the total angular momentum per unit mass of a cloud complex) is an important parameter for understanding its history. Although much has been written on the evolution of angular momentum in connection with the formation of individual stars (see, e.g., Mouschovias 1991a; Chapter by McKee et al., and references therein), little is known about the angular momentum of GMCs. Mestel (1966b) considered the problem of the angular momentum of a planet condensing from a protoplanetary disk; this work is applicable in part to the problem of GMC formation from the disk of the Galaxy. In the case of a GMC that condenses from the general interstellar medium, however, it is possible, perhaps even likely that magnetic fields play a role (see, e.g., Mouschovias et al. 1974), a possibility not considered originally by Mestel, but which is discussed in his chapter in *Protostars and*

Planets II (Black and Matthews 1985). In what follows below we will first evaluate the evidence for the overall rotation of GMCs. We will then consider how the specific angular momentum of a GMC compares to that of the material from which a cloud formed.

A. Rotation vs Shear

That GMCs rotate has long been inferred from the velocity gradients observed across them (see, e.g., Kutner et al. 1977). The Kutner et al. observations of the Orion cloud show a continuous velocity gradient suggestive of solid body rotation (see Fig. 1 above). However, the velocity gradients may also be due to shear resulting from the momentum deposited by energetic stellar winds. Bally (1989) has argued, for example, that the large-scale velocity gradient in the L1641 cloud in Orion results from the interaction of the molecular gas with the energetic stellar winds from the O stars in the association, and that the gradient is due to a wind induced differential linear acceleration of the molecular material rather than rotation. Could it be that the large-scale gradients of all GMCs in which they are found are the result of similar stellar wind activity?

Table III gives the values of the largest known velocity gradients for entire GMCs. The values are uncertain by about 20%. The negative sign indicates that the inferred angular velocity is antiparallel to the angular velocity vector of the galactic disk.

TABLE III
Measurable Velocity Gradients for Giant Molecular Clouds

Cloud	Gradient $\text{km s}^{-1} \text{ pc}^{-1}$	$1/2 R^2 \Omega$ $\text{km s}^{-1} \text{ pc}$	Reference
Rosette	-0.18	-47	Blitz and Thaddeus (1980)
Mon R1	~ -0.20	-45	Blitz (1978)
W3	0.30	27	Thronson et al. (1985)
Orion	-0.10	-74	Kutner et al. (1977)
Typical GMC	$< \pm 0.05$	$< \pm 15$	various; Blitz (1980)

Other velocity gradients published for GMCs are significantly smaller in absolute value than the values quoted above. Note that the observed gradients listed in Table III are much larger than the galactic shear due to differential rotation. In each case, the most recent burst of star formation has taken place at or near the edge of a prolate molecular cloud, and, with the exception of the W3 cloud, the gradient is in a direction roughly parallel to the galactic plane along the long axis of the cloud. In the W3 cloud, the gradient is nearly perpendicular to the plane of the Galaxy in a layer argued by Lada et al. (1978*b*) and Thronson et al. (1985) to be swept up by the Cas OB6 association. It appears likely that the velocity gradient in this cloud is related to the sweeping action of the stellar association. Can an OB association

accelerate the molecular gas in a GMC along the *long* axis of the cloud in such a way as to induce the observed velocity gradients if the stars are situated at one end? The linear shear thus induced can in principle produce a positive or negative velocity gradient depending on the orientation of the cloud with respect to the line of sight. In what follows, we consider only the three clouds with gradients roughly parallel to the plane; we omit W3.

If GMC velocity gradients were due to the acceleration of cloud material by stellar winds, then the geometry of the complexes must have undergone a considerable rearrangement. Consider the last panel shown in Fig. 1. The stars capable of producing stellar winds are located just beyond the upper edge of the cloud along the line defined by the long axis of the cloud. The material most distant from the accelerating stars must have at one time been closest to them. The time scale required to reach the present state is ~ 10 to 20 Myr. The material must have remained at all times molecular, because there is no evidence in any of the clouds that the gas has condensed from a previously atomic or ionized state. Nevertheless, we know that H II regions tend to ionize and evaporate the molecular gas rather than simply to accelerate it. A good example is the molecular gas most closely associated with the Rosette Nebula. The mean density of the optical nebula is nearly equal to the mean density of the molecular cloud suggesting that the stars have simply caused a phase change in the pre-existing gas. Also, there is remnant molecular gas seen in projection against the optical nebula, the well-known optical globules, and these have been shown to be evaporating (Herbig 1974; Schneps et al. 1980). In the three GMCs of interest here, the clouds are prolate with the long axis pointing away from the direction of the accelerating stars. It is hard to understand how it would be possible to accelerate such a large mass of neutral material so that the acceleration is linear rather than shell-like.

Perhaps the most serious objection to a wind induced gradient for the GMCs comes from the conservation of linear momentum. If the clouds in Table III have a mean mass of $\sim 10^5 M_{\odot}$, the linear momentum imparted to the clouds has a typical value of $\sim 5 \times 10^5 M_{\odot} \text{ km s}^{-1}$. This implies, from Newton's third law, that gas must have been accelerated in the opposite direction with the same momentum. Orion has a bubble of ionized gas expanding in a direction opposite to the molecular cloud (Reynolds and Ogden 1979), but the mean radial velocity of the ionized gas has the wrong sign to conserve the linear momentum. The ionized gas, therefore, should have no relation to the velocity gradient in the cloud. Furthermore, no such "counterjets" of material are evident in the vicinity of any of the other two GMCs in either atomic, molecular or ionized gas. Moreover, if the mass of any such gas is small compared to that of the GMC itself, it would be accelerated to velocities that would stand out clearly in spectral line surveys of such gas in the galactic plane.

It therefore seems reasonable to conclude that the velocity gradients observed in CO are due to rotation rather than shear, and the remainder of this section proceeds from this conclusion.

B. Conservation of Angular Momentum

1. Initial Angular-Momentum States. The specific angular momentum, J/M , of the general ISM with which one wants to compare that of a GMC depends in detail on how a cloud forms and the angular momentum distribution of the disk of the galaxy in which it is located. We might consider, for example, that a cloud forms when a disk-like region becomes gravitationally unstable and collapses. In this case, we expect a result similar to that considered analytically by Mestel (1966*b*) who showed that for a cloud that has condensed from a disk with a flat or rising rotation curve, the angular momentum is always prograde in an inertial frame of reference. If the rotation curve is falling, then the rotation can be either prograde or retrograde depending on the details of the cloud formation. Furthermore, it is the form of the rotation law *locally* that determines the initial angular momentum of the cloud.

We wish to calculate $1/2R^2\Omega$, the specific angular momentum for the interstellar medium from which a local GMC forms. The quantity R is the size of the region that has collapsed to form a GMC. Let us assume first that the cloud is formed from the condensation of atomic gas only. We now ask from what radius must a cloud contract to form a cloud with a mass of $2 \times 10^5 M_\odot$? Let us assume that the geometry of the initial configuration of the condensing gas is that of a cylinder with a diameter equal to that of its height. This assumption will not have a large effect on the final results unless the initial geometry is very different in one direction from the others. The surface density of atomic gas in the vicinity of the Sun is $5 M_\odot \text{ pc}^{-2}$ (Henderson et al. 1982). The local effective scale height of the atomic gas is 200 pc (Falgarone and Lequeux 1973); thus the midplane density of atomic gas is 0.5 cm^{-3} . The radius of a cylinder that would contract to form a typical GMC in the solar vicinity is therefore 140 pc.

If the GMCs formed from initially *molecular* gas, R would increase to 220 pc because the surface density of molecular gas locally is $1.3 M_\odot \text{ pc}^{-2}$ (Dame et al. 1987). However, it is difficult to see how a GMC could form from molecular gas without dragging some atomic gas along with it. If the GMCs form from a combination of atomic and molecular gas, R will of course have some intermediate value. The dependence of R on the initial geometry is weak because it scales as the $1/3$ power of the initial mass. We may then take the value of 140 pc for R to be a reasonable lower limit, but even considering the uncertainties of geometry and the inclusion of molecular gas, it is probably not in error by more than about 50%.

The initial value of Ω depends on the details of the collapse (or equivalently accretion) of the gas that forms the GMC. Consider what happens for collapse along a line of constant radius in the limit that all of the collapsing gas lies at a single distance from the galactic center. This needle-like collapse has zero angular velocity in the rotating frame centered on the local standard of rest (LSR) (which I will call the LSR frame), and is $+0.025 \text{ km s}^{-1} \text{ pc}^{-1}$ in the inertial frame. Consider now a similar collapse which takes place in the

perpendicular direction, along a line of galactic radius. In the LSR frame, Ω is determined by the large scale shear in the Galaxy. Assuming a flat rotation curve, the value of Ω in the solar neighborhood is $-0.025 \text{ km s}^{-1} \text{ pc}^{-1}$; in the inertial frame, Ω is zero. We find therefore that the value of the initial angular momentum depends on the details of the collapse. The angular momentum of the gas that initially forms a GMC can have a range of values, therefore, from 0 to $250 \text{ km s}^{-1} \text{ pc}$ (or 0 to $7.7 \times 10^{25} \text{ cm}^2 \text{ s}^{-1}$) assuming that the GMC formed in a location where the rotation curve is flat. Allowing for the uncertainty in R , this value can be higher by about a factor of 2.

2. Final Angular-Momentum States. Consider a typical GMC in the solar vicinity with a mass of $2 \times 10^5 M_{\odot}$. Such clouds have a typical dimension of 45 pc (Blitz 1978), a maximum dimension of about 100 pc and tend to be elongated along the galactic plane (Stark and Blitz 1978; Blitz 1980). If the true shape of the clouds is that of a cigar, the specific angular momentum is $1/3R^2\Omega$; if it is a disk, then the specific angular momentum is $1/2R^2\Omega$. As stated above, the values given in Table III are the largest published velocity gradients for entire GMCs. The velocity gradient of a *typical* GMC is less than half that of the L1641 cloud, and published maps make it difficult to discern gradients smaller than about $0.02 \text{ km s}^{-1} \text{ pc}^{-1}$. In a survey of the literature, Blitz (1980) found that only half of the GMCs known at that time had a measurable velocity gradient. Thus, if the velocity gradient is entirely due to rotation, Ω has an extreme value for GMCs of $0.3 \text{ km s}^{-1} \text{ pc}^{-1}$ in the solar vicinity, but has a typical value somewhat less than $0.05 \text{ km s}^{-1} \text{ pc}^{-1}$. The specific angular momentum of a typical GMC is therefore somewhat less than about $\pm 15 \text{ pc km s}^{-1}$ or $5 \times 10^{24} \text{ cm}^2 \text{ s}^{-1}$, for clouds with a typical diameter of 45 pc. The specific angular momentum for the four clouds considered in Table III is listed in the table.

For the clouds with measurable gradients, the sense of the rotation is *retrograde* with respect to the galactic rotation in a rotating coordinate frame of reference centered on the LSR; that is, the three clouds (other than W3) have higher velocities on the low longitude side of the cloud. To transform to an inertial frame of reference, we must add the angular velocity of the LSR, Ω_0 , to the observed angular velocities; about $0.025 \text{ km s}^{-1} \text{ pc}^{-1}$. This value is small compared to the measured angular velocities for the GMCs in the table above. Thus, the sense of the angular momenta of the three clouds with negative gradients is retrograde even in an inertial frame of reference. The GMCs without measurable gradients have angular momenta consistent with zero in the inertial reference frame. It was noted above that most of the mass in GMCs typically resides in dense clumps which may themselves be spinning. However, because of the R^2 dependence of the angular momentum, and because clumps do not, as a general rule, show large velocity gradients (although there are many specific counterexamples), the angular momenta of the clumps are not likely to contribute significantly to the total angular momentum of a GMC.

3. Comparison. Because the clouds listed in Table III are strongly

counter-rotating, that is, rotating in a sense opposite to the Galaxy, in the inertial frame, these clouds cannot have conserved angular momentum from the initial states calculated above. Mestel (1966*b*) pointed out that retrograde rotation can occur if the disk from which the clouds form has a falling rotation curve. The Oort A constant expected in the solar vicinity for a flat rotation curve is $12.5 \text{ km s}^{-1} \text{ kpc}^{-1}$. However, almost all measurements of this quantity suggest that the value is $15 \text{ km s}^{-1} \text{ kpc}^{-1}$ (Kerr and Lynden-Bell 1986), a value which implies that locally the rotation curve is falling. Such local variations are expected in the vicinity of a spiral arm. The value of the Oort A constant does not affect the collapse of a cloud along a line of constant radius. However, for the case of radial collapse, Ω has a value of $-0.005 \text{ km s}^{-1} \text{ pc}^{-1}$ in the inertial frame. The corresponding specific angular momentum is $\sim 50 \text{ km s}^{-1} \text{ pc}$, but may be somewhat higher if the initial geometry is different from the one considered above.

Thus all of the clouds with large gradients have angular momenta within the values expected from collapse from the diffuse interstellar medium. However, the counter-rotating clouds put a severe constraint on how the clouds can have formed. That is, unless they did not form by condensation, they must have formed where the rotation curve is locally falling, and they must have collapsed very nearly along a line of galactic radius. Because this constraint is so severe, it is important to establish unequivocally that the large velocity gradients are due to rotation and not to shear. In this way, statistical studies of the angular velocities of many GMCs can provide important information about how the clouds formed.

Now, consider the *typical* GMCs. These have angular momenta which are only a small fraction of the allowable range. Does this mean that clouds only form from low angular-momentum initial states, or does it tell us that the initial angular momentum is frequently large, but in most cases is shed at an early stage as might be the case for magnetic braking? With the current data there is no way of deciding between these alternatives. Nevertheless, finding the answer to this question will likely tell us much about how GMCs form and evolve.

It is important to recognize that the observed values of J/M quoted above are reasonably well determined. For a molecular cloud, the velocity differences across a cloud can be measured to an accuracy of about 1 km s^{-1} (measurement errors are considerably smaller). Large velocity gradients are therefore measurable to an accuracy of 10 to 20%. The major source of uncertainty is probably the distance to a cloud, which, for clouds like Orion and the Rosette are probably as low as about 20%. For the ISM, the largest uncertainties are the value of the Oort A constant, which is probably known to an accuracy of 20%, and the midplane density of the atomic hydrogen gas, which translates into the distance R out to which the ISM must be collected to form a GMC. The uncertainty in the density is probably less than 50%, but in any event, the distance R depends only on the $1/3$ power of the midplane density, and thus J/M on the $2/3$ power. The major uncertainty for the

are formed. For example, if the efficiency of transformation of the ISM into molecular material is low, then R may be bigger, and the resulting J/M may be larger.

Studies of the angular momentum distribution among the GMCs simply do not exist at present in spite of the importance that they have for understanding how the molecular clouds form from the interstellar medium. It is unknown, for example, whether there are any examples of clouds with measurable prograde rotation in the LSR frame. Even the results quoted above come partly from unpublished analyses of molecular clouds and from personal communications. There is a wealth of information, however, in the large-scale surveys of the CO distribution in the Galaxy. For example, there have been hundreds of GMCs that have been catalogued (Solomon et al. 1987; Scoville et al. 1987) in the inner Galaxy. It would be an easy task to determine to what degree GMCs which exhibit measurable velocity gradients will have the sense of the angular momentum antiparallel to the angular momentum of the Galaxy, yet this has never been done. Nor has a detailed study of the angular momentum of GMCs as a function of galactic radius been done. Many other questions about the distribution of angular momentum are answerable with existing data.

V. CLOUDS IN DIFFERENT EVOLUTIONARY STATES

Within have at least some traces of star formation. However, in 1985, Maddalena and Thaddeus found a cloud in the outer Galaxy with a mass of $\sim 10^6 M_\odot$, a longest diameter of about 150 pc (both of these numbers assume a kinematic distance of 3 kpc), without any obvious traces of star formation activity. Moreover, the cloud has relatively weak, broad CO lines which appear to be different from those seen in most of the clouds observed in the local solar neighborhood. Maddalena and Thaddeus speculated that the cloud is so young that it has not yet had time to form stars.

If this hypothesis is correct, there should not be any buried or embedded population of stars within the cloud. It is possible, for example, that there is a large H II region on the far side of the cloud which is obscured by the intervening dust (even this hypothesis is unlikely because H II regions are almost always accompanied by strong CO peaks). In order to look for the effects of heating from an embedded population of stars, maps of the cloud have been made using the IRAS 100 μm database, and the result is shown in Fig. 2a (Puchalsky and Blitz, in preparation). Figure 2b shows the CO emission associated with the Maddalena-Thaddeus cloud taken from their paper. For comparison, a similar map of the 100 μm emission from the Rosette Molecular Cloud is shown in Fig. 3a, and the molecular cloud is shown in Fig. 3b. Both maps have the zodiacal emission removed and have had a background subtracted. Remarkably, the highest contour in Fig. 2a is lower than the *lowest* contour in Fig. 3a. The average 100 μm emissivity for the Maddalena-Thaddeus cloud is more than 2 *orders of magnitude* lower

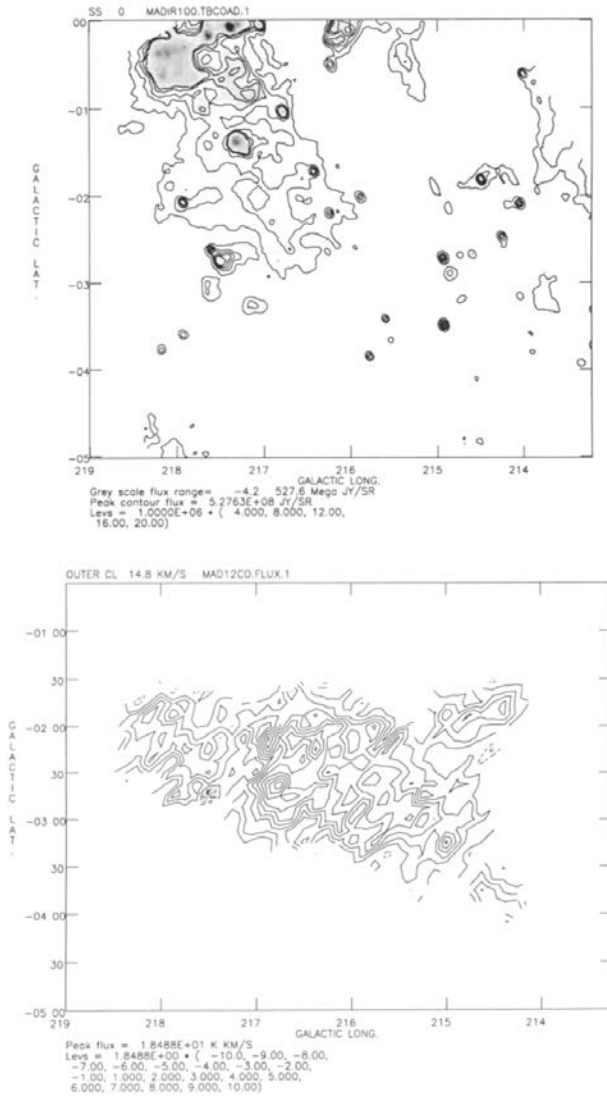

Figure 2. Figures 2 and 3 show IRAS $100\mu\text{m}$ emission and CO emission from two GMCs in apparently different evolutionary states. (a) IRAS $100\mu\text{m}$ emission from the region of the Maddalena-Thaddeus GMC. The molecular cloud is located in the range $-1^{\circ}45' > b > -3^{\circ}30'$ and $214^{\circ} > l > 219^{\circ}$. There is no IRAS flux detectable in the figure that can be definitely associated with the molecular cloud. The largest flux detected in the direction of the cloud is about 20 MJy sr^{-1} . (b) CO emission integrated over all velocities associated with the Maddalena-Thaddeus Cloud. Both (a) and (b) are on very nearly the same angular scale. Note the almost complete absence of infrared emission from the region where the CO emission is detected.

for the Maddalena-Thaddeus cloud is more than 2 *orders of magnitude* lower than that of the Rosette Molecular Cloud. Because the far-infrared emission is generally thought to come from reradiated starlight, by comparison with the Rosette, which has an infrared emissivity typical of GMCs in the solar vicinity (Boulanger and Perault 1988), the Maddalena-Thaddeus cloud is extremely deficient in embedded stars.

This evidence supports the hypothesis that the Maddalena-Thaddeus cloud is so young that it has not yet had time to form stars. It is therefore an excellent candidate to examine the differences in structure between it and a more evolved cloud like the Rosette Cloud, or the Orion Molecular Cloud. But if the Maddalena-Thaddeus cloud is too young to have yet formed stars, and the Rosette and Orion clouds are middle aged clouds still in the throes of star formation, is it possible to find a demonstrably old cloud, one which is now showing only the last vestiges of star formation? The answer appears to be yes. Probably the best candidate for a remnant molecular cloud is the small cloud associated with the Lac OB1 association. Although no systematic study of the molecular gas in this region has yet been undertaken, the overall morphology can be seen in Fig. 4 which shows an IRAS map of the region at a wavelength of $100\ \mu\text{m}$.

The Lac OB1 association is one of the oldest OB associations in the solar vicinity with an age of ~ 20 Myr (Blaauw 1964). There are two subassociations, the younger of which has an age of ~ 6 Myr. Very sparsely sampled observations (Blitz, unpublished) indicate that there is almost no molecular gas remaining in the region; what there is appears to be concentrated in the knot centered at $\alpha = 22^\circ 30'$, $\delta = 40^\circ 5'$. This knot is the location of the reflection nebula DG187. The stars, on the other hand, are spread throughout the area of the map. At the 500 pc distance of the OB association, the remnant cloud appears to be no more than 10 pc in extent. The large loop seen in the figure is probably dust associated with a shell of atomic hydrogen, and is evidently the result of the stellar winds, and possibly supernovae from the stellar association, which, together with the ionizing radiation from the O stars, appear to have effectively destroyed the molecular cloud. Very little is known about the overall gas and dust content of the region, but it presents a good opportunity to study what appears to be the last gasp of the star-formation process. Studies of such regions promise to explain how the gas and dust in a molecular cloud that has not been converted into stars is ultimately returned to the interstellar medium.

It is also possible to find clouds in different evolutionary states statistically, as has been done by Leisawitz (1990). He has surveyed the molecular gas near numerous open clusters of varying ages and finds that molecular clouds associated with open clusters older than 10 Myr are significantly smaller than the clouds associated with younger clusters. He argues that this result is not due to observational selection and suggests that molecular clouds are destroyed or dispersed on a time scale of ~ 10 Myr.

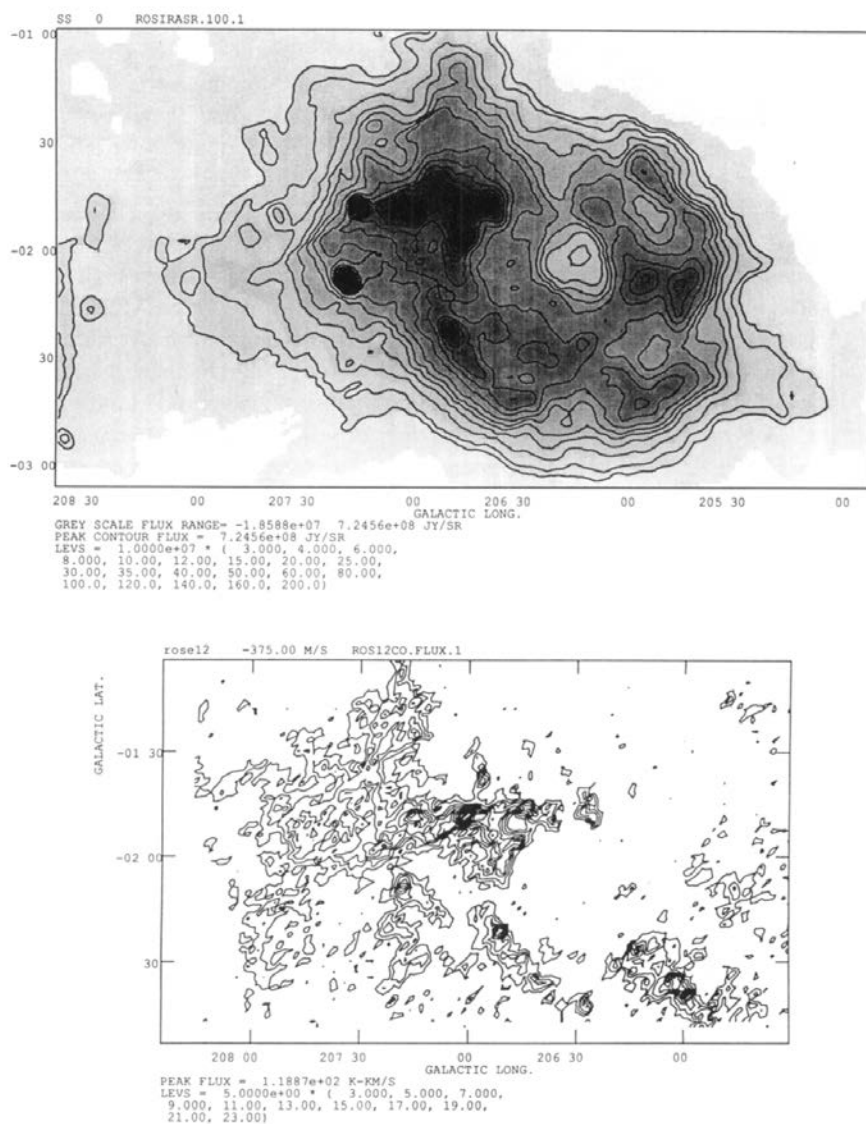

Figure 3. (a) IRAS μ m emission associated with the Rosette Molecular Cloud. Note that the *lowest* contour in the emission is 50% higher than the *highest* contour in Fig. 2a. The difference in the mean emission from the two clouds is at least 2 orders of magnitude. The optical nebula is centered on the hole in the infrared emission at $l = 206^{\circ}2b = -2^{\circ}$. (b) Map of the CO emission integrated over all velocities associated with the Rosette Molecular Cloud from data taken with the Bell Labs' 7-m antenna. The angular scale is very nearly the same as that shown in (a) (figure from Blitz et al., in preparation).

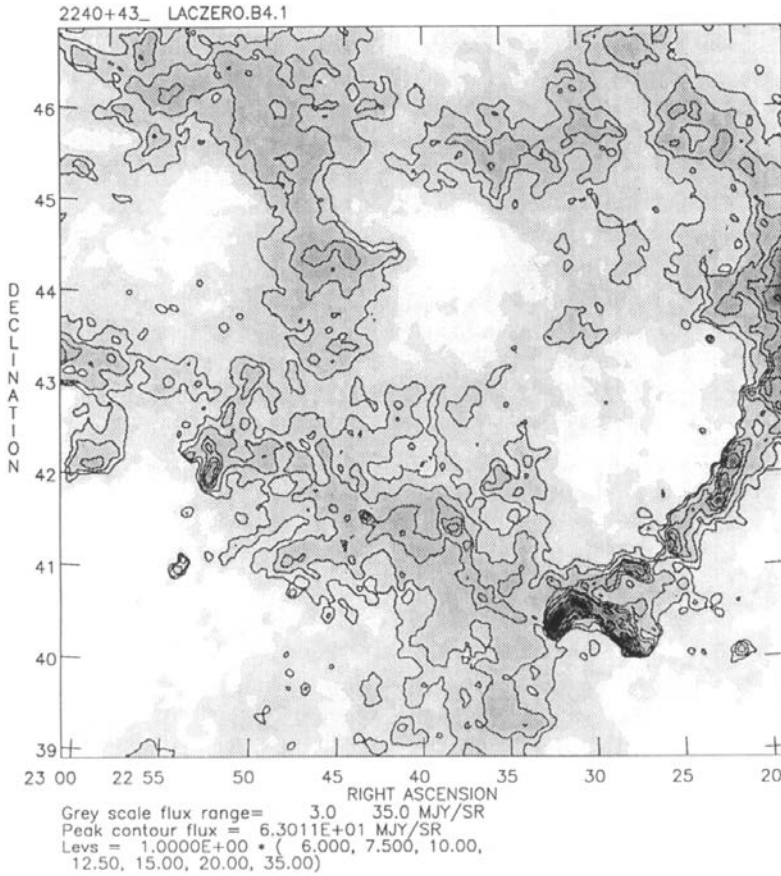

Figure 4. IRAS 100 μ m emission from the region of Lac OB1. The only location from which CO has been detected to date is the small knot at $\alpha = 22^h 30^m \delta = 40^\circ 5'$ which is associated with the reflection nebula DG187. This figure was produced by E. de Geus.

VI. RELATIONSHIP TO ATOMIC HYDROGEN

The relatively sharp boundaries of GMCs are inferred from the quantitative analysis of Blitz and Thaddeus (1980), and the appearance of many GMCs on the Palomar Observatory Sky Survey prints. In the latter case, a well-defined region of dust obscuration is observed for many GMCs, and these follow the outermost contours of the CO emission quite closely. This is especially true for GMCs within 1 kpc of the Sun where the contrast between the foreground dust obscuration and the background stars is the highest. Good examples are the Orion Molecular Cloud (especially the boundary at the lowest galactic

latitudes (see the CO maps of Kutner et al. [1977] and the ^{13}CO maps of Bally et al. [1987]), the Mon OB1 molecular clouds (see Blitz 1980), and the Ophiuchus molecular clouds (see the CO maps made by de Geus et al. [1990] and Loren [1989a]). There are many other examples that illustrate this point.

These sharp boundaries suggest that there is a phase transition that takes place at the boundaries of the clouds, but what then is the state of the gas at the low-density side of the phase transition of the GMC? Wannier et al. (1983) have shown that for a few GMCs, there is a thin layer of atomic hydrogen in a transition zone probably associated with a photodissociation region. In a larger-scale unpublished analysis of the atomic clouds associated with local GMCs, Blitz and Terndrup (unpublished) have analyzed the HI emission from the velocity range detected in CO for a number of GMCs in the solar vicinity. One such map was shown in Blitz (1987a). Figure 5 is another such map; it shows the HI column density associated with the molecular cloud accompanying the Per OB2 association (this is the cloud that contains the NGC 1333 star-forming region). The map contours are in units of 10^{21} cm^{-2} ; the contour marked 10 therefore is associated with an extinction (A_v) of about 0.5 mag. The map itself shows the HI emission integrated over the velocity range 4.2 to 12.7 km s^{-1} , the velocity range associated with the Per OB2 cloud, which is shown as the shaded area in the figure. The association of the atomic gas with the molecular cloud is quite obvious. All of the GMCs surveyed to date show atomic envelopes similar to that shown in Fig. 5.

In order to quantify the relationship between the atomic and molecular gas, Blitz and Terndrup estimated the mass of atomic gas associated with the molecular clouds they studied by estimating the angular extent to which the atomic gas shows an excess over the background in the relevant velocity range. These masses are then plotted as a function of $M(\text{H}_2)$ derived from the CO maps using the CO/ H_2 conversion ratio of Bloemen et al. (1986). The results are plotted in Fig. 6. The error bars are from estimates of the uncertainty in defining the background level for the atomic clouds, and in determining the CO/ H_2 conversion ratio for an individual molecular cloud. What the figure clearly shows is that the molecular clouds have atomic envelopes that are as massive as the molecular clouds in most cases. Note, however, that the atomic clouds are much more extended; the HI masses pertain to the entire region in which HI is seen above the background. The individual maps show a very small range in the peak column density of the atomic gas associated with the molecular clouds; that is, only 1 to $2 \times 10^{21} \text{ cm}^{-2}$, or an A_v of 0.5 to 1.0 mag. A similar result has been found for diffuse molecular clouds in the Milky Way (Savage et al. 1977), and for a GMC in M31 (Lada et al. 1988a).

VII. THE CLUMPY STRUCTURE OF GMCs

As early as 1980, Blitz and Shu noted that all GMCs that have been observed up until that time exhibit clumpy structure. The evidence at the time suggested that the density contrast between the clumps and the interclump medium is

Figure 5. Map of the atomic hydrogen emission associated with the Per OB2 molecular cloud. The emission is integrated over the velocity range 4.2 to 12.7 km s^{-1} , and the contours are in units of 10^{20} cm^{-2} . The molecular cloud is shown as the shaded region. There is clearly enhanced emission in the vicinity of the molecular cloud. This map is typical of all of the GMCs in the solar vicinity.

large because the densities required to detect CO at the observed antenna temperatures are an order of magnitude greater than the mean densities inferred if the clouds have dimensions along the line of sight comparable to their dimensions in the plane of the sky and the CO is uniformly distributed within it. Thus, if the H_2 is clumped so that the volume filling fraction is ~ 0.1 or less, implying a clump/interclump density contrast $\gtrsim 10$, the discrepancy disappears. This conclusion was qualitatively confirmed from the velocity structure observed in the ^{13}CO maps of the dense ridge of the Rosette Molecular Cloud (Blitz and Thaddeus 1980).

Recently, Scalo (1988,1990) has attacked much of the standard picture of the description of the interstellar medium. He has argued that concepts such as clouds and clumps are frequently artifacts of the limited dynamic range inherent in many observations, selection biases, etc. However, high-quality three-dimensional data cubes have recently become available from

Figure 6. Plot of the mass of atomic hydrogen emission associated with a number of GMCs in the solar vicinity. The atomic hydrogen mass associated with the GMC is taken over a narrow velocity range centered on the molecular cloud velocity and the molecular mass is taken from the CO emission integrated over the area of the molecular cloud.

observations of the generally optically thin ^{13}CO molecule. These cubes have high signal-to-noise ratios, and have many resolution elements across the projected cloud areas. Furthermore, the inclusion of the velocity information can circumvent many of the objections raised by Scalo in his provocative study. It is the inferences made from the ^{13}CO observations that are discussed below.

In principle, an understanding of the clumpy structure of molecular clouds holds a great deal of information about their evolution. For example, is the clumpy structure a result of the process of star formation, or is the clumpiness primordial? If the clumpiness is primordial, one should be able to see the process of clump formation taking place in the diffuse interstellar medium. In either case, detailed observations of the kinematics of the clumps should be able to resolve the issue. Does the interclump medium play a role in the structure and evolution of the GMCs? In what form is the interclump medium? How do the clumps eventually form stars? OB associations and massive star clusters must eventually form from large massive clumps. Can

we find these clumps? Because collisions between clumps should be highly inelastic, the kinematics of the clump ensemble should provide a great deal of information about the history of a GMC.

The density structure of GMCs is best inferred from a pervasive optically thin molecule. The best current candidate is ^{13}CO , but receivers sensitive enough to observe ^{13}CO over the large angular extents needed to map a GMC fully have been available only since the early 1980s. Thus, fully quantitative information on the density structure of GMCs has not become available until fairly recently. Large scale ^{13}CO maps which delineate the clumpiness of GMCs are now available for the Rosette Molecular Cloud (Blitz and Stark 1986), the Orion Molecular Cloud (Bally et al. 1987a), parts of the Cep OB3 molecular cloud (Carr 1987), parts of the Ophiuchus molecular cloud (Loren 1989a; Nozawa et al. 1991), and some anonymous CO clouds toward $l=90^\circ$, $b=3^\circ$ (Perault et al. 1985). Extensive observations of the clumpiness of molecular clouds also have been made in the Orion B molecular cloud using CS (Lada et al. 1991a) and in part of the M17 molecular cloud using C^{18}O (Stutzki and Güsten 1990).

We review here some of the results from the ^{13}CO observations of the Rosette Molecular Cloud (Blitz et al., in preparation) and compare them to other published work on clumpiness. Blitz and Stark (1986) showed that the clumpy structure of the Rosette Molecular Cloud becomes especially clear when analyzed using position-velocity diagrams. Such plots are superior to channel maps (maps made in two spatial dimensions at a particular velocity interval) because small differences in clump velocities are not as apparent in the channel maps. Because the velocity differences between clumps are frequently smaller than the line-width of the CO emission from an individual clump, channel maps tend to blend the emission from several adjacent clumps into one large entity. On the other hand, because the velocity resolution of the position-velocity maps is generally high enough that the individual line profiles and the velocity differences between clumps is easily seen, the identification of separate kinematic units is easier to accomplish.

For the Rosette Molecular Cloud, analysis by means of position-velocity maps has made it possible to produce a catalog of individual clumps because in that cloud the separation between the clumps is large enough to make the identifications of individual objects possible by eye. A similar procedure has been carried out by Loren (1989a) for the streamers in Ophiuchus, and by Carr (1987) for a piece of the Cep OB3 molecular cloud. What makes the Rosette study different is that enough of the molecular cloud has been observed to make conclusions about the structure of the cloud as a whole. It is unclear, however, to what degree the procedure of identifying clumps by eye will work for other GMCs. This is simply another way of saying that it is unclear at present to what degree the structure of the Rosette Molecular Cloud is typical of other GMCs. It should be pointed out, however, that in terms of its size and mass, the Rosette Molecular Cloud is quite typical of other GMCs in the solar vicinity.

Blitz, Stark and Long reach the following conclusions from an analysis of their data:

1. Between 60 and 90% of the H_2 mass resides in the clumps they have identified in their catalog. Therefore, most of the molecular mass is in the clumps and is not in a distributed component.

2. The mean H_2 density for all of the clumps is $\sim 1 \times 10^3 \text{ cm}^{-3}$. The volume averaged density for the entire complex is $\sim 25 \text{ cm}^{-3}$ (Blitz and Thaddeus 1980); therefore the volume filling fraction of the clumps is $\sim 2.5\%$. A similarly low-volume filling fraction of 3% is derived for the G90+03 molecular cloud complex observed by Perault et al. (1985). If we assume that 10 to 50% of the H_2 mass is in a diffuse component not related to the clumps, then the interclump density is ~ 2.5 to 12.5 cm^{-3} . The existence of the HI envelopes suggests that the interclump medium in GMCs also contains an atomic component, but because the envelopes are much more extended than the molecular clouds, the average HI density within the volume of the molecular cloud is unlikely to be more than about $\sim 15 \text{ cm}^{-3}$. Thus, the clumps are not small density enhancements in a relatively smooth substrate, but are dense blobs held together by their mutual gravitational attraction which are moving through a tenuous interclump medium.

It should be noted that although the ^{13}CO observations provide the best quantitative estimates of the density contrast of the clumps, important confirmation of this contrast comes from the large spatial extent of the C II/C I regions around O stars (Stutzki et al. 1988; Genzel 1991*b*). That is, the large penetration of the C II emission regions into molecular clouds requires a clump/interclump density ratio of 10 to 100, similar to what is found from ^{13}CO mapping of the Rosette and G90+03 clouds. Thus, very different kinds of observations of GMCs in different parts of the sky reach similar conclusions about the density contrast of their clumps.

An interesting question arises as to whether the clumps themselves have internal structure. Because the clumps have a mass spectrum different from the Salpeter or Miller-Scalo Initial Mass Function (see below), the implication is that the clumps in which the star formation takes place must be fragmented on still smaller scales. Direct evidence for this comes from the C^{18}O mapping of two clumps in G90+03 by Perault et al. (1985), and from unpublished maps of ^{13}CO , C^{18}O , and CS of a large clump in the Rosette Molecular Cloud (Blitz and Puchalsky, unpublished). However, to date, this subclumping has not been well characterized quantitatively. Presumably it is the subclumping within a GMC, that is, the fragmentation of the individual clumps, that is the direct precursor of individual stars (see Sec. IX).

3. The distribution of clump mass follows a power law such that

$$dN(m) = N_0 M^{-1.54} dM \quad (2)$$

where $dN(m)/dM$ is the number of clouds per solar mass interval, and N_0 is 460 M_\odot^{-1} .

There are a number of studies that have been done to date which indicate that the clump mass spectrum is a power law and that the power-law exponent is similar to that obtained for the Rosette Molecular Cloud. The observations are summarized in Table IV below. The Cep OB3 spectrum was calculated from the original unpublished list kindly provided by J. Carr and does not include the lowest-mass bin, which is likely to suffer from incompleteness. The Loren value, quoted in the original paper as -1.1 is incorrect, the value given in Table IV was recomputed from the data presented in his paper.

TABLE IV
Clump Mass Spectrum Power Law

Exponent	Tracer	Source	Reference
-1.5	^{13}CO	Rosette	Blitz et al. (1991a)
-1.6	CS	Orion B	Lada et al. (1991)
-1.4	^{13}CO	Cep OB3	Carr (1987)
-1.7	C^{18}O	M17SW	Stutzki and Güsten (1990)
-1.7	^{13}CO	Ophiuchus	Loren (1989a)
-1.7	^{13}CO	Ophiuchus	Nozawa et al. (1991)

That all five studies should obtain such a similar power law is even more remarkable than the similarity of the power-law exponent in the linewidth-size relation for GMCs given in Sec. II. The data for the different clouds are sensitive to different ranges of mass and density, and use different reduction and analysis techniques. Furthermore, unlike the data used to obtain the molecular cloud distribution, all of the measurements are determined from fundamentally different sources. Given the uncertainties in the determinations of the slopes, it is reasonable to conclude that for the molecular clouds that are well studied to date, there is a universal mass spectrum for the clumps within a GMC, and that the spectrum is a power law with an exponent of -1.6 with an uncertainty of $\sim 10\%$ and that the power law seems to hold over three orders of magnitude in mass, i.e., from $\sim 1 M_{\odot}$ to about $3000 M_{\odot}$. A reasonable inference is that the processes that determine the distribution of clump masses are rather similar from cloud to cloud. Clouds that show significantly different values of the mass spectrum are then likely to have had different dynamical histories.

It is noteworthy that none of the power-law exponents resembles the initial mass function, however. This suggests that the clumps that are observed in these studies are not the ones that form individual stars. Unless the clumps somehow have a star formation efficiency that varies with the mass of the clump (Zinnecker 1989b), the formation of individual stars lies deeper within the clumps that have so far been identified. Some of the larger clumps have sufficient mass to form entire clusters or OB associations, so this result is not entirely surprising. At some level, one expects to find the IMF mirrored in the spectrum of condensations within a GMC, but it appears that these condensations will be identified as the substructure within individual clumps.

This concept has meaning only if it is possible to identify a scale or a parameter that can differentiate the clumps within a complex from the structure within the clumps, but this has not yet been accomplished. It is likely that high-resolution interferometric observations will be needed to observe the true star-forming condensations in most GMCs.

Figure 7. Map of the ^{13}CO emission from the Rosette Molecular Cloud taken from Blitz and Stark (1986). The shaded areas are the locations of the eight most massive clumps associated with the molecular cloud complex.

4. Although most of the mass in the Rosette Molecular Cloud is in clumps that are at or near the point of being gravitationally bound, most of the clumps are not gravitationally bound. That is, half of the mass is in the 10 most massive clumps of the 86 catalogued; however, the 40 or so lowest mass clumps do not appear to be gravitationally bound. A similar conclusion was reached by Carr (1987) and Loren (1989a) who found that virtually none of the clumps in the clouds they observed are gravitationally bound. This point is discussed in greater detail in the following section.

5. The most massive clumps in the Rosette Molecular Cloud lie close to the midplane. This can be seen from Fig. 7 which shows the eight most massive clumps shaded on the map of the velocity integrated ^{13}CO emission published by Blitz and Stark. These clumps as a group are the most tightly bound of all of the clumps as measured by the ratio of their gravitational to internal kinetic energy. Thus, the next cluster of stars to form in the cloud complex is most likely to form from one of these clumps.

6. The clumps show a strong velocity segregation with mass. Figure 8 is a plot of the clump-to-clump velocity dispersion as a function of mass for the 86 catalogued clumps. The most massive clumps, the ones that lie closest to the midplane of the complex, also show the smallest velocity dispersion. *These results strongly suggest that the clumps have undergone dynamical evolution in the time since the complex has formed.* That is, the clump maps and the clump kinematics show a clear signature of inelastic collisions that indicate that the cloud has evolved considerably since it first formed. Because the observations were made in a part of the complex that has not been affected by the Rosette Nebula itself, and because there is little evidence for star formation in the mapped area, it appears that the observed structure and kinematics are the result of the dynamics of the clumps themselves without the intervention of energetic phenomena associated with star formation (e.g., H II regions, stellar winds, protostellar outflows, supernova explosions). Furthermore, the young stars that are found within the mapped boundaries (Cox et al. 1990) all appear to be embedded in dense clumps and would not therefore affect the overall dynamics. If the young stars and molecular clumps in this region are the result of either photoionization-regulated star formation such as that described by McKee (1989) or by the mechanism of Norman and Silk (1980), then substantial numbers of T Tauri stars which have not yet been identified would have to be found projected on the cold part of the molecular cloud.

7. There is a strong correlation between the embedded IRAS point sources and the clumps identified in ^{13}CO (Cox et al. 1990). The brightest infrared sources are associated with the most massive clumps. In the Rosette Molecular Cloud, most of the sources have flux densities that are strongly increasing functions of wavelength suggesting that they are very young. Except for GL-961, none of the sources has been investigated in any detail.

VIII. BOUNDEDNESS OF THE CLUMPS

In the Blitz et al. (in preparation) study of the clumps associated with the Rosette Molecular Cloud, at least half of the clumps are not gravitationally bound. The precise fraction is difficult to assess because of the uncertainties in the luminous masses derived from the ^{13}CO line strengths. Carr (1987) and Loren (1989a) find that *none* of the clumps in the clouds they observed are gravitationally bound. The latter two authors conclude that because the clumps are so far from being gravitationally bound that the clumps must be expanding. This conclusion is, however, difficult to accept. First, the clumps

Figure 8. Plot of the clump-to-clump velocity dispersion as a function of mass in the Rosette Molecular Cloud. The straight line is a least squares fit to the data and has a power law index of -0.27 .

would be expanding on the scale of a crossing time which, for the clumps they measured is less than 1 Myr. The clumps would all be dissolving unless there were also clumps that were forming at the same rate, but such clumps have not been identified. Second, unless all three clouds were observed at some special epoch, then mass conservation would require that

$$\frac{n(\text{clump})}{n(\text{interclump})} = \frac{t(\text{dissolve})}{t(\text{form})}. \quad (3)$$

Direct evidence from the Rosette Molecular Cloud indicates that the left-hand side of the equation is of the order of 100 or more, which requires that the formation time scale is no more than ~ 0.01 Myr if the structure of the Rosette Molecular Cloud and the Ophiuchus clouds is similar. This improbably short time would seem to require that the interclump medium would be filled with stars that could sweep the interclump gas together quickly to form the clumps as quickly as they dissolve, a requirement which does not seem to be supported by the observations.

On the other hand, the clumps could be bound together by the pressure of the interclump medium. Such a medium would be in hydrostatic equilibrium with the gravitational potential of the GMC. Let us calculate what is required and compare it to the observations of the Rosette GMC. The pressure inside

a clump is given by:

$$\frac{P(\text{clump})}{k} = \frac{nm(\text{H}_2) \langle v_{1D}^2 \rangle}{k} \quad (4)$$

where we obtain from observations of the Rosette Molecular Cloud the following mean values: $n = 500 - 1000 \text{ cm}^{-3}$; $\langle v_{1D}^2 \rangle^{0.5} = 0.70 \text{ km s}^{-1}$; and $P/k = 6 - 12 \times 10^4 \text{ K cm}^{-3}$.

This pressure is a kinetic pressure determined from the linewidth of a typical clump. The thermal pressure, given by nT , is frequently less than the value quoted above away from regions of active star formation; typical excitation temperatures are 5 to 15 K as derived from the optically thick CO line. Therefore, the linewidth and pressures within a clump are generally dominated by nonthermal bulk motions of the gas.

The mean pressure within a GMC due to its self-gravity is given by:

$$\frac{P_{\text{grav}}}{k} = \frac{\alpha GM \langle n \rangle m(\text{H}_2)}{Rk} \quad (5)$$

where M and R are the mass and radius of the GMC and $\langle n \rangle$ is the volume averaged density of the complex. The constant α is of order unity and depends on geometry and viewing angle. It has recently been computed by Bertoldi and McKee (1992) for a variety of interesting geometries. Again for the RMC we have: $\langle n \rangle = 23 \text{ cm}^{-3}$; $M = 1.1 \times 10^5 M_{\odot}$; $R = 23 \text{ pc}$; and $P_{\text{grav}}/k = 12 \times 10^4 \text{ K cm}^{-3}$. Here R is found by taking the square root of the projected surface area, and α is taken to be 1.

Thus, the pressure that the interclump gas would have if it were in pressure equilibrium with the self-gravity of the complex is equal, within the uncertainties, to the pressure needed to confine the clumps. It was argued in Sec. VI above that the atomic hydrogen is very likely to be the interclump gas. Indeed, detailed observations of the atomic hydrogen associated with the Rosette (Kuchar et al., in preparation) made with the Arecibo telescope suggest that there is a detailed anticorrelation between CO and HI maxima in the cloud, lending support to the idea that warm HI is likely to be the interclump gas. The pressure of this gas can be obtained from published observations of the HI associated with the Rosette Molecular Cloud at low resolution made by Raimond (1966). These are as follows:

$$\frac{P(\text{HI})}{k} = \frac{nm(\text{HI}) \langle v_{1D}^2 \rangle}{k} \quad (6)$$

where n in this case is the mean HI interclump density estimated from both the Raimond (1966) and the Kuchar et al. (in preparation) observations, and the other values are as follows: $\langle n \rangle = 7 \text{ cm}^{-3}$; $\langle v_{1D}^2 \rangle^{0.5} = 10.6 \text{ km s}^{-1}$; and hence $P(\text{HI})/k = 10 \times 10^4 \text{ K cm}^{-3}$. Thus it seems quite reasonable that the clumps are confined by the pressure of the interstellar gas.

But why is it then, that *all* of the clumps in the Ophiuchus and Cep OB3 observations are found not to be bound by gravity, whereas many of the clumps in the Rosette Molecular Cloud are self-gravitating? The answer is the differing linear resolutions of the observations. In both the Loren and Carr observations, the clouds are considerably nearer than the Rosette; for the Ophiuchus observations, the difference is an order of magnitude. With one exception, the most massive clumps in the Loren and Carr samples are all within the mass range for which only unbound clumps are found in the Rosette. Their observations are therefore quite compatible with the Rosette observations. In fact, the three sets of observations can be combined to conclude that there seems to be a mass below which the clumps at the densities sampled by the ^{13}CO molecule are not gravitationally bound, and above which the clumps are bound. This mass appears to be ~ 300 to $500 M_{\odot}$. Apparently, then, low-mass clumps such as the cores investigated by Myers and Benson 1983 must be much denser than the clumps observed in ^{13}CO to be gravitationally bound.

Bertoldi and McKee (1992) have extended the arguments presented here to include the effects of magnetic fields. In an extensive work on the gravitational stability of the clumps, they show, among other things, that the magnetic pressure is insufficient to support the most massive clumps, thus internally generated turbulence is necessary to stabilize them. They suggest that low-mass star formation, which is observed in at least some of these clumps, is the source of this turbulence.

IX. STAR FORMATION IN THE CLUMPS

If the clump mass spectrum suggests that the clumps (at least those that have been identified in studies made to date), are not the progenitors of individual stars, then what is the role of the clumps in the star formation process? Since Roberts (1957) first showed that most stars form in clusters and associations, a result that was later confirmed by Miller and Scalo (1978), it seems natural to suppose that the more massive clumps give rise to these stellar groups. The masses of the largest clumps in the Rosette Molecular Cloud, for example, are comparable to the masses of OB associations (assuming that they form with a normal IMF) and open clusters.

A significant advance in understanding the star formation in GMCs was recently made by Lada et al. (1991a) who examined the Orion B molecular cloud for CS clumps and also did a near-infrared survey to look for embedded stellar objects. She was able to identify 39 dense clumps of molecular gas in her survey; of these nearly all the star formation is limited to the three most massive clumps. These three clumps account for only 30% of the mass of dense gas and $\leq 8\%$ of the total gas mass in the area she surveyed. Yet when account is taken of background sources, she finds that $\sim 96\%$ of the of the star formation in the surveyed region is associated with the dense clumps. This work is discussed in more detail in the Chapter by Lada et al.

The conclusion seems to be that the clumps, especially massive, dense clumps are the units of star formation in GMCs. It will be important to extend Lada's work to other clouds to see to what degree her results can be generalized. But the evidence seems to indicate that regions of incipient star formation can be identified from the molecular observations. The key to understanding how molecular clouds form stars now seems to require detailed investigations into the structure of the dense clumps with an eye to understanding how density inhomogeneities develop in these objects and what is the cause of their internal motions.

X. THE EVOLUTION OF GIANT MOLECULAR CLOUDS

The observations cited in this review, taken together, suggest a tentative picture of the evolution of a GMC. We imagine first, that by some process, the interstellar medium collects enough mass together to form a GMC. Methods by which this can in principle be done include spiral arm shocks (Roberts 1957; Cowie 1981; Elmegreen 1982*b*), shear instabilities (see, e.g., Toomre 1964; see also Elmegreen 1991*a* and references therein), Rayleigh-Taylor instabilities (see, e.g., Mouschovias et al. 1974), and through "supershells" driven by multiple supernovae (Öpik 1953; Heiles 1979; McCray and Kafatos 1987). Evidence that some other method is also at work comes from observations of other galaxies which suggest that the star-formation rate is not strongly dependent on spiral arm morphology; even galaxies without coherent spiral arms form stars quite efficiently (Stark et al. 1987). In any event, the dominant process by which the diffuse interstellar medium is collected into clouds in the solar vicinity has not yet been identified.

As enough material is collected together to form a cloud, when the column density of atomic hydrogen exceeds a threshold of about 10^{21} cm^{-2} , the associated visual extinction of about 0.5 mag is sufficient to shield the gas from the ultraviolet radiation that dissociates the molecules that form, and the cloud begins to turn molecular. It is presumably early in the process of turning molecular that the clumps have begun to form. Evidence for this comes not only from the Rosette Molecular Cloud, where the kinematics suggest that clumpiness precedes the star-formation process and then evolves, but from observations of high-latitude molecular clouds very close to the Sun. Many of these clouds appear to be very young ($\leq 2 \text{ Myr}$), and all show evidence of clumpiness that must surely be primordial (Magnani 1986). Furthermore, the properties of these clouds are quite similar to the gravitationally unbound clumps in the Rosette Molecular Cloud, Cep OB3, Ophiuchus and M17.

It is not necessary for the interstellar medium to produce proto-GMCs that are gravitationally bound. A gravitationally neutral cloud, that is, one in which the internal kinetic energy is just equal to its potential energy, can become gravitationally bound, because the clumps that have formed will collide, and the kinetic energy of the ensemble of clumps can be radiated away because the clump collisions are so inelastic. The details of such a process

are amenable to numerical modeling. If a GMC forms in this way, then it is natural that the atomic gas from which it formed remains as the interclump gas. The H I envelope that remains in this case is largely the remnant of the primordial GMC. All of the gas will remain in pressure equilibrium, and as the cloud becomes gravitationally bound, the interclump medium will respond to the gravitational potential well of the GMC. The pressure of the interclump medium will therefore increase above the nominal interstellar value, putting the clumps within the cloud under higher pressure than they had initially.

The magnetic field can support a clump against gravity up to a certain critical mass (see, e.g., Mestel and Spitzer 1956; Mouschovias 1987a; McKee 1989). Once a clump becomes magnetically supercritical, then even the magnetic field cannot prevent collapse. Thus star formation will take place in the clumps that have grown to be the largest and densest through collisions. Some support of the clumps themselves can also come from the energy input from protostellar and neostellar winds (see, e.g., Margulis et al. 1988). It may very well be that a process of self-regulating star formation similar to that described by McKee (1989) may then take place, until the cloud is ultimately consumed from the dissociating effects of the H II regions, stellar winds, and supernova remnants of the stars that formed within it.

Note, however, that the process of molecular cloud evolution described above has no need for sequential star formation. This is not to say that sequential star formation is irrelevant, but that some of the difficulties with the original theory of Elmegreen and Lada (1977) can be avoided with the evolutionary scheme outlined above. For example, Elmegreen and Lada noted that there is a need for an initial trigger to generate the first subgroup of O stars in their theory. Furthermore, the theory is based on the assumption that an ionization front propagates into an initially *homogeneous* molecular cloud; as discussed above, such clouds are not observed. Furthermore, in some cases, young OB subgroups have been identified that lie *between* older subgroups; as for example in Cep OB3 (Sargent 1977), and in the Sco-Cen OB association (Blaauw 1964; de Geus 1988). In the outline of GMC evolution described here, star formation proceeds in a quasi-random way within a molecular cloud. That is, the collisions between clumps in a molecular cloud proceed until one of the clumps becomes unstable to the process of formation of an OB subgroup. The stellar activity will ionize the molecular gas in its vicinity, and in a time probably less than 1 Myr (depending on a number of variables), this subgroup and its attendant H II region will appear to be at the edge of the molecular cloud. The next large clump to form an OB association will then be determined by the collisional processes between the remaining clumps in the complex, and will be independent of the previous star formation history of the cloud. In this way, there is no need to postulate a special event to produce the first generation of stars, and the subsequent generations of stars do not necessarily have a causal connection to previous generations. The apparently random orientation of the subgroups associated with many GMCs occurs quite naturally. Cases like the ordered orientation of the subgroups of

the Orion complex therefore would be the result of chance (and are not very unlikely).

The degree to which this evolutionary picture is true will depend on the results obtained from the ^{13}CO mapping of a number of GMC complexes, the identification of more complexes in different evolutionary states and the identification of embedded cluster of stars within the complexes. Once the process of the formation and evolution of GMCs is better understood in the Milky Way, we can then apply our understanding to other galaxies where the environmental conditions are often markedly different.

The different processes that can affect the chemical composition of matter as it evolves from quiescent molecular clouds into protostellar and protoplanetary regions are discussed. Millimeter observations show that the chemical state of dense interstellar clouds prior to star formation is highly inhomogeneous: cold, dark clouds such as TMC-1 and L 134N show large chemical gradients on scales of a few tenths of a parsec, which are not well understood. Chemical models based on gas-phase ion-molecule reactions are moderately successful in reproducing the observed molecular abundances, but their predictive power is limited by unknown rates for several crucial reactions. Also, observational data for several important molecules are lacking. As a result, the abundances of the dominant oxygen- and nitrogen-bearing molecules prior to star formation are poorly determined. Some atoms and molecules are found to be depleted significantly onto grains, but the mechanisms for returning species to the gas phase in cold clouds are still uncertain. In star-forming regions, the high temperatures induced by radiation from newly formed stars can evaporate volatile grain mantles, and can open up additional gas-phase reaction channels. Powerful shocks associated with the outflows can also return more refractory material such as silicon and sulfur to the gas phase. These processes are operative in the best studied high-mass star-formation region Orion/KL, where interferometric observations reveal a complex chemistry with variations on scales of <2000 AU. For low-mass stars, observations of the chemistry in circumstellar disks on scales of 500 to 10,000 AU are only just becoming available. Initial studies of the young stellar object IRAS 16293–2422 also show large chemical gradients on scales of less than 1000 AU, but the chemical abundances appear less affected by the star-formation process than in Orion/KL. Systematic studies of the chemistry in star-forming regions are still lacking. On smaller scales of 50 to 500 AU corresponding to the outer solar nebula, observations of only the nearest and brightest objects are now possible, and detailed models of the chemistry have yet to be made. On scales appropriate to the solar nebula, 5 to 50 AU, material is thought to be physically

and chemically modified in a number of ways: accretional shock heating, gas-drag heating on grains, and lightning are possible sources of energy. In the inner part of the nebula, temperatures are high enough for gas phase reactions to alter the molecular composition significantly; however, the amount of radial mixing between the inner and outer parts of the nebula may be limited. The extent to which outer solar nebula material retained its interstellar composition is therefore a highly complex issue, dependent on the body and the molecular/isotopic signature being considered. Comets almost certainly contain the most pristine matter, and a detailed comparison between the observed abundances in comet Halley and those found in interstellar clouds is made.

I. INTRODUCTION

The chemical evolution of protostellar nebulae is intimately related to the chemical state of the molecular clouds from which the stars form. It is well known that molecular clouds come in different varieties, ranging from the diffuse clouds to the giant molecular clouds, with distinctive chemical characteristics. The major question addressed in this chapter is the extent to which this chemical state is retained during the formation of stars and planets.

That the chemical state of an interstellar cloud will be modified by the star-formation process is evident. Young embedded or neighboring stars can raise the kinetic temperature from 10 K to a few 100 K. In addition, energetic protostellar outflows create shocks which can raise the temperature locally to more than 2000 K. Such high temperatures not only drive the chemistry from the cold, ion-molecule gas-phase scheme toward an equilibrium chemistry, but they can also evaporate the icy organic mantles of the grains and return material to the gas phase. A major goal of astrochemistry is to understand this chemical evolution well enough that the various molecules can be used as tracers of specific physical activity in the protostellar environment. For example, can the abundances and distribution of some molecules be used to probe the outflow activity of a protostellar system? If so, what is driving the chemical selectivity, and how does it depend on stellar type or evolutionary state? Another important question concerns the amount of gas-phase depletion of molecules onto the grains in a collapsing molecular cloud. When does it occur and how? To what extent are the molecular abundances modified by grain chemistry, and what are the critical processes controlling the return to the gas phase?

The reverse question of how the initial chemical state of a cloud affects the star-formation process is equally important. On theoretical grounds, the rates of collapse, and ultimately the efficiency of star formation in the cloud, are expected to depend on the cooling rates, which, in turn, are governed by the chemical composition of the gas. The efficiency of forming stars also depends sensitively on parameters such as the fractional ionization in the cloud, which is controlled by the cosmic-ray ionization rate and subsequent chemical processes. Similarly, the evolution of the grain size distribution and composition in a collapsing molecular cloud may influence profoundly

the chemical and physical state of the early solar system. Unfortunately, few observational or theoretical facts regarding these points are yet available, so that they will receive relatively little attention throughout the rest of the chapter.

Once the interstellar matter enters a protostellar nebula, it will be subjected to numerous physical processes which can further alter its composition. The amount of transformation will depend on the exact position in the solar nebula, with only minor changes occurring in the cool outer part, but nearly complete reprocessing of grains and molecules taking place in the hot inner part. One of the major uncertainties here is the distance at which the transformation from kinetically controlled interstellar chemistry to "nebular" equilibrium chemistry occurs, and the amount of mixing between the two phases. The chemical composition of the various objects in our own outer solar system, such as the outer planets, comets and meteorites, may provide important clues in this respect.

While the above areas of research cover a wide range of physical and chemical problems in all phases of the life cycle of molecular clouds, they share the common thread that a combination of observational and experimental data with detailed theoretical modeling is required to make significant headway. Indeed, vigorous complementary laboratory and theoretical programs addressing fundamental chemical physical problems are essential to unravel the myriad of chemical processes occurring during the star-formation process.

This chapter summarizes systematically our current understanding of the chemical state of each of the phases of the star-formation process on scales ranging from interstellar clouds to that appropriate to the solar nebula. Sections II and III contain a critical discussion of the chemistry in interstellar clouds prior to star formation on scales $> 10,000$ AU, both from a theoretical and an observational point of view. This is followed (Sec. IV) by a summary of the observational data on the chemistry in regions of recent high-mass and low-mass star formation on scales of 500 to 10,000 AU. The availability of a new generation of large aperture single dishes and interferometers at millimeter and submillimeter wavelengths, combined with boosts in receiver sensitivities, have increased our information in this area significantly in recent years. However, the molecules have so far been used mostly as diagnostics of physical conditions such as temperature, density and velocity structure, with little regard to the chemistry. Detailed chemical studies have been performed for a few specific objects, but systematic observations of molecular abundances as functions of, for example, luminosity of the central star or evolutionary state have yet to be carried out. As a consequence, the discussion in Sec. IV is highly fragmentary and incomplete, and focuses only on those molecules whose abundances are thought to be most affected by the star-formation process. Section V summarizes more quantitatively our current understanding of the abundances of the major carbon-, oxygen- and nitrogen-bearing species, both in the gas and solid phase.

TABLE I
Angular Sizes of Protostellar Objects and Capabilities of Telescopes^a

Although several millimeter interferometers are now operative, these facilities still lack the sensitivity to achieve spatial resolutions which directly probe the chemistry in the circumstellar disks on scales of 50 to 500 AU in any but the nearest sources. This problem is illustrated in Table I, which summarizes on the right-hand side the capabilities of current millimeter telescopes in terms of spatial resolution, and compares them with typical sizes of the (pre-) solar nebula and parental cloud core on the left-hand side. It is seen that cloud cores are readily resolved up to distances comparable to Orion with large single-dish telescopes, but that the outer pre-solar nebula can only be probed by interferometers in the nearest molecular clouds such as Taurus and Ophiuchus. In spite of this lack of observational data for stars other than our Sun, Sec. VI discusses the processes which may affect the chemical state during formation of protosolar and protoplanetary nebulae. On scales of 1 to 30 AU, the recent appearances of a number of bright comets, as well as the Voyager encounters with the outer planets, have provided a wealth of new observational data on the chemical composition of bodies in the outer solar nebula, which can be used to test the various formation and evolutionary scenarios, at least for our own solar system.

II. INTERSTELLAR CHEMISTRY

Any study of the chemical evolution of protostellar regions must start with a description of the physical and chemical state of the natal interstellar molecular cloud. It has become apparent in recent years that this initial chemical state is still poorly constrained, both observationally and theoretically. At the time when *Protostars and Planets II* was published (Black and Matthews 1985), the more optimistic view was that the chemistry in molecular clouds is reasonably well described by gas-phase ion-molecule chemistry, apart from some minor details (Irvine et al. 1985; Herbst 1985). Although in a broad sense these models are still valid, the large amount of new observational data poses significant problems to the "standard" description, and no coherent picture has yet emerged to account for the sometimes bewildering array of observed chemical variations from cloud to cloud. In the following, we will first give a general description of the physical characteristics of the different kinds of molecular clouds. This is followed by a general discussion of interstellar molecules and observational techniques. Finally, a brief summary of the various modeling efforts is given. There has been no shortage of reviews on interstellar chemistry recently (for more details, see, e.g., Irvine et al. 1985, 1987; Dalgarno 1987, 1991; Herbst and Winnewisser 1987; van Dishoeck 1988a; Guélin 1988; Turner and Ziurys 1988; Turner 1989c; Irvine and Knacke 1989; Millar 1990; Genzel 1991a; Walmsley 1991). Books on the subject in general include *Interstellar Chemistry* by Duley and Williams (1984), *Astrochemistry*, *IAU Symposium 120*, edited by Vardya and Tarafdar (1987), *Molecular Astrophysics*, edited by Hartquist (1990), and *Astrochemistry of Cosmic Phenomena*, *IAU Symposium 150*, edited by Singh (1992).

A. Molecular Clouds

Table II summarizes the different kinds of molecular clouds that can be distinguished on the basis of their physical characteristics (see, e.g., Turner 1988, 1989c; Wilson and Walmsley 1989; Friberg and Hjalmarsen 1990; Chapter by Blitz). The most tenuous are the diffuse molecular clouds, which are characterized by their low total visual extinction, $A_V \approx 1$ mag. These clouds are studied observationally primarily by the electronic absorption lines of their constituents against bright background stars. Ultraviolet photons from the interstellar radiation field can penetrate diffuse clouds and rapidly destroy most molecules, so that the atomic fraction is high and only the very simplest diatomic species are found. The translucent clouds with $A_V \approx 1$ to 5 mag form the bridge between the diffuse and the dark molecular clouds. Their densities are somewhat higher and the temperatures lower than those in diffuse clouds. Photoprocesses still play a significant role in the outer part of translucent clouds, but their importance diminishes rapidly toward the center. The high-latitude cirrus molecular clouds, seen by their CO millimeter and IRAS 100 μm emission, fall into the same category, as do the outer envelopes of dark molecular clouds. No star formation has yet been observed to occur in diffuse or translucent clouds, probably because of the high fractional ionization. A detailed overview of their physical and chemical structure has been given by van Dishoeck and Black (1988a) and van Dishoeck (1990).

The cold, dark molecular clouds are visible as dark patches on the sky, and show a complex morphology. In Fig. 1, the outlines of the CO $J=1 \rightarrow 0$ emission from the well-studied dark cloud complex in Taurus are presented (Ungerechts and Thaddeus 1987). It consists of a large number of clouds with average densities of 10^3 to 10^4 cm^{-3} which are part of one or more cloud complexes with average densities of 10^2 to 10^3 cm^{-3} . These complexes can extend over several tens of parsecs, corresponding to several square degrees on the sky. Their *average* densities are simply obtained by dividing the total mass by the observed dimensions. Further mapping at higher angular resolution reveals small individual cores or clumps in the clouds, with densities of 10^4 to 10^5 cm^{-3} or more and temperatures as low as 10 K. It is in these cores that low-mass ($< 2 M_\odot$) star formation has been observed to occur. In addition, they are the sites where many complex molecules have been detected. It is clear that the distinction between cloud complexes, clouds and cores or clumps is rather arbitrary and ill defined (Goldsmith 1987), and the term cloud will be used rather loosely throughout this chapter to refer also to the dense cores or clumps, which are the main topic.

The giant molecular clouds (GMC) have a similarly complex morphology, but differ from the dark clouds by being more massive and warmer. The *average* density in the GMC complexes and clouds is similar to that of their dark cloud counterparts, but densities as high as 10^8 cm^{-3} have been found in GMC cores or clumps. These GMC cores are the sites of massive star formation, and are heated significantly by young embedded or neighboring

^a Table adapted from Goldsmith (1987), Turner (1989*a*) and Friberg and Hjalmarson (1990).

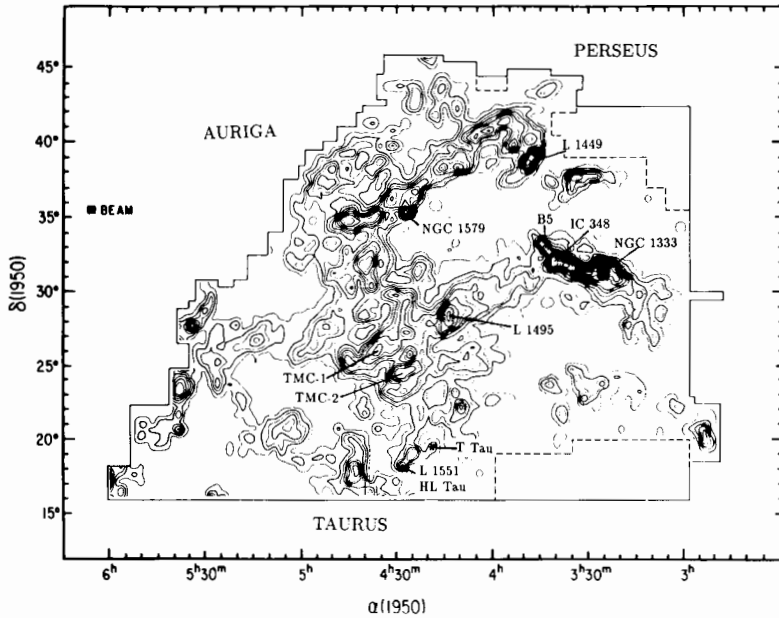

Figure 1. Velocity integrated intensity of CO emission in the Taurus molecular cloud complex. The lowest contour is 0.5 K km s^{-1} , and the separation between contours is 1.5 K km s^{-1} . The border of the surveyed region is indicated by the outer solid line. Various clouds such as B5 and cloud cores such as TMC-1 discussed in the text are indicated (figure adapted from Ungerechts and Thaddeus 1987).

stars, which may raise the kinetic temperatures as high as 200 K. The chemical signatures of clouds in which massive star formation occurs are therefore likely to differ from those in cold, dark clouds. Low-mass star formation also takes place in the GMC; the question whether our own Sun formed in a Taurus-like cloud or in a GMC is therefore not settled, and both scenarios need to be investigated.

Analysis of masses and line widths suggests that the dark and GMC complexes, clouds and cores are probably close to virial equilibrium, so that self-gravity is important in controlling their structure and evolution. The diffuse and translucent clouds are not in virial equilibrium, but are probably bounded by some external pressure.

In discussing the chemistry of the various types of clouds, it is instructive to have some indication of their ages and expected lifetimes. Unfortunately, there are very few observational constraints on these parameters (Myers 1990). The age of a cloud in virial equilibrium is probably at least the time needed to reach equilibrium, which is a few free-fall times. This leads to lower limits on the ages of $\sim 10 \text{ Myr}$ for the dark and giant molecular cloud complexes, which

are consistent with those derived from the ages of the oldest nearby stars which presumably formed from the same cloud. Dark and giant molecular cloud complexes can be disrupted by a variety of processes such as energetic winds and radiation from embedded stars, supernovae, and cloud-cloud collisions, on time scales of 10^7 to 10^8 yr.

More relevant for the discussion in this chapter are the ages and expected lifetimes of the cores in the clouds, which may be significantly shorter. If star formation has already occurred, the lifetime of the core may be limited by the dynamical time scale of the associated molecular outflows, which is only 10^4 to 10^5 yr. Cores without stars may be disrupted by the onset of star formation, which has a time scale of $\sim 10^5$ to 10^6 yr (Myers 1990). On the other hand, observations suggest that cores are supported against collapse by turbulence or other mechanisms for longer periods of time. Also, gaseous disks around young stellar objects appear to persist as long as 10^7 yr (see Chapter by Beckwith and Sargent). Therefore, the ages and expected lifetimes for cores and dense clumps are highly uncertain, and may range from 0.1 to 10 Myr.

B. Interstellar Molecules

1. Gas Phase. Table III summarizes the nearly 80 different molecules that have been detected in interstellar clouds. This table does not include the many isotopic varieties studied, and also lacks the many molecules that have been searched for but not detected, such as molecular oxygen (O_2), metal hydrides (MgH, NaH), and even amino acids like glycine. Often, stringent upper limits on these species are available (see, e.g., Irvine et al. 1987, 1991 for overviews), which can be as useful in constraining the chemistry as the actual detections. Molecular hydrogen, H_2 , is by far the most abundant molecule in the clouds, with other molecules present only in trace amounts. Their abundances with respect to H_2 range from 10^{-4} (CO) to 10^{-10} or less (e.g., HCS^+ , PN).

The first conclusion to be drawn from Table III is that the chemical composition of interstellar clouds is far from thermodynamic equilibrium. This is evidenced, for example, by the fact that most of the detected organic molecules are linear and highly unsaturated, in spite of the reducing environment. Although the lack of detected saturated, branched hydrocarbons is partly an observational selection effect owing to their more unfavorable partition function, the available detections and upper limits clearly suggest that they are less abundant than the unsaturated linear ones. Also, the relatively large abundances of molecular ions such as HCO^+ attest to a kinetically controlled, rather than an equilibrium chemistry.

In spite of the wealth of chemical information contained in Table III, there are several important limitations to the data. First, most of the molecules have been discovered by their rotational emission lines at millimeter and submillimeter wavelengths. Thus, only molecules with a permanent dipole moment can be detected. Symmetric molecules such as H_2 , CH_4 , C_2H_2 and N_2 cannot be observed in this way. Molecules like H_2 and C_2 have been seen by their electronic absorption lines at optical wavelengths against bright

* Detected in circumstellar envelopes only.

† Tentative.

background stars, but this technique is limited to relatively diffuse interstellar clouds. Other molecules, such as H_3^+ , CH_4 and C_2H_2 have been searched for through their vibration-rotation absorption lines at infrared wavelengths against embedded or background sources. The drawback of these studies is that they can only be applied to a specific line of sight in a dense cloud in which star formation has often already occurred. Finally, the Earth's atmosphere prevents the detection of the principal lines of molecules like H_2O , O_2 and CO_2 . As a result, our information on the abundances of some of the *dominant* carbon-, oxygen- and nitrogen-bearing molecules in interstellar clouds is very indirect and incomplete, in spite of the fact that the abundances of some trace molecules are known quite accurately.

Second, the column densities and abundances of molecules that have been detected are often uncertain by factors of at least 2 or 3, and, in some cases, up to an order of magnitude. The difficulties in deriving molecular abundances from millimeter observations have been clearly outlined, for example, by Irvine et al. (1985,1987). One of the major problems is that H_2 cannot yet be observed directly in dense quiescent clouds, so that its column density needs to be inferred indirectly from some trace molecule like CO (van Dishoeck and Black 1987).

Third, most of the molecules listed in Table III have been detected in only two or three well-studied sources: the Orion and Sgr B2 giant molecular clouds, and the cold, dark Taurus molecular cloud, TMC-1. To what extent these regions are representative of other molecular clouds is still an open question. In fact, it will be argued in Secs. III and IV that the observed positions are probably chemically quite distinct from most other clouds, or even from other positions in the same cloud, and that their chemical richness may be due to a very specific time in their chemical evolution, a time at which we are observing them fortuitously. This is evidenced by some striking differences between the observed molecular abundances in the Orion, TMC-1 and Sgr B2 clouds. For example, saturated molecules such as $\text{CH}_3\text{CH}_2\text{OH}$ are much more abundant in Sgr B2 than in the specific part of the Orion cloud called the extended ridge or in TMC-1, whereas molecules like SO_2 and SO are much more prominent in Orion than in the Taurus clouds. On the other hand, TMC-1 is one of the few interstellar regions with high abundances of carbon-chain molecules like HC_7N and C_4H . In spite of their different physical characteristics, however, it appears that the abundances of some simple molecules like CO, HCN and CS are fairly similar in the three regions.

The rate at which new discoveries are made is unlikely to decrease over the next decade owing to the continuing improvements in detector sensitivities and the availability of new large observational facilities at millimeter and submillimeter wavelengths (see Table I). Some highlights of the discoveries in the last few years are listed below (see van Dishoeck [1988a] for references to the original observations):

1. *Carbon-chain molecules*: New carbon-chain molecules continue to be found in cold dark clouds, in particular in TMC-1. The sequence:

has been known to exist for more than a decade (Avery 1987), although even-numbered varieties such as HC_2N and isomers such as HCCNC are much less abundant. In recent years, several new members of the series:

have been discovered. In addition, the detection of the first interstellar carbon carbenes, H_2CCC and H_2CCCC has just been reported (Cernicharo et al. 1991a, b).

2. *Ring molecules*: In contrast with the wealth of carbon-chain molecules, only two ring molecules have so far been discovered in interstellar clouds: $c\text{-C}_3\text{H}_2$ and $c\text{-C}_3\text{H}$. However, $c\text{-C}_3\text{H}_2$ appears to be more widespread throughout the interstellar medium than the carbon-chain molecules, as it has been detected not only in cold dark clouds and warm giant molecular clouds, but also in relatively diffuse clouds (Madden et al. 1989). The cyclic form C_3H_2 appears to be 2 orders of magnitude more abundant than the linear form H_2CCC .
3. *Protonated molecules*: Molecules like HCO^+ and N_2H^+ , i.e., protonated CO and N_2 , have been known for some time. More recently, protonated CS and $\text{CO}_2\text{-HCS}^+$ and HOCO^+ , as well as protonated HCN and $\text{H}_2\text{O-HCNH}^+$ and H_3O^+ (Wootten et al. 1991; Phillips et al. 1992) have been added to the list. Observations of these ions are important, because they provide indirect information on the abundances of molecules like N_2 and CO_2 , which cannot be measured directly.
4. *Deuterated molecules*: Observations of deuterated molecules continue to show significant fractionation effects, not only in cold clouds, but also, quite surprisingly, in some warm regions. Table IV summarizes the observed abundance ratios. Recently, the first discovery of a doubly deuterated molecule, D_2CO , has been reported (Turner 1990).
5. *Second-row molecules*: Sensitive searches have been made for molecules containing second-row atoms, as relatively little is yet known about the chemistry of these species (Ziurys 1990; Turner 1991). Of particular interest are searches for metal-hydrides like MgH , which may provide information on the depletion of the metals.
6. *Silicon carbides*: The molecules SiC , $c\text{-SiC}_2$ and SiC_4 have been detected in the gas phase in the carbon-rich circumstellar envelope IRC+10216 (Thaddeus et al. 1984; Cernicharo et al. 1989; Ohishi et al. 1989). This

raises the question whether a large fraction of the metals in general could be locked up in metal carbides such as FeC and MgC. Laboratory spectra of most of these species are still lacking, however.

More details on the abundances of the various molecules will be presented in Sec. V and the Appendix.

2. *Solid Phase.* Although there is still considerable discussion concerning the composition and origin of interstellar grains, some basic features appear well established. The central element in all grain models is a population of "refractory" grains, which are presumed to provide the extinction in diffuse clouds. These refractory particles are composed of silicates plus some carbonaceous material, possibly graphite, and range in size from $\gtrsim 0.25 \mu\text{m}$ down to $\sim 0.01 \mu\text{m}$ or smaller. They "lock up" a substantial fraction of the chemically active elements, such as C, Si and Fe. In dense clouds, there is direct evidence from infrared spectroscopic observations that these refractory cores are surrounded by icy grain mantles consisting of molecules like H_2O , CO and CH_3OH . In more diffuse clouds, the cores may have an organic refractory layer containing complex molecules resulting from ultraviolet processing of mantles. In addition, large molecules or ultra-small grains consisting of 25 to 200 carbon atoms are thought to be present in interstellar clouds on the basis of infrared emission features observed in the 3.3 to $11 \mu\text{m}$ range toward reflection nebulae and the 12 to $60 \mu\text{m}$ IRAS emission. The most popular identification of the species responsible for the infrared features is some type of polycyclic aromatic hydrocarbons (PAH). More details about the grain composition can be found in Sec. V and the Appendix.

C. Chemical Models

1. *Types of Models.* The observed composition in interstellar clouds discussed above indicates that the chemistry is not in thermodynamic equilibrium, but that it is kinetically controlled by two-body processes in a low-density, low-temperature environment. About 20 years ago, it was realized that reactions between ions and molecules are much more rapid at low temperatures than reactions between two neutral species (Herbst and Klemperer 1973). The latter reactions often have barriers which are much higher than the available energies in the clouds. This realization led to a network of gas-phase ion-molecule reactions, which was very successful at explaining at least qualitatively many of the observed characteristics, and which has since become the basis of nearly all modeling efforts. A brief introduction to this chemistry is given in the Appendix. That gas-phase processes continue to play a dominant role even in the densest interstellar clouds is evidenced by the large observed abundances of ions and the high deuterium fractionation in organic molecules in cold clouds. An important question is to what extent the *pure* gas-phase networks can reproduce the measured abundances, and whether the grains play an active or passive role in the chemistry in the cloud.

The importance of grains in various aspects of the chemistry is evident.

TABLE IV
Observed Deuterium Fractionation Ratios*

Molecule	TMC-1	Warm Clouds	Hot Cores ^a	Halley	Outer
DCO ⁺ /HCO ⁺	0.015	≤ 0.002	—

* Table adapted from Millar et al. (1989) and Irvine and Knacke (1989). ^aTabulated values refer to the Orion hot core or compact ridge, which both have $T > 50$ K. ^bMangum et al. (1991). ^cTurner (1989a). ^dTurner (1990). ^eRe-assessment of Turner (1990) of data of Walmsley et al. (1987). ^fJacq et al. (1990). ^gEberhardt et al. (1987a). ^hMauersberger et al. (1988). ⁱLutz et al. (1990). ^jGerin et al. (1992a). ^kGerin et al. (1992b).

Clearly, they are crucial in shielding the molecules from the dissociating ultraviolet radiation. Also, the large abundance of H_2 even in diffuse clouds can only be understood if the formation of this molecule takes place on the surfaces of grains. Moreover, solid H_2O and CO have been observed directly in dense interstellar clouds. This is not surprising, since the time scale for a species to be deposited on a grain surface is only

$$\tau \approx 2 \times 10^9 / (\alpha n_{\text{H}}) \text{ yr} \quad (1)$$

where α is the probability that the species will stick to the grain, which is thought to lie between 0.1 and 1 (see Appendix). As Fig. 2 shows, this time scale is short compared with, e.g., the free-fall time scale or the expected lifetime of the cloud for densities $n_{\text{H}} > 10^4 \text{ cm}^{-3}$. In fact, the grain accretion process by itself removes heavy species from the gas phase so fast that one would expect many opaque dense clouds devoid of gas-phase molecules like CO . As no such cloud has yet been found, there must be efficient mechanisms which return the adsorbed molecules back to the gas phase. Several possible mechanisms in cold, dark clouds are discussed in the Appendix, but no consensus has yet been reached as to their relative importance. Of course, in regions of star formation, the higher temperatures can sublime the grain mantles. The temperature required for thermal sublimation of pure CO ice is only 17 K, whereas that for pure H_2O ice is 90 K. "Dirty ice" mixtures probably have sublimation temperatures in between these values.

On the basis of these considerations, the models can be divided into several categories. First, there are the pure gas-phase models which adopt the basic ion-molecule chemistry scheme. Recent examples can be found in Herbst and Leung (1989), Langer and Graedel (1989) and Millar et al. (1991*b*). In the simplest "standard" form, these models are homogeneous with a fixed temperature and density. They solve the set of rate equations either at steady-state or as a function of time. Several recent improvements to this standard model are discussed in the Appendix, such as efforts to include the clumpy structure of molecular clouds; calculations of the effects of cosmic-ray-induced photodissociation processes inside dense clouds; studies of the influence of large molecules such as the PAH on the chemistry and ionization balance; considerations of the depth-dependent structure of clouds located close to young, hot stars; and treatments of evolutionary processes.

Second, several models have been developed which include the effects of grains on the chemistry. The simplest models of, e.g., Iglesias (1977) and Millar and Nejad (1985) consider only the time-dependent accretion of molecules onto grains in a dense cloud, but ignore any surface processing. The models of, e.g., Tielens and Hagen (1982) and Brown and Charnley (1990) include subsequent reactions on the surfaces to form other molecules, but have no mechanism for returning the molecules to the gas phase. Nevertheless, they make important predictions about the composition of the grain mantles. The most sophisticated models are those of d'Hendecourt et al. (1985) and

Figure 2. Comparison of free-fall and depletion time scales. The dashed lines represent the time scale for molecules to condense out on grain surfaces as a function of hydrogen density for two values of the sticking coefficient α . The figure shows that even for $\alpha = 0.1$, a large fraction of the molecules is expected to “freeze-out” in one free-fall time at a density of 10^5 cm^{-3} . For comparison, the time scale to reach chemical equilibrium is typically 10^6 to 10^7 yr, the expected lifetime of a cloud is 10^6 to 10^8 yr, and the dynamical time scale of molecular outflows is typically 10^4 to 10^5 yr (figure adapted from Walmsley 1991).

Breukers (1991), which include desorption mechanisms and investigate the influence of the returned molecules on the gas-phase composition as a function of time. As is discussed in more detail in the Appendix, different compositions of grain mantles can occur under different conditions. In an atomic hydrogen-rich atmosphere, which is the situation that most likely prevails in the clouds, molecules like H_2O , H_2CO , CH_3OH , and possibly NH_3 and CH_4 are expected to dominate (see Fig. 3). The major effect on the gas-phase chemistry is an increase in the abundances of these molecules when they are released from the surface by some mechanism.

Third, detailed models have been developed to investigate the chemistry at high temperatures, $T \gtrsim 2000 \text{ K}$, such as encountered in shocks. As described in the Appendix, two different kinds of shocks can be distinguished. The so-called J shocks are usually powerful enough to dissociate molecules completely. Only when the post-shock gas cools can the molecules reform, although often in different configurations compared with the pre-shock gas. Recent examples have been given by Neufeld and Dalgarno (1989) and Hollenbach and McKee (1989). Such powerful shocks can also destroy the

Figure 3. A comparison of the calculated gas-phase and solid-state composition of a molecular cloud. When atomic H dominates over heavy species in the gas phase, the accreting species will be hydrogenated. Otherwise grain mantles will reflect the gas phase more directly. Large deuterium enrichments are expected to be a characteristic of grain mantles as a result of the high atomic D/H ratio in the gas phase (Tielens 1989).

refractory grain cores and return Si and Fe to the gas phase. In C-type shocks, the peak temperatures are lower, so that most molecules survive the passage of the shock wave. The chemistry is dominated by neutral-neutral rather than ion-molecule reactions, although subtle effects due to differential streaming of the ions and neutrals can occur (Draine et al. 1983). Compared with the low-temperature cases, the shock models are characterized by large abundances of H_2O and OH, of sulphur-bearing molecules such as H_2S , and silicon-containing molecules such as SiO.

The adopted gas-phase elemental abundances are crucial parameters in the models. The fraction of species X in the solid phase with respect to the solar abundance is denoted by the depletion factor δ_X . [Note that in some papers δ_X refers to the abundance fraction in the gas phase.] We adopt as our reference the abundances of the solar system at its time of formation ~ 4.5 Gyr ago as summarized by Anders and Grevesse (1989): $\text{O}/\text{H} = 8.5 \times 10^{-4}$, $\text{N}/\text{H} = 1.1 \times 10^{-4}$ and $\text{Si}/\text{H} = 3.6 \times 10^{-5}$. The only exception is carbon, for which we use $\text{C}/\text{H} = 4.0 \times 10^{-4}$ as derived by Grevesse et al. (1991).

Oxygen and nitrogen are usually assumed to be relatively undepleted ($\delta_X \lesssim 0.25$), but carbon can be depleted by 60% or more in dense clouds and silicon is often taken to be nearly completely removed (see Sec. V). It should be noted that most molecular abundances do not scale linearly with the depletion factors, because of the complicated structure of the chemistry networks. Of particular interest is the C/O ratio in the gas phase. For any reasonable grain model (see Sec. V), this ratio is less than unity so that virtually all gas-phase

carbon is locked up in CO. The remainder of the gas-phase oxygen is then thought to be tied up in molecules such as H₂O and O₂. If C/O were greater than unity in the gas phase, all oxygen would be locked up in CO and the remaining carbon would be contained in more complex carbon-containing molecules.

It is important to recognize that elemental abundances in the interstellar medium today may differ appreciably from solar abundances, which represent a particular $\sim 1 M_{\odot}$ sample from the interstellar medium 4.5 Gyr ago. In fact, detailed modeling of the Orion H II region (Baldwin et al. 1991) indicates a gas-phase O/H ratio only 30% of the solar value. Isotopic studies of meteorites, revealing remarkably high abundances of radioactive ²⁶Al at the time of chondrite formation, may indicate contamination of the primordial solar nebula by fresh nucleosynthetic material from a nearby supernova explosion, nova, or wind from an asymptotic giant branch star (Chapter by Cameron). The hypothesized sources of ²⁶Al may also have affected the abundances of C, N and O.

2. *Comparison with Observations.* As an illustration of the reliability of the model results, we summarize in Table V the computed abundances in the latest gas-phase models of Herbst and Leung (1989), Langer and Graedel (1989) and Gredel et al. (1989), and compare them with observations in TMC-1. The first conclusion to be drawn from Table V is that at steady state, the abundances in the different models disagree in some cases by more than an order of magnitude, even for simple molecules. Although some of these discrepancies can be traced to slight differences in adopted physical conditions and elemental abundances, they mostly result from differences in the adopted reaction schemes. Indeed, recent comparisons between the groups have been very valuable in establishing the sensitivity of various aspects of the models to differing assumptions about one or two key reactions (Dalgarno 1986; Millar et al. 1987). They also provide a warning that, in spite of their relative agreement in some cases, the computed abundances should not be trusted to more than an order of magnitude on an absolute scale, and that special care must be taken in quoting older model results which use outdated chemical reaction sets.

When compared with observations, it appears that the pure gas-phase steady-state models can reproduce the observed abundances of simple molecules like CO, CS and HCO⁺, but that they fail to produce enough complex molecules like C₃H₂, C₄H and HC₅N by several orders of magnitude. They also result in too little NH₃ if the latest experimental information on its formation processes is taken into account, and in many cases too much O₂ and H₂O compared with the measured values or upper limits for other clouds. One possible explanation for the discrepancy with the complex molecules is that the cloud chemistry has not yet reached steady state. In particular, the complete conversion of C to CO in a cloud that is initially mostly atomic takes approximately 1 Myr. Thus, at earlier times, there is a significant amount of atomic carbon available in the cloud which can be inserted into the carbon

^a From Herbst and Leung (1989) for $n(\text{H}_2) = 2 \times 10^4 \text{ cm}^{-3}$ and $T = 10 \text{ K}$ with low metal abundances and standard rates. The early results refer to $t \approx 10^5 \text{ yr}$.

^b From Langer and Graedel (1989), their run 8 with $n(\text{H}_2) = 5 \times 10^4 \text{ cm}^{-3}$ and $T = 20 \text{ K}$. These models employ low metal abundances, and take cosmic-ray-induced photodissociation of CO into account. ^c From Gredel et al. (1989), their case C with $n(\text{H}_2) = 10^4 \text{ cm}^{-3}$ and $T = 50 \text{ K}$. These models employ low metal abundances, and take cosmic-ray-induced photodissociation of all molecules into account. ^d Observed abundances from Irvine et al. (1987), unless otherwise indicated. ^e Friberg et al. (1988). ^f McGonagle et al. (1990).

^g Minh et al. (1989). ^h Ziurys et al. (1989).

chains to produce more complex hydrocarbons. As Fig. 4 illustrates, their abundances reach maximum values at early times that are 3 to 4 orders of magnitude larger than the steady-state results. On the other hand, the concentrations of molecules like CO, NH₃ and O₂ increase steadily with time. For the carbon- and oxygen-bearing species, the equilibrium abundances are reached in a few Myr. Although this time scale is uncertain by a factor of a few due to uncertainties in crucial reaction rates, it is comparable to the estimated lifetime of a clump in a molecular cloud complex (see Sec. II.A). The abundances of nitrogen-containing molecules such as N₂ and NO do not attain steady state until 10 Myr, because they are produced by slow neutral-neutral reactions.

Figure 4. *Left:* Abundances of C⁺, C and CO with respect to H₂ as functions of time for a cloud with $n_{\text{H}} = 2 \times 10^4 \text{ cm}^{-3}$ (Leung et al. 1984). *Right:* Abundance of a typical complex carbon-bearing molecule as a function of time. The dashed line is for a similar model as in the left figure. The full line refers to a model in which more rapid ion-polar molecule reaction rates are employed (Herbst and Leung 1986).

It should be noted that the scenario of a young age for TMC-1 is not the only possible explanation for the large observed abundances of carbon-chain molecules: in fact, only a large fraction of atomic or ionized carbon in the gas phase is required in the models, which may result from incomplete conversion of carbon to CO due to any other mechanism (Suzuki 1983).

The above example reinforces the general conclusion about interstellar cloud models, namely that they are only moderately successful in reproducing the observed abundances. A large source of uncertainty still lies in the adopted reaction rates, which can introduce orders of magnitude uncertainty in the predicted abundances, but which are not always widely recognized. Nevertheless, the gas phase models have at least some predictive, quantitative power. Our understanding of processes involving grains is still much more limited and these models can be used only for qualitative statements at best. Much more basic laboratory study of reactions on surfaces representative of interstellar grains needs to be performed in order to remedy this situation.

III. CHEMICAL STATE OF DENSE CLOUDS PRIOR TO STAR FORMATION

The discussion in Sec. II focused on interstellar molecules and chemical models in general, and compared the models with observed molecular abundances at one specific position in the Taurus clouds. In this section, we investigate from an observational point of view how representative the chemistry at this position is of that of other clouds or clumps which currently show no indication of ongoing star formation. It appears that these dark, dense clouds are very inhomogeneous on scales of 20 to 60'', and that as a result their chemical state is poorly constrained observationally.

A. TMC-1 Cloud

The TMC-1 core is a small elongated, dense ridge of approximate dimensions 0.6×0.06 pc in the Taurus clouds, with a total mass $< 40 M_{\odot}$ (see Fig. 1). Although low-mass star formation occurs throughout the Taurus cloud complex, including sites close to TMC-1, no direct evidence for recent star formation has been found within the TMC-1 ridge. It appears to be a quiescent, self-gravitating clump of gas with a minor axis of the order of a Jeans length. The narrow observed molecular line widths ($< 1 \text{ km s}^{-1}$) show no signs of collapse. Thus, TMC-1 is thought to be a cloud close to hydrostatic equilibrium, which may be the site for the next generation of pre-main-sequence stars.

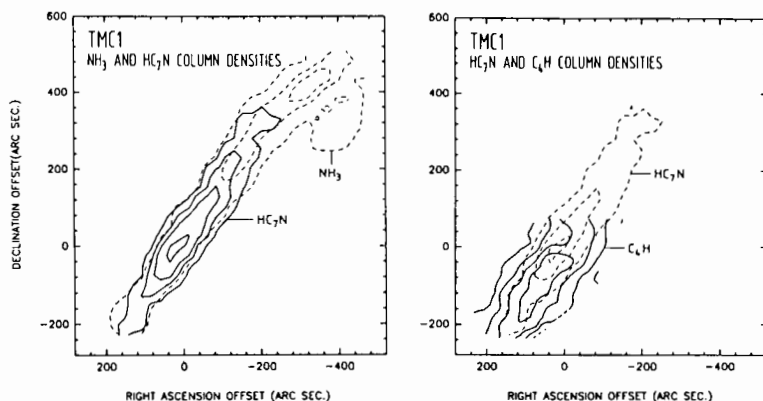

Figure 5. (a) Column density distribution of HC_7N (full lines) in TMC-1 compared with that of NH_3 (dashed lines). (b) Column density distribution of C_4H (full lines) compared with that of HC_7N (dashed lines). Possible gradients in excitation temperature across the TMC-1 core have been neglected in making these maps (see text) (Olano et al. 1988).

Figure 5 shows the NH_3 and HC_7N column density distribution along the TMC-1 ridge at about $40''$ (0.03 pc at the adopted distance of 140 pc) resolution (Olano et al. 1988). The (0,0) position is the peak in the cyanopolyynes emission to which most of the observations of the molecules listed in Table V refer. It is apparent that these two molecules have very different distributions along the ridge, as was also found in earlier studies at lower angular resolution (see, e.g., Little et al. 1979; Tölle et al. 1981). The ammonia column density peaks about $7'$ (0.3 pc) to the NW of the maximum of the complex carbon-bearing molecules. Care has to be taken in interpreting these maps, however, because variations in the emission can be caused either by variations in the excitation conditions, or by true chemical abundance variations along the ridge (see, e.g., Bujarrabal et al. 1981). For TMC-1, these two possibilities have been considered carefully, and it was concluded that the $\text{HC}_7\text{N}/\text{NH}_3$ abundance ratio varies genuinely by more than an order of magnitude over the scale of a few tenths of a pc. The physical conditions have been constrained from a variety of diagnostics. The temperature, as determined from the NH_3 (1,1) and (2,2) excitation, is about 10 K, whereas estimates of the densities range from $\sim 3 \times 10^4$ to 10^5 cm^{-3} . There is no consensus yet whether there is any gradient in density along the ridge. In any case, it is insufficient to explain the different distributions shown in Fig. 5 in terms of different excitation effects. On the other hand, small differences of order $1'$ (0.04 pc) have been found in the distribution of, e.g., HC_7N and C_4H in the southern part of the ridge, which may well be caused by excitation effects if the H_2 density falls off rapidly to the south (Fig. 5b). Maps of HC_3N and C_3H_2 in the southern part at even higher angular resolution of $20''$ have been presented by Guélin and Cernicharo (1988). It is seen that the ridge breaks up into a chain of tiny clumps with a characteristic size of $1'$ (0.04 pc or 8000 AU), which is comparable to the size of the gas disks surrounding young stellar objects such as HL Tauri (see Chapter by Beckwith and Sargent).

What can cause the striking chemical differences between the northern and southern peak? As discussed in Sec. II, most chemical models have attempted to reproduce the observed abundances in the southern peak, but have succeeded only in a time-dependent calculation at an early age of a few times 10^5 yr. These models are somewhat artificial in that they presuppose that the carbon is initially mostly atomic, but that hydrogen is in molecular form, and that the physical conditions are fixed with time. Nevertheless, this chemical time scale is comparable to the probable age of the TMC-1 ridge (Olano et al. 1988). However, in order to explain the abundance variation along the ridge, the northern part would have to be significantly older than the southern part. This would be consistent with the larger abundances of nitrogen- and sulfur-bearing molecules such as NH_3 , NO and H_2S in the north, because the chemical time scales for these species are longer. TMC-1 may be an unusual cloud because of its elongated structure, which has been speculated to arise through a shock caused by cloud-cloud collisions. On the other hand, the observed small line widths and the absence of any significant

velocity gradient indicate that all the energy of a possible shock has already been dissipated, so that we are probably seeing the “fossilized remnant” of this collision, which is being preserved by self-gravitation (Tölle et al. 1981). In this picture, an age gradient across the ridge is not easily accounted for. Variations in density along the ridge from 10^4 to 10^5 cm^{-3} have little effect on the computed abundances in a pure gas-phase model, but do significantly affect the time scale for depletion onto the grains (cf. Fig. 2). If the density were higher in the northern part, more carbon-chain molecules could be removed from the gas phase. However, there appears little evidence for differential depletion of other molecules between the two peaks, and NH_3 , which may form on grains, is even more abundant in the north. Better observational constraints on possible density gradients along the ridge, combined with more detailed modeling of the grain depletion processes are needed to elucidate the cause for the observed variations.

B. L 134N Cloud

A second example of a cold, dark cloud which shows no obvious evidence of star formation is the L 134N cloud, also known as L 183. The chemical structure of the densest part of this cloud has been studied in great detail by Swade (1989*a, b*). Figure 6 reproduces his observed contour maps of integrated emission of a number of representative molecules.

The core region of L 134N, as seen in C^{18}O , extends over an area of about $8' \times 8'$, which, at a distance of 160 pc, corresponds to about 0.3×0.3 pc. Its estimated total mass is about $20 M_{\odot}$. It is apparent that the emission of some molecules is fairly similar (e.g., C^{18}O and CS), but that other molecules (e.g., HCO^+ , SO and NH_3) show widely different distributions. For example, the CO and CS maps both have a NE-SW extension, whereas the HCO^+ and NH_3 maps are much more elongated in the N-S direction. C_3H_2 also peaks in the northern part, but does not show a corresponding peak in the south at the same position as NH_3 or HCO^+ . The SO emission, on the other hand, peaks more to the west than that of any other molecule. To what extent are these differences due to varying excitation conditions or to actual abundance variations? The physical conditions in L 134N have been derived from a number of diagnostic species, and a kinetic temperature $T \approx 12$ K and peak density $n(\text{H}_2) \approx 3 \times 10^4 \text{ cm}^{-3}$ have been found, very similar to the conditions in the TMC-1 ridge. Some variations are seen in density across the L 134N core, but the different map morphologies are mostly due to chemical abundance variations on scales of a few tenths of a pc. Swade and Schloerb (1992) have suggested that the different distributions of CS and SO indicate an oxygen abundance gradient across the L 134N core, with oxygen being depleted in the highest density core around the (0,0) position. Atomic carbon has been detected near the (0,0) position in L 134N (Phillips and Huggins 1981), but no data are available on other positions in this cloud or TMC-1 to test the hypothesis. Also, no detailed chemical modeling has yet been done to investigate how large such a gradient would have to be to explain the different

CS and SO distributions, and how it could account for the observations of other molecules. The age of the L 134N core is estimated to be at least 1 Myr, so that time-dependent effects probably play a smaller role in the chemistry of this cloud than in TMC-1.

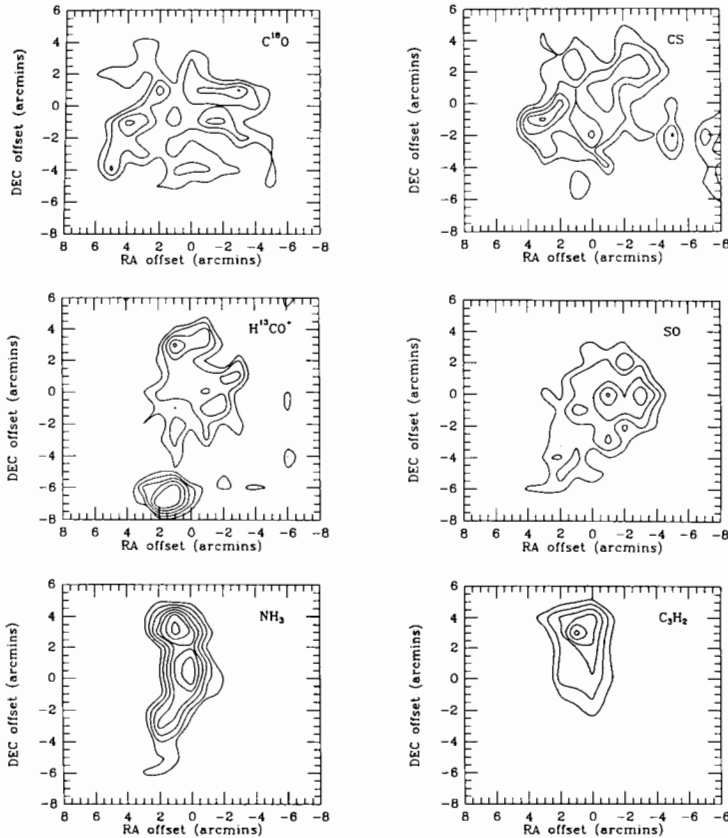

Figure 6. Contour maps of the integrated intensity of various molecules in the L 134N molecular core. The different map morphologies are thought to reflect true chemical abundance variations on scales of a few arcmin (0.2 pc) (Swade 1989a).

C. Discussion

The cases of TMC-1 and L 134N illustrate that significant chemical abundance gradients occur over scales of only a few tenths of a pc within a single, supposedly quiescent, cloud. Comparison of the abundances in the TMC-1 and L 134N cores shows some interesting differences and similarities between

the two clouds as well, which are illustrated in Table VI of Sec. IV. For example, the long-carbon chain molecules are 1 to 2 orders of magnitude less abundant anywhere in L 134N than in the southern part of TMC-1. On the other hand, SO and SO₂ are more abundant in the western part of L 134N compared with the southern part of TMC-1. If anything, the chemistry in L 134N resembles that found in the northern part of TMC-1. In spite of these differences, some molecules have similar abundances in the two clouds, such as the fairly complex molecule methanol (Friberg et al. 1988). The fact that methanol does not peak at the position of that of the long-carbon chain molecules suggests that it has a different origin.

Limited surveys of the chemistry have been made for a number of other dark cores, both with and without star formation. None of these cores has as rich a chemistry as TMC-1, although carbon-chain molecules have been detected in nearly half of them (Cernicharo et al. 1984; Suzuki et al. 1992). One striking result is that the complex carbon molecules are not found in any region in which star formation has already occurred, such as L 1551. On the other hand, more than 2/3 of the cores seen in NH₃ have associated IRAS sources (Benson and Myers 1989). These surveys appear to confirm the picture that regions in which NH₃ is abundant represent a later stage in the evolution of the cloud than regions in which the complex carbon molecules are present. Whether the larger NH₃ abundance in regions of star formation is solely the result of the longer time scales or different physical conditions, or whether, e.g., release from grain mantles plays a role, is still an open question. More detailed comparisons of the abundances of other molecules in such surveys will be very valuable.

The observed correlation between NH₃ cores and star formation also raises the question whether there may yet be alternative explanations for the observed chemical gradients in the TMC-1 and L 134N clouds. If cold, low-luminosity protostars in a very early stage of evolution were present, they would not show up as strong IRAS point sources, but may still affect the chemistry if they are already in the outflow stage. Such outflows could, for example, evaporate grain mantles and create local shocks in which sulfur-bearing molecules could be formed. In fact, a low-luminosity IRAS source with associated high-velocity CO outflow emission has been detected only 2' W of the northern TMC-1 NH₃ peak (Terebey et al. 1989). More information on the distance over which such outflows could affect the chemistry would be very useful. Deeper searches for protostellar activity in the L 134 N core are warranted.

In summary, the question "what is the chemical composition of a dark cloud prior to star formation" cannot be answered in detail at present without an understanding of the physical and chemical processes that give rise to the observed variations. Several possible causes have been identified, such as age gradients, elemental abundance gradients, and maybe even star formation in its earliest stages, but detailed modeling and systematic observations are still lacking.

IV. CHEMICAL STATE OF STAR-FORMING REGIONS

The preceding sections outline the chemical composition and evolution of molecular clouds prior to and during the incipient stages of star formation. As is outlined below, observationally we are now in a position to examine *directly* the chemical evolution which accompanies the star-formation process, at least on scales of 500 to 10,000 AU. It is generally accepted that, as stars condense out of molecular clouds, the circumstellar gas will gradually become flattened so that eventually the remnant cloud around the protostellar object will have a disk-like morphology. Until very recently, the structure of this circumstellar gas could be inferred only from indirect clues. However, with the advent of interferometric techniques at millimeter and infrared wavelengths, it has become possible to identify such disks directly. Around the low mass objects HL Tauri, L1551 IRS5 and IRAS 16293–2422, for example, are extended, flattened structures with radii of order a few 100 AU (Mundy et al. 1986*b*; Sargent and Beckwith 1987; Sargent 1989; Keene and Masson 1990). Thus far, observations have concentrated on the dust continuum and isotopic CO emission from these objects with the intent of obtaining an overview of the spatial structure, mass and kinematics of the system, but little work has been reported on their chemical structure. While dynamical studies ultimately require the resources of instruments capable of higher resolution, the large-aperture millimeter and sub-millimeter telescopes which have recently come on-line (IRAM, JCMT, CSO, Nobeyama) are well suited for initial exploration of the chemical nature of these disks and their surroundings (see Table I). For example, broadband molecular line surveys can delineate the “initial conditions” accompanying the collapse of dense clouds into protostellar objects; while deep integrations on selected species and interferometric mapping can examine the chemical heterogeneity of the circumstellar disks or cores themselves.

As a result of recent surveys of young stellar systems at millimeter (Wilk-
ing et al. 1989*b*) and sub-millimeter (Beckwith et al. 1990) wavelengths, over 100 cold compact dust regions associated with young stellar objects have been identified. In addition, new mid-infrared cameras and high resolution far-infrared data are beginning to reveal more detailed information about the warm dust. This list contains sources which span stellar luminosities from 1 to $10^5 L_{\odot}$ and a range of obscuration from visible stars to objects so deeply embedded that no 2- μm source is detected. Estimates of the masses of circumstellar material range widely from <0.1 to $10 M_{\odot}$ or more. As two of the nearest and brightest star-forming molecular clouds, the core of the Orion nebula and the IRAS 16293–2422 core in the ρ Ophiuchi cloud present unique opportunities to examine the complexity and evolution of interstellar chemistry in two very dissimilar environments, i.e., high- vs low-mass star formation. These two regions have been studied chemically in so much more detail than any other regions that it is instructive to discuss them first. Empha-

sis will be placed on the alteration of the chemical composition of the parent molecular cloud by the star formation process.

A. High-Mass Star-Forming Regions

1. Orion/KL: Observations. The Orion/KL or OMC-1 molecular cloud core, centered behind the Trapezium stars in the sword of the Orion constellation and including the luminous infrared sources BN and IRc2, is perhaps the most widely known and best studied example of a young stellar nebula in which high-mass star formation occurs. Indeed, because of its proximity, large intrinsic luminosity (2 to $10 \times 10^4 L_{\odot}$), and enormous quantity of surrounding material, the IRc2 region is one of the brightest compact objects in the sky from mid-infrared to millimeter wavelengths. Its unique strength in molecular line emission is obvious from its central role in molecular line searches since the early days of molecular radio astronomy. In more recent years, these strong lines have made IRc2 an irresistible source for millimeter interferometer studies of molecular spatial distributions (Plambeck et al. 1985; Vogel et al. 1985; Masson and Mundy 1988; Plambeck and Wright 1987, 1988; Mangum et al. 1990).

The connection of the Orion/KL core with the Orion-Monoceros giant molecular cloud complex is visible in maps of many molecular species as a strip, or ridge, of material running roughly N-S near the Trapezium. The linewidths in the ridge material are at most 4 to 5 km s^{-1} , and decrease with increasing spatial resolution. Condensations in the Orion ridge are nicely sampled by high-density tracers such as CS, as is demonstrated in the left-hand side of Fig. 7. Three condensations are clearly visible, with dimensions from 0.03 to 0.11 pc and virial masses from 30 to $80 M_{\odot}$. The largest condensation is centered on the main source in the region, IRc2, a roughly $25 M_{\odot}$ star deeply embedded in the local material (Genzel and Stutzki 1989). The $1.5'S$ source is the only other clump in Fig. 7 which also shows obvious molecular signposts of star formation activity (Ziurys et al. 1989).

In addition to the “spike” or ridge gas, a number of other distinct kinematic components are detected near IRc2. Centered approximately $2''$ south of IRc2 is the “hot core” component which is a $\sim 10 M_{\odot}$ clumping of gas and dust about $15''$ (0.03 pc or 7000 AU) in extent. This material is associated with and strongly heated by IRc2 to at least 100 to 200 K , but does not appear to be a protostellar disk itself (Plambeck and Wright 1987; Genzel and Stutzki 1989), although such a disk may exist within 80 AU of IRc2 (Plambeck et al. 1990). A strong bipolar outflow from IRc2 has interacted with the structure in the local molecular cloud to create a “doughnut” of slowly expanding shocked cloud material (the “low-velocity plateau” component characterized by line widths $\Delta V \leq 25 \text{ km s}^{-1}$) roughly normal to the flow axis. Along the flow axis the velocities are correspondingly higher due to the faster density decrease (the “high-velocity plateau”), as is evident in the emission from CO, HCO^+ and H_2 (Vogel et al. 1984; Masson and Mundy 1988). Finally, a compressed clump of cloud material called the “compact ridge” is visible some 10 to

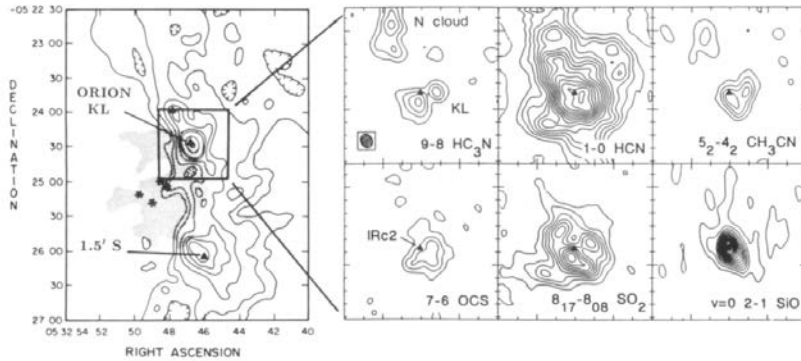

Figure 7. *Left:* OVRO/Onsala image of the integrated CS $J=2 \rightarrow 1$ emission from the Orion ridge. The asterisks denote the positions of the Trapezium stars, while the triangles mark the positions of the millimeter continuum sources (Mundy et al. 1988). *Right:* Hat Creek aperture synthesis maps of molecular emission towards Orion/KL. The contour levels for the first four 2" square maps step by 5 K, while for the last two the interval is 10 K. The tickmarks are spaced by 10" (Plambeck and Wright 1988).

15" to the southwest of IRc2. Figure 8 summarizes the various components surrounding IRc2 graphically in more detail.

Chemistry adds considerably to the complexity of the region as variations in temperature, atomic abundances, and chemical history drive variations in the molecular composition of each component. For example, interferometer maps of species are often very different in appearance, as the right-hand side of Fig. 7 demonstrates. This figure, obtained by the Hat Creek millimeter-wave interferometer (now called BIMA), outlines dramatic differences in molecular emission on the 3 to 4" scale. When combined with the temperature and overall abundance constraints provided by the spectral line surveys outlined below, these maps demand that true chemical heterogeneity exists on scales of 2000 AU or less.

Due to the opaque nature of the atmosphere in many wavelength regions and the relatively insensitive nature of early receiver/telescope combinations, much of the initial work on the chemistry of dense molecular clouds proceeded through a biased selection of molecules on a line-by-line basis, such as discussed in Sec. III. However, *unbiased* surveys of small regions in the millimeter-wave spectrum have been recorded for the brightest objects in the sky like Orion/KL (Lovas et al. 1976,1979; Johansson et al. 1984; Sutton et al. 1985; Blake et al. 1986; Turner 1989*b*; Jewell et al. 1989). More recently, the new submillimeter facilities have allowed the surveys to be extended to high-frequency atmospheric windows. The main advantage of line surveys

Figure 8. Schematic model for the Orion/KL outflow region around IRC2. The hot core material (shaded region) lies mainly in front of IRC2. It is being ablated by a wind from IRC2; the resulting material forms the high-velocity plateau. The volume around IRC2 has been largely cleared of material except where the outflow has been stopped by the dense ridge gas. The resulting shocked region (dotted) is responsible for the low-velocity plateau (figure adapted from Masson and Mundy 1988).

vs selected observations is completeness, but they also result in better calibration, certainty of identification, and in a measurement of the total integrated line flux.

These points are illustrated by a recently completed CSO 345 GHz survey of the Orion/KL region, which yields dramatically more intense emission than is prevalent at longer wavelengths due to the high temperature and large mass of the central source (Groesbeck et al. 1993). Two positions have been observed to examine the nature of chemical abundance variations on small size scales, in this case the classical Orion/KL "plateau"/hot core source and the warm core 1/5 S (Fig. 7). The differences in the spectra between the two sources are striking, as is demonstrated by Fig. 9.

Indeed, an incredible complexity is revealed for Orion/KL, but only few lines are visible at the 1/5 S position in spite of the fact that the total H_2 column density is very similar. The myriad lines in the Orion/KL spectra arise mostly from high-energy levels (>300 K) of asymmetric top molecules such as methyl formate, sulfur dioxide, or methanol, and result in a quasi-continuum. Only in a few selected bands can the true continuum level of

Figure 9. CSO 500 MHz double sideband spectrum of the Orion/KL and Orion 1.5' S sources near the $\text{H}^{13}\text{CN } J=4 \rightarrow 3$ transition at 345.34 GHz. Both spectra have the same vertical scale, and the total integration time was < 10 minutes. Note the enormous difference in the number of lines between the two sources (Groesbeck et al. 1993).

$T_A^* \approx 1.7$ K be reached. The most striking chemical difference between the 1.5' S source and the Orion/KL region is the nearly complete absence of SO_2 in the former, despite easily observable SO and SiO spectral lines. In addition, several of the species more traditionally associated with cooler molecular clouds, such as C_2H , are observed to have greater abundances in the southern source. The difference in line density between the two sources also illustrates that care has to be taken in the interpretation of continuum measurements of distant unresolved sources: if the source is like the 1.5' S source, the continuum is mostly due to dust emission, whereas if it is like Orion/KL, a significant fraction of the continuum may actually be due to lines. This could lead to erroneous conclusions, e.g., about the gas-to-dust ratio.

Orion/KL: Chemistry. In the following, the different chemistries of the Orion core region (the extended ridge, the plateau, the hot core, and the compact ridge) will be discussed in more detail. Results for selected molecules are summarized in Table VI in Sec. IV.B. In spite of the tremendously heterogeneous composition of this region, it is heartening to note that it may be interpreted at least qualitatively in the framework of the interaction between a quiescent molecular cloud chemistry and that induced by massive star formation (Blake et al. 1987).

The chemistry of the extended ridge material is similar to that observed in

a number of other cool, quiescent clouds described in Sec. III: a temperature increase from 10 to 50 K and an increase in density by an order of magnitude seem to have little influence on the chemistry. In contrast, the chemical composition of the Orion/KL plateau source is dominated by high-temperature chemistry, including shocks and grain-mantle evaporation. The most striking result for the plateau source is the large drop in the abundances of carbon-rich species like C, C₂H and CN and the concomitant rise in the abundances of oxygen- and sulfur-containing species such as H₂O, SiO, H₂S and SO₂. The observed ratio of carbon and oxygen contained in molecules other than CO and water is $C/O \leq 0.5$ in the plateau source. In contrast, the same ratio is greater than unity in the ridge material. The higher oxygen abundance and the very high temperatures behind shock fronts are expected to drive most of the oxygen into H₂O and OH and carbon into stable forms such as CO. Also, they will enhance the abundances of more refractory species such as sulfur and silicon via grain disruption or evaporation, as is evidenced by large abundances of gas-phase atomic silicon (Haas et al. 1991). The considerable abundance of "fragile" species such as H₂CO and the large residual deuterium enhancement in water imply an extremely clumpy density structure in the outflowing wind.

High-temperature chemistry is also evident in observations of the hot core, but with a considerably different signature. Again, the abundances of reactive, carbon-rich species are significantly reduced, with the observed C/O ratio in molecular form less than unity. Because the heating is caused by radiation rather than by shocks, grain vaporization does not occur and the abundances of the refractory sulfur and silicon species remain low. The high densities and temperatures in the hot core reduce the effectiveness of ion-molecule networks, and are sufficient to release much of the grain-mantle material stored over the cloud lifetime. Indeed, the composition of the hot core is most consistent with a chemistry that was dominated by ion-molecule reactions in a cold, quiescent dense cloud with accretion onto grains, followed by evaporation of the molecules from the grains once star formation has occurred (Brown et al. 1988). Because of the relatively slow gas-phase reactions, the ejected mantle material has not yet been chemically modified. It is worth recalling, however, the considerable uncertainties in quiescent cloud gas-phase and grain-mantle chemistries outlined in Secs. II and III, so that it is difficult to test this scenario in detail. Nevertheless, support for this picture comes from the unexpectedly large observed abundances of HDO (Jacq et al. 1990), NH₂D (Walmsley et al. 1987), CH₃OD (Mauersberger et al. 1988), DCN (Mangum et al. 1991), and D₂CO (Turner 1990) in the hot core/compact ridge region, which indicate that significant fractionation is retained even though the kinetic temperature is well above 100 K (see Table IV). The most likely explanation is that the observed deuterated molecules are "fossil" water, ammonia, methanol etc. resulting from efficient deuterium fractionation at low temperatures both in the gas and/or the grains, trapped onto grains throughout the cloud lifetime, and released only recently because of heating by a newly formed star (Plambeck and Wright 1987; Brown and

Millar 1989*a, b*; Walmsley 1992; see also the chapter Appendix and Fig. 3). If IRC2 is responsible for this heating, it cannot have existed for more than $\sim 10^4$ yr, because otherwise the deuterium enhancements would have been reset by chemical reactions to their high-temperature values. This time scale is comparable to that derived from the SiO and H₂O maser flows. Grain chemistry may also be responsible for the enhanced abundance of H₂CO, and for the conversion of unsaturated carbon-chain molecules into more hydrogenated species like ethyl cyanide, because the relevant gas phase routes are highly endothermic.

Finally, the importance of chemical mixing between active cores like Orion/KL and surrounding cloud material is demonstrated by the composition of the compact ridge source in the southwest. It is here that the abundances of complex oxygen containing organics such as CH₃OCH₃ and HCOOCH₃ peak. These species could either be produced by grain-mantle hydrogenation of CO, etc., or by gas-phase routes. An earlier gas-phase suggestion involving mixing of water from the plateau source with ion-rich gas from the ridge (Blake et al. 1987) does not appear to explain the observed abundances via an ion-molecule route when subjected to detailed numerical tests, although the direct injection of methanol from grain surfaces followed by an ion-molecule chemistry appears to be more promising (Millar et al. 1991*a*). These mixed gas/grain models could most likely account for the abundances, but do not currently explain why the chemical composition in the compact ridge is different from that in the hot core. Also, it is difficult with such models to account quantitatively for the observed selectivity, namely that dimethyl ether (CH₃OCH₃) and methyl formate (HCOOCH₃) are found to be much more abundant than their isomers ethanol (CH₃CH₂OH) and acetic acid (CH₃COOH). Another point in favor of a different chemistry in the compact ridge than that proposed for the hot core is provided by recent high angular resolution observations of methanol (Plambeck and Wright 1988; Wilson et al. 1989). If methanol and the other related species were produced by grain-mantle catalysis, then they should show observational correlation with other grain-mantle products. For example, ammonia, ethyl cyanide and water (as traced by HDO) show striking similarities by peaking at the hot core position. Methanol, however, appears to be *anticorrelated* with these species by peaking at the compact ridge; and thus any model which accounts for its chemistry cannot be similar in its details to the hot core. Specifically, a mechanism must be found to alter grain mantle chemistry on small size scales (cf. Tielens et al. 1991).

2. *Other Regions.* The Orion/KL observations show that several chemically distinct regions occur on scales of 2000 to 10,000 AU, corresponding to 5 to 25'' at the distance of Orion. Thus, for regions at greater distances observed with comparable beam sizes, we may expect enormous unresolved complexity if the region is at a similar stage in its evolution as Orion/KL. The Sgr B2 giant molecular cloud complex has been surveyed at various wavelengths and shows, not surprisingly, significant chemical heterogeneity on small angular scales (Goldsmith et al. 1987; Sutton et al. 1991). However, be-

cause these clouds are very far removed, the origin of the chemical variations is even less clear than in the case of Orion. Some regions with physical and chemical properties similar to the Orion hot core have recently been found, such as G 34.3+0.15 (Henkel et al. 1987; Heaton et al. 1989), but these are also at much larger distances. Distant massive GMC such as M 17 (see, e.g., Stutzki et al. 1988), W3 (see, e.g., Wright et al. 1984; Dickel and Goss 1987; Hayashi et al. 1989), NGC 7538 (Pratap et al. 1990), and NGC 6334 (Bachiller and Cernicharo 1990) show strong atomic and molecular emission lines, but have been studied in much less detail chemically and are difficult to interpret, owing to the poor spatial resolution.

The only other nearby molecular clouds with high-mass star formation which have been studied in some detail are the NGC 2024 region, also known as Orion B (see, e.g., Mundy et al. 1987; Barnes and Crutcher 1990), the region surrounding NGC 2071 IRS 1 (Yamashita et al. 1989; Zhou et al. 1990a) and the ρ Ophiuchi A and B cloud cores (see, e.g., Martin-Pintado et al. 1983; Zeng et al. 1984; Loren and Wootten 1986; Wootten and Loren 1988; Sasselov and Rucinski 1990; Loren et al. 1990), although the latter cases are sometimes classified under low-mass star formation. All these cores are known to have energetic molecular outflows, and molecules such as SO_2 , HCO^+ and even DCO^+ are readily detected. In addition, multitransition observations of H_2CO , NH_3 and CS have been used to constrain the density structure of the clumps. True molecular abundance gradients may be present across the cores, and molecules appear to be depleted from the gas phase in the densest parts (Mezger et al. 1992; Mauersberger et al. 1992). Another interesting study in this respect is that of Loren and Wootten (1986), who systematically observed a number of molecular lines at 3 positions in the ρ Ophiuchi A and B cores.

Because the observational data on these other regions are so fragmentary, it is difficult to establish any possible evolutionary sequence for the chemistry in high-mass star-forming regions. For example, is the 1'5 S source in Orion indeed at an earlier evolutionary stage than Orion/KL as argued by McMullin et al. (1992)? How long does the Orion/KL phase in which molecules such as SO_2 are so much more abundant last, and what is the underlying cause? What is the fate of the so-called photodissociation regions in, e.g., M 17, which are close to young hot stars? Is their fractional ionization too high for star formation to occur? More systematic studies on the chemical abundances in warm and cold dense clumps, such as those initiated by Loren and Wootten (1986) for ρ Ophiuchi, are needed to settle these issues. Clearly, only the warmest of them resemble Orion/KL in terms of chemical complexity, emphasizing the unique evolutionary state of this object.

Another important method to probe both the cold gas of the molecular core and the warm, dense gas close to the massive protostar is through infrared absorption lines toward embedded sources such as Orion BN/KL, AFGL 2591 and NGC 2264 (Scoville et al. 1983; Mitchell et al. 1989, 1990). Such studies are valuable not only to constrain the physical structure of the circumstellar gas

environment on much smaller scales than is currently possible with millimeter techniques, but may also provide information on the chemistry in this inner part, if extended to other molecules (Evans et al. 1991). Such high-resolution infrared observations are expected to become more important in the near future due to rapid technological advances in this area, and planned space-based missions such as the Infrared Space Observatory.

B. Low-Mass Star-Forming Regions

As noted above, by combining high angular resolution interferometric observations to image molecular distributions with broadband single-dish spectroscopic surveys to accurately constrain excitation and abundances, it has become possible to examine in detail the nature of the chemistry of bright sources such as Orion. Observations of fainter, low-mass star-forming regions have become possible only recently. We focus the discussion here on IRAS 16293–2422, one of the better studied examples of local low-mass star formation.

1. IRAS 16293–2422 Object. IRAS 16293–2422 is a young, far-infrared object of $27 L_{\odot}$ located in the nearby (160 pc) Ophiuchus cloud complex. It was originally identified as a possible protostar with a molecular outflow (Walker et al. 1986; Wootten and Loren 1987) and was suggested to have a spherically symmetric infall (Walker et al. 1986). While the claim for infall is still controversial (Menten et al. 1987), the central object associated with the far-infrared emission is a rich source of molecular line and long-wavelength dust emission.

Dust continuum emission from IRAS 16293–2422 has been observed at a wide range of wavelengths with the most revealing data being recent $\lambda = 2.7$ mm interferometer maps at high resolution ($4''.3 \times 2''.4$) (see Fig. 10d), which resolve this region into two components separated by 830 AU ($5''.2$) along a northwest-southeast axis (Mundy et al. 1986*b*, 1992). The majority of the dust in the system is contained in these two components which are coincident with weak centimeter emission from ionized gas (Wootten 1989). The southeastern source is marginally resolved with a source size of 640 AU ($4''$); the northern source is unresolved (FWHM < 200 AU; $1''.5$). Observations with the Kuiper Airborne Observatory at 50 and $100 \mu\text{m}$ have confirmed that the majority of the far-infrared emission emanates from these sources with a maximum allowable source size of $15''$ (Butner et al., in preparation). The overall spectral energy distribution of the region is well-fitted by 40 K dust with a λ^{-1} to λ^{-2} emissivity law. Recent groundbased 10 and $20 \mu\text{m}$ measurements have failed to detect emission, consistent with the cool dust temperature.

Interferometer maps of molecular line emission in the $\text{C}^{18}\text{O } J=1 \rightarrow 0$, $\text{NH}_3 (1,1)$ and $\text{CS } J=2 \rightarrow 1$ transition have revealed elongated gas structures coincident with the dust distribution (Mundy et al. 1990; Walker et al. 1990). The C^{18}O emission, seen in Fig. 10*a*, shows a velocity shift from northwest to southeast of 2.4 km s^{-1} consistent with orbital motion. Assuming point masses, the mass of the system is around $1.5/\sin i M_{\odot}$, where i , the orbital

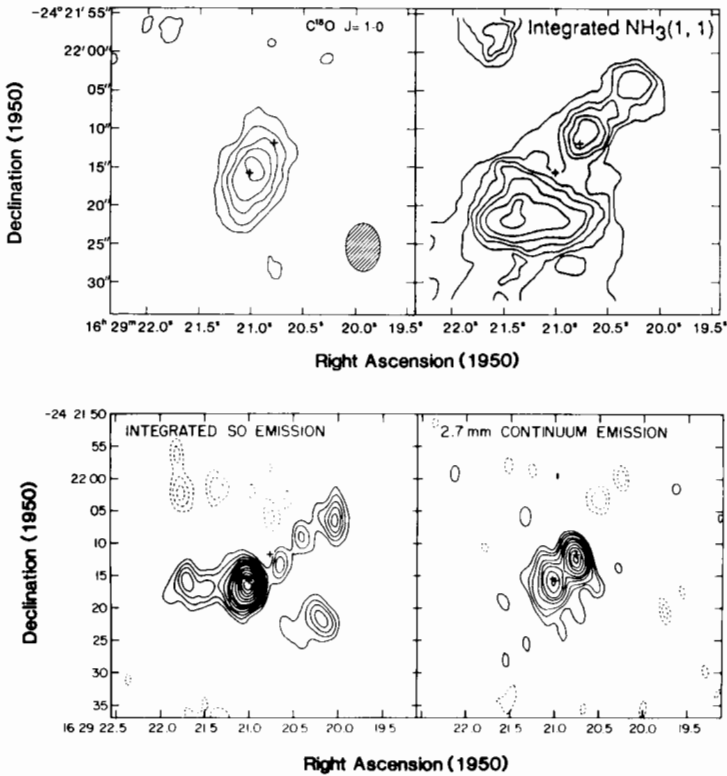

Figure 10. Composite of emission maps of IRAS 16293-2422. (a) Velocity integrated $\text{C}^{18}\text{O } J=1 \rightarrow 0$ emission obtained with the Owens Valley Interferometer at $6''.3 \times 4''.5$ resolution; (b) $\text{NH}_3(1,1)$ emission obtained with the VLA at $6'' \times 6''$ resolution; (c) and (d) Integrated $\text{SO } 2_3-1_2$ and 2.7 mm continuum emission mapped at $2''.4 \times 4''.2$ with the Owens Valley Interferometer. The pluses indicate the positions of the 2 cm radio sources. Note that the object has broken into two sources separated by 830 AU, but that the SO emission is mainly associated with only one of the two.

inclination, is likely to be near 90° . The $\text{CS } J=2 \rightarrow 1$ emission reveals a similar structure. On the other hand, the NH_3 emission, shown in Fig. 10b, arises from a larger (8000 AU diameter) region with a kinetic temperature of 15 to 20 K and a total mass of $\sim 0.2 M_\odot$ in the outer region. Yet a different distribution is seen for the SO molecule, as Fig. 10c demonstrates: very strong $\text{SO } 2_3-1_2$ emission arises from the southeastern component, but no detectable emission comes from the other component (Mundy et al. 1992). Finally, the $\text{HCO}^+ 1-0$ emission appears more associated with the outflow, being extended considerably NE-SW (Mundy 1990). Thus, at 500 to 800 AU resolution, the various molecular species exhibit significantly different spatial distribution, much as is the case in the Orion/KL region.

IRAS 16293–2422 therefore appears to be a very young binary system in which both components are still surrounded by significant amounts of gas and dust. The southeastern source is the more active of the two with the double-lobed radio emission, strong SO emission, as well as H₂O masers tracing its outflow activity (Wilking and Claussen 1987; Menten et al. 1990). The NH₃ emission appears to be distributed in a ring with radius 3000 to 4000 AU surrounding the central sources. The dearth of ammonia emission from the central components is likely to be due to an actual decrease in NH₃ abundance. These points are summarized graphically in Fig. 11.

Figure 11. Graphical depiction of the IRAS 16293–2422 molecular cloud core and circumstellar disk(s) (Mundy et al. 1990).

Single-dish spectra at submillimeter wavelengths cannot spatially resolve such distributions (see Table I), but can provide valuable information on the overall chemical composition of the region. Figure 12 demonstrates the quality of data that is now obtainable in only a few minutes of integration time (Blake et al. 1993). Many different molecules are readily detected, and in several cases more than one line is visible, so that rotation excitation diagrams can be constructed. The rotation diagram temperatures of SO₂ and CH₃OH are ~80 K, significantly higher than the dust temperature of 40 K.

The rich molecular spectrum observed for IRAS 16293–2422 does not, however, imply much higher abundances compared with, e.g., cold clouds. The main reason that the lines in this source are so strong is simply that the total

Figure 12. Composite of sub-millimeter spectra of IRAS 16293-2422 obtained with the CSO: (a) CH₃OH $J_K = 7_K \rightarrow 6_K$ band; (b) SO and SiO emission; (c) the HCN $J=4 \rightarrow 3$ transition with various SO₂ lines nearby; and (d) the HCO⁺ $J=4 \rightarrow 3$ transition. All spectra are double sideband, with the frequency ranges observed labeled on the top and bottom axes.

column density of matter is at least an order of magnitude higher compared with, e.g., TMC-1. In addition, the higher temperature and density facilitate observation of the high-lying transitions. The inferred abundances for IRAS 16293–2422 averaged over a 20'' beam are presented in Table VI, and are surprisingly similar to those found in the cold clouds, with the exception of SiO. Silicon monoxide is suspected to have at least moderate activation barriers which affect its formation, consistent with its larger abundance in IRAS 16293–2422 (Ziurys et al. 1989; Langer and Glassgold 1990), and is also enhanced by shock destruction of grains (Martín-Pintado et al. 1992).

One might therefore draw the conclusion from Table VI that the abundances of molecules like SO in low-mass regions such as IRAS 16293–2422 are not affected by the star-formation process. However, the interferometer observations of SO clearly show that this is an oversimplification, because the molecule is only concentrated around one of the two sources. The SO abundance in the southern source is close to the value listed in Table VI, but that in the northern source is roughly a factor 10 below even the dark-cloud value. As most of the protostellar activity arises from the southern source, it is tempting to speculate that the SO is in that case an interaction product of the outflow with the surrounding molecular material, which probably releases sulfur and oxygen back into the gas phase, much the same as in the Orion plateau source. However, the similarity of the SO abundance in the southern source and that in cold clouds suggests that this process is not very effective, presumably because the outflow is less powerful than in Orion. The difference with the northern source may result from larger depletion of SO onto grains. The northern source is presumably younger than the southern one, given its unusual continuum flux distribution and the lack of an outflow (Mundy et al. 1992).

The disparity in relative distributions of C¹⁸O and NH₃, seen in Fig. 10, may shed additional light on this question. It is clear that gas-phase NH₃ is down by at least an order of magnitude in the inner core. This behavior is also seen in ammonia relative to CS and dust in the more massive NGC 2071 IRS1 region (Zhou et al. 1990a). The question is whether the NH₃ surrounding IRAS 16293–2422 is remnant interstellar cloud material, or whether it has been depleted and/or formed on grains in the inner part and subsequently returned back to the gas phase. If anything, the NH₃ abundance around the northern source appears larger than that in the southern part, opposite to the case of SO. It should be recalled that variations in the NH₃ abundance on small scales have also been seen in cold clouds such as TMC-1 and L 134N, where freeze-out is probably not the explanation. On the other hand, NH₂D is also prominent in IRAS 16293–2422 with NH₂D/NH₃ $\approx 3 \times 10^{-3}$, as are other deuterated molecules such as HDCO. This amount of deuterium fractionation is similar to that found for the Orion hot core, where it is thought to result from grain-surface processes. Water is predicted to have the largest abundance and excitation contrast between the protostellar source and the surrounding molecular cloud, but is presently unobservable due to atmospheric attenuation

TABLE VI

Abundances of Selected Molecules in Quiescent and Star-Forming Clouds^a

Species	Low-Mass Star Formation				High-Mass Star Formation			
	TMC-1 S	Ref. ^b	L 134N	Ref. ^b	IRAS 16293-2422	Ref. ^b	Orion/KL Plateau	Orion Hot core

even at airborne altitudes, except for the masing lines. However, the HDO abundances may exhibit similar characteristics, so that further searches for this species in star-forming regions will be very valuable.

2. Other Regions. Many other dark cloud cores in which low-mass star formation is currently taking place have been observed in a variety of molecules. Most of these cores, such as B1, B5, B335 and L1551, contain extended bipolar outflows, and have associated IRAS or far-infrared sources, with luminosities ranging from <5 to $30 L_{\odot}$. As for the high-mass regions, they have been studied principally in lines of the CO, NH_3 , CS and H_2CO molecules with the aim of deriving the physical structure of the clouds (Fuller and Myers 1987; Benson and Myers 1989; Zhou et al. 1989; Menten et al. 1989; Zhou et al. 1990*b*). Little coherent information is available on the chemistry in these cores. Single-dish data are available for a number of molecules scattered throughout the literature, but they have often been obtained with widely different beam sizes ranging from $20''$ to $5'$, which complicates the determination of relative abundances. Nevertheless, as mentioned in Sec. III.C, it appears that long carbon-chain molecules are much less abundant in star-forming regions than, e.g., in the southern part of TMC-1. On the other hand, molecules such as NH_3 and CH_3OH seem to have abundances similar to those found in, e.g., L 134N. A recent study of the B1 cloud indicates that its SiO abundance is enhanced compared with TMC-1, especially in the direction of the IRAS source located near the center of the NH_3 core where high-velocity CO gas has also been found (Bachiller et al. 1990*b*). The same trend as observed for IRAS 16293–2422, namely that most molecular abundances are similar to those in cold clouds, but that selected species such as SiO are enhanced, thus appears to occur in other star-forming clouds. On much smaller scales, however, significant chemical gradients may be present.

An intriguing case for further study is provided by the B5 cloud, which has been mapped in detail in CO by Goldsmith et al. (1986) and Fuller et al. (1991). They suggest that in B5 (and probably in most other low-mass star-forming regions) material cycles continuously between the clumps and a tenuous interclump medium, on a time scale of a few Myr (Charnley et al. 1990). The clumps are formed in the collapse of the interclump gas, and are destroyed by T Tauri winds from stars forming at the centers of the clumps. Dynamical models for this scenario have been constructed by Charnley et al. (1988, 1990), but not enough observations of other species in B5 have yet been reported to test them in detail. Nevertheless, such models are an important first step to include the star-formation process into the chemistry of a cloud as a whole.

IRAS 16293–2422 is the only low-mass protostellar disk in which the chemistry has been studied in some detail using interferometer techniques. Observations of the distribution of molecules other than CO on scales of 500 to 1000 AU in well-established circumstellar disks such as those of HL Tau and T Tau are becoming feasible with current interferometer facilities, and significant advances in our understanding are expected in the coming years

(Ohashi et al. 1991). These young stellar objects are clearly at a further stage in their evolution, as most of the associated molecular cloud material has been dispersed already. As a result, the molecular lines are much weaker than those seen in, e.g., IRAS 16293–2422, when observed with a single-dish telescope at 20 to 30'' resolution because of the smaller *averaged* column densities. Initial studies by Blake et al. (1992) suggest that the abundance and excitation of molecules like CS may be different in the circumstellar disk of HL Tau compared with, e.g., IRAS 16293–2422. In particular, polar molecules like CS appear significantly depleted from the gas phase. The observed molecular abundances in disks may eventually help to place limits on the distance at which the transition from LTE chemistry to interstellar chemistry occurs, and to probe the chemistry which occurs across the accretion shock.

Of particular chemical interest is the recent detection of extremely high-velocity molecular flows associated with young stellar objects (Lizano et al. 1988; Koo 1989,1990; Masson et al. 1990; Bachiller et al. 1990*b*). The best-studied case is that of HH 7–11, where CO with velocities extending up to 160 km s⁻¹ from line center has been found. The major question is whether the CO is present in the jet itself, or whether it is ambient material which has recently been swept up by the jet. The first possibility was suggested by Lizano et al. (1988), and detailed chemical models of molecule formation in fast winds were developed by Glassgold et al. (1989,1991). They find that significant quantities of CO can indeed be formed in the winds, provided that the temperature decreases rapidly with distance from the protostar. However, Masson et al. (1990) argue on the basis of higher spatial resolution data that the high-velocity CO is mostly swept-up ambient material accelerated by the interaction with the jet. The high-velocity CO is found to be highly localized and coincides with the strong HCO⁺ (Rudolph and Welch 1988) and shocked H₂ emission (Garden et al. 1990). The main difficulty with this model is that the CO is unlikely to survive such a powerful shock. Searches for atomic species such as C I should indicate whether some of the CO has indeed dissociated downstream. Detailed chemical models for this scenario are being developed by Wolfire and Königl (1991). It would be interesting to determine how ubiquitous these extremely high-velocity flows are, and whether they represent a specific phase in the evolution of young stellar objects.

3. *An Evolutionary Chemical Sequence?* Although the discussion in the previous sections has been highly fragmentary, an attempt has been made in Table VI to summarize the abundances of a few characteristic species in an evolutionary sequence. The earliest stage is thought to be formed by the TMC-1 S position, which is very rich in large carbon-chain molecules, and which is presumably very young, <1 Myr. The next phase is given by cold cores such as L 134N, in which no star formation has yet occurred or in which nearby star formation is in its very earliest stages. These clouds are characterized by an absence of complex carbon-bearing molecules, and by larger abundances of NH₃ and SO. The related stage, in which the molecular cloud core has collapsed and in which a young star is being formed, has not yet

been clearly identified, but most molecules are expected to be condensed onto grains at this phase, complicating the detection (Rawlings et al. 1992). These stages are followed by that of the IRAS 16293–2422 core, in which low-mass star formation is obviously taking place, but in which the young star is still surrounded by a significant amount of the original cloud material. A powerful outflow has already developed, although accretion may still be occurring. At this point, the source has a rich molecular spectrum, mostly because of the large mass associated with it and because of the higher temperatures and densities. Many molecular abundances are still similar to those found in L 134N, but interferometric images show dramatic variations of at least a factor 10 on the 500 to 600 AU scale. Thus, the low-mass star-formation process may alter molecular abundances selectively, but the degree of alteration is not as severe as for the high-mass case, at least not at the point of evolution of IRAS 16293–2422. Finally, the young stellar object reaches the stage in which most of the surrounding cloud material has been blown away and a well-established circumstellar disk remains, such as seen for HL Tau and T Tau. When viewed with 20 to 30'' beams, these objects do not contain strong molecular lines, although species such as HCN and HCO^+ are readily detectable in T Tau. Much higher spatial resolution is necessary to probe the chemistry in the circumstellar disks.

V. ABUNDANCES OVERVIEW

In Secs. III and IV, a discussion of abundances and small-scale chemical heterogeneity has been given at various stages of the star formation process. These sections focused mostly on those molecules whose abundances are most affected by the star-formation process, but which are often only minor species in terms of overall composition. Here we investigate more quantitatively the actual composition of the major species in the various regions and the fraction of elemental abundances locked up in the different molecules in the gas or solid phase. All fractional abundances have as reference the solar abundances quoted in Sec. II.

A. GENERAL DISCUSSION

1. Gas-Phase Overview. In Tables V and VI, the observed molecular abundances in the various clouds have been summarized. Inspection shows that this list contains mostly molecules with very small abundances of $<10^{-7}$, which lock up only a small fraction of the available elements. Only carbon monoxide may contain up to 25% of the carbon budget. As noted in Sec. II, virtually no observational constraints on the principal oxygen and nitrogen species are available, because neither H_2O , nor O_2 , O, N_2 or N can be observed in cold clouds directly from the ground. In what form are these elements? Model results are unfortunately not very reliable. The models of Herbst and Leung (1989), which use $f \approx 0.5$ for the branching ratio to H_2O and OH in the H_3O^+ dissociative recombination, predict that most of the

gas-phase oxygen is taken up in steady state by O_2 , followed by O and H_2O in proportions 1:0.46:0.04. If cosmic-ray-induced photodissociation is included, Gredel et al. (1989) predict oxygen to be mostly in atomic form, with $O:O_2:H_2O = 1:0.25:0.20$. It appears that there is no consensus yet about the dominant form of gas-phase oxygen, which may affect the model predictions for other molecules in the clouds as well. In warm clouds, indirect limits on the gas-phase O_2 abundance have been obtained from searches for the $^{16}O^{18}O$ transition at 234 GHz (Black and Smith 1984; Goldsmith et al. 1985; Liszt and Vanden Bout 1985), which indicate $O_2/CO < 0.1-0.5$. In such clouds, the higher-lying transitions of H_2O can also be observed, but lead to abundances of gas-phase H_2O with respect to CO of only 1 to 10%. Thus, neither O_2 nor H_2O appear to tie up a significant fraction of the oxygen budget in the gas phase.

Some indirect limits on the N_2 abundance are available from observations of the N_2H^+ ion. For the well-studied case of L 134N, $N_2/CO \approx 0.08$ is found, corresponding to $N_2/H_2 \approx 8 \times 10^{-6}$, if $CO/H_2 \approx 10^{-4}$. For comparison, $NO/CO \approx 7 \times 10^{-4}$ and $NH_3/CO \approx 10^{-3}$, so that N_2 is apparently the dominant nitrogen-bearing molecule, consistent with the steady-state models (McGonagle et al. 1990; Womack et al. 1992; van Dishoeck et al. 1992). However, the amount of nitrogen still unaccounted for may be as large as 90%. Part of this nitrogen is probably in the form of atomic nitrogen, which is predicted to be the dominant form at early times, and part of it may be depleted onto grains.

2. Solid-Phase Overview: Refractory Components. The refractory grain cores are thought to lock up a substantial fraction of the chemically active elements Si, Fe and C. Several types of refractory material appear to be present, based on the spectral features produced by dust in diffuse clouds: these spectral features are listed in Table VII. For each spectral feature, this Table gives: (1) the central wavelength λ ; (2) $\Delta\tau_\lambda/N_H$, the maximum optical depth per H atom; (3) $\Delta\tau/N_H$ integrated over $d\tilde{\nu}$ (where $\tilde{\nu} \equiv \lambda^{-1}$); (4) proposed identification(s); (5) for each identification X , the expected value of σ_λ , the cross section per X at band center; (6) the "band strength" $\int \sigma d\tilde{\nu}$; and (7) the abundance of X (relative to H) required to account for the observed feature.

The strong interstellar $9.7 \mu m$ feature is identified as the Si-O stretching mode in amorphous silicate material. The identification as silicate appears to be secure. First, silicates are theoretically expected as major condensates in cooling gas with cosmic abundances; second, the feature is seen in *emission* in dusty outflows from oxygen-rich red giants; and third, the expected feature due to O-Si-O bending is seen at $\sim 18 \mu m$. The strength of the $9.7 \mu m$ feature demands that a substantial fraction of the refractory material be in some form of silicate, perhaps amorphous olivine ($Mg_xFe_{1-x}SiO_4$), containing practically 100% of the interstellar Si and Fe (see, e.g., Draine and Lee [1984] for a discussion of the silicate band strength and the depletion of interstellar Si). Assuming 4 O per Si, and $\delta_{Si} \approx 1$, these silicate grains probably account for $\delta_O \approx 0.17$ of the oxygen.

^a For mean extinction law with $N_{\text{H}}/E(B-V) = 5.8 \times 10^{21} \text{ cm}^{-2}$ (Bohlin et al. 1978), $E(B-V)/E(J-K)=1.91$ (Rieke and Lebofsky 1985), $A_{9.7} = 0.35E(J-K)$ (Roche and Aitken 1984; Draine 1989a), $\Delta A_{9.7} \approx 0.30 E(J-K)$ (cf. Draine 1989a).

^b Notes: 1. $\Delta\tau/N_{\text{H}}$ is based on mean Drude fit parameters of Fitzpatrick and Massa (1986); 2. σ_λ is for 2:1 oblate spheroids with $a_{\text{eff}} < 0.01 \mu\text{m}$ (Draine 1989b), and assumed density $\rho = 2 \text{ g cm}^{-3}$; 3. From $W_{.433}/E(B-V)=2.04 \text{ \AA}$ for 25 stars, and $\Delta\tau/W = 0.51/\text{\AA}$ toward HD183143 (Herbig 1975). Here $f_{.433}$ is the (unknown) oscillator strength for the $0.443 \mu\text{m}$ band; 4. From $W_{1.32}/E(B-V)=0.42 \text{ \AA}$ and $\text{FWHM}=4.0 \text{ \AA}$ (Joblin et al. 1990). Here $f_{1.32}$ is the (unknown) oscillator strength for the $1.32 \mu\text{m}$ band; 5. $\Delta\tau/N_{\text{H}}$ is estimated from $\Delta\tau_{3.4}$ toward Galactic center (McFadzean et al. 1989) and VI Cyg 12 (Adamson et al. 1990), with N_{H} estimated from $\Delta\tau_{9.7} \approx 3.6$ toward GC (Roche and Aitken 1985) and 0.6 toward VI Cyg 12 (Roche and Aitken 1984); 6. $\int \Delta\tau d\tilde{\nu}/\Delta\tau_{3.4} = 100 \text{ cm}^{-1}$ from GC-IRS7 (Burchart et al. 1986; Adamson et al. 1990); 7. σ_λ and $\int \sigma d\tilde{\nu}$ for hydrogenated amorphous carbon with $H/C \approx 0.5$ (Dischler et al. 1983); 8. $\int \sigma d\tilde{\nu} = A_{3.82} \times 10^{-17} \text{ cm}$, where $A \approx 0.1-0.5$ per C in saturated hydrocarbons (Wexler 1967); we take $A \approx 0.25$; 9. $\Delta A_{9.7}/E(J-K) \approx 0.30$ (see footnote a). Note, however, that Cohen et al. (1989a) argue for a significantly smaller value; 10. $\int \Delta\tau d\tilde{\nu}/\Delta\tau_{9.7} \approx 250 \text{ cm}^{-1}$ based on μ Cep emissivity of Roche and Aitken (1984); 11. σ_λ and $\int \sigma d\tilde{\nu}$ are estimates based on assumption that features are produced by silicates with approximately cosmic silicon abundance $\sim 4 \times 10^{-5}$; 12. $A_{19}/A_{9.7} \approx 0.4$ (cf. Draine 1989a). The $19 \mu\text{m}$ feature is broad and blended with long-wavelength tail of $8.7 \mu\text{m}$ feature; choice of baseline is therefore difficult. We take $\Delta A_{19} \approx A_{19}$. $\int \tau d\tilde{\nu}$ is integrated from $15-23 \mu\text{m}$.

There are several reasons for believing carbon to be an important component of diffuse-cloud dust. The most prominent interstellar extinction feature is the 2175 Å “bump” (see the recent review by Draine 1989*b*). While noncarbonaceous “carriers” such as OH[−] on small silicate grains have been proposed (Steel and Duley 1987), the λ 2175 Å feature is generally attributed to $\pi \rightarrow \pi^*$ transitions in small ($a \lesssim 100$ Å) grains of graphite or some other carbon-rich material. If due to graphite, $\delta_C \gtrsim 0.15$ is required to account for the 2175 Å feature.

A broad extinction feature at 3.4 μm has been seen toward the Galactic center and recently detected toward VI Cyg No. 12 (Adamson et al. 1990) and other sources (Sandford et al. 1991). Existing upper limits do not rule out the presence of this feature on *all* diffuse-cloud lines of sight. The feature is generally considered to be due to C-H stretching modes, but the specific material is uncertain. If due to hydrogenated amorphous carbon (HAC), as proposed by Duley et al. (1989), the HAC must lock up $\delta_C \approx 0.45$, based on the bandstrength measured by Dischler et al. (1983). If, on the other hand, the feature is due to some mixture of saturated hydrocarbon molecules, perhaps only $\delta_C \approx 0.05$ – 0.10 may be required (cf. note 8, Table VII; Sandford et al. 1991).

In addition to the above features, there is a large number of so-called “diffuse interstellar bands” which remain unidentified. Two diffuse interstellar bands have been selected for inclusion in Table VII: the strongest at 4430 Å and the longest-wavelength DIB at 1.32 μm . If these features are due to “allowed” electronic transitions with oscillator strengths $f \gtrsim 0.1$, then the features could be ascribed to minor trace constituents of the grains. On the other hand, if the 4430 Å feature is caused by a “forbidden” electronic transition with $f \lesssim 10^{-3}$, then the substance responsible for the feature could contribute a significant fraction of the interstellar grain mass. The 1.32 μm feature is much weaker, but might be due to a vibrational mode, perhaps an overtone of a “fundamental” band at 2.6 or 4.0 μm , in which case an oscillator strength $f \lesssim 10^{-4}$ would be expected, and the material responsible could possibly be a significant grain constituent.

Finally, recent models to explain either the infrared emission features observed in the 3.3 to 11 μm range toward reflection nebulae (see, e.g., Léger and Puget 1984; Léger et al. 1989; Allamandola 1989) or the 12 to 60 μm emission observed by IRAS (Draine and Anderson 1985) postulate the existence of large numbers of clusters of 25 to 200 carbon atoms, which may be considered either as large molecules such as the PAH or ultra-small grains. Models which attempt to quantitatively account for both the near-infrared emission features and the continuous emission from 1 to 20 μm appear to require $\delta_C \approx 0.1$ in these ultra-small grains (Léger et al. 1989; Désert et al. 1990).

What overall depletions are therefore expected for C in the different refractory grain models? The “graphite-silicate” model (Draine and Lee 1984) has $\delta_C \approx 0.62$ in graphite grains, assuming a density $\rho = 2 \text{ g cm}^{-3}$ for the

graphite grains; the model of Duley et al. (1989) has $\delta_C \approx 0.45$ in hydrogenated amorphous carbon coatings on the silicate grains; and Greenberg's model (Greenberg 1989a, b; Hong and Greenberg 1980) uses $\delta_C \approx 0.64$, of which ~ 0.39 is in a photoprocessed refractory organic residue coating the silicates, and ~ 0.25 in small graphitic grains. A reasonable estimate would appear to be $\delta_C \approx 0.6 \pm 0.2$.

3. *Solid-Phase Overview: Volatile Components.* In dark clouds, new spectral features make their appearance, which are attributed to the presence of icy mantles deposited on top of the refractory grain cores. The strongest feature is the $3.08 \mu\text{m}$ feature which is securely identified as amorphous H_2O ice. A list of well-established absorption features and their proposed identifications is given in Table VIII; the reader is referred to several recent review articles (Tielens and Allamandola 1987a, b; Whittet 1988, 1992; Tielens 1989) in which the observations and identifications are discussed. Table VIII is organized in a manner similar to Table VII, except that: (1) the observed feature strengths in column 2 are given relative to the strength of the $3.08 \mu\text{m}$ feature; (2) column 3 gives the observed "width" of the feature in cm^{-1} ; and (3) proposed abundances are given relative to H_2O . Many of these absorption features have been discovered only recently due to rapid improvements in the sensitivity and resolution of infrared spectrometers.

Only for H_2O , CO , CH_3OH , and possibly CO_2 are the identifications secure. Basic laboratory spectroscopy of icy mixtures is needed to remove the many remaining question marks in Table VIII. A $2.97 \mu\text{m}$ feature in the spectrum of BN, originally attributed to NH_3 mixed with H_2O (Knacke et al. 1982), has recently been ascribed to scattering into a large beam by H_2O grains (Knacke and McCorkle 1987), although this explanation has been questioned by Smith et al. (1988, 1989), who argue that the $2.97 \mu\text{m}$ feature is a true absorption feature. Of particular interest are the recent possible identifications of solid CO_2 and solid CH_4 . The presence of solid CO_2 has been proposed by d'Hendecourt and de Muizon (1989) on the basis of IRAS LRS spectra toward two stars. The inferred abundance of solid CO_2 is comparable to that of solid CO . Unfortunately, no solid H_2O data are available for these same lines of sight. Solid CH_4 has tentatively been identified by Lacy et al. (1991) from high-resolution spectra toward W33A and NGC 7538, with an abundance comparable to that of solid CO .

It is important to realize that Table VIII attempts to summarize a highly inhomogeneous set of data—some of the weaker features have only been detected on a single line of sight (toward W33A), and the possible variability relative to H_2O for these features is therefore unknown. Even along a single line of sight, different grain components may be present (Tielens et al. 1991). Note also that our depletion estimates, based on the ratio $\Delta \tau_{3.08} / \Delta \tau_{9.7}$ (because the total column density N_{H} cannot be measured directly) are somewhat uncertain because of the need to correct for silicate emission features in the spectra of the sources. Finally, most of the data in Table VIII refer to clouds

in which star formation has already occurred, so that part of the mantles may have evaporated.

For each identification in Table VIII, the inferred abundance relative to H_2O is listed. It is evident that the abundances are in general small compared to H_2O . The only possible exception is CH_3OH , for which the abundance (and therefore the identification) is controversial: the $3.53\ \mu\text{m}$ band gives a much lower abundance than the $6.85\ \mu\text{m}$ band, which may indicate that the $6.85\ \mu\text{m}$ band is primarily due to some other substance, e.g., NH_4^+ (see also Schutte et al. 1992). Using $\Delta\tau_{9.7}/N_{\text{H}}$ from Table VII, and $\sigma_{3.08}$ from Table VIII, we obtain

$$\frac{N(\text{H}_2\text{O, ice})}{N_{\text{H}}} \approx 4.4 \times 10^{-5} \frac{\Delta\tau_{3.08}}{\Delta\tau_{9.7}} \quad (2).$$

Excluding the stars Elias 3, 16 and 18, for which the measured silicate absorptions may be suspect, the largest value of $\Delta\tau_{3.08}/\Delta\tau_{9.7}$ found in the Taurus clouds is 1.2 (Whittet et al. 1988), indicating that H_2O contains up to $\delta_{\text{O}} \approx 0.06$ of the total oxygen. The largest value of $\Delta\tau_{3.08}/\Delta\tau_{9.7}$ reported for dense clouds is 0.8 toward AFGL 961 (Willner et al. 1982), implying that $\sim 4\%$ of the oxygen is in the form of solid H_2O in this cloud. In no case has the bulk of the oxygen been found to be condensed into solid H_2O . The amount of carbon taken up in ices is even less: at most 1% is found in solid CO , CO_2 or CH_4 . Up to 5% of the nitrogen may be in the form of solid NH_3 .

In summary, the refractory and volatile-grain components together contain up to 23% of the available oxygen in the cloud in known species, about $60 \pm 20\%$ of the disposable carbon, close to 100% of the available silicon and iron, but only a few % of the nitrogen. Substantial amounts of oxygen and nitrogen may still be tied up in unobservable species such as solid O_2 and N_2 .

B. Orion/KL Abundances

Because Orion/KL, and in particular the hot core, is one of the best chemically characterized sources, it is instructive to summarize the observed gas-phase and grain-surface abundances for this case in detail. Orion has several observational advantages over other regions. First, it is warm so that lines of molecules like H_2O which are not excited in cold clouds become observable. Second, at least two bright embedded infrared sources, BN and IRC2, are available against which absorption line observations of both solid dust features and molecules can be performed. Absorption lines toward IRC2 sample mostly hot core material, whereas those toward BN probe mainly extended ridge material and a little bit of the high-velocity plateau gas, in addition to the immediate circumstellar gas and dust.

The results are summarized in Table IX. It is seen that CO is by far the most abundant gas-phase molecule in the hot core with $\text{CO}/\text{H}_2 \approx 1.2 \times 10^{-4}$, accounting for $\sim 15\%$ of the carbon in the cloud. The amount of atomic C in the gas phase is uncertain, but is unlikely to be more than 10% of that of CO , and may be as low as 1% in the hot core. Limits on the CH_4 abundance of $\text{CH}_4/\text{CO} < 0.01$ have been obtained from searches for the millimeter CH_3D

lines (Blake et al. 1987), and from limits on the infrared absorption lines of CH_4 toward BN (Knacke et al. 1985, 1988b). These limits are consistent with the probable discovery of CH_4 by Lacy et al. (1991) toward IRC2 at a level $\text{CH}_4/\text{CO} \approx 10^{-3}$. Acetylene, C_2H_2 , has also been detected toward IRC2 with an abundance $\text{C}_2\text{H}_2/\text{CO} \approx 10^{-3}$ (Lacy et al. 1989b). Thus, neither gas-phase methane nor acetylene are significant, and the total amount of carbon accounted for in the gas phase is about 15%. The amount of carbon in the solid phase has been estimated to be $60 \pm 20\%$, so that at most a small fraction of the carbon could be hidden in some as yet unidentified species.

In contrast, the oxygen budget in the cloud is much more uncertain. H_2O has been observed directly in Orion by its transitions at 183 GHz (Waters et al. 1980) and 380 GHz (Phillips et al. 1980) from the Kuiper Airborne Observatory, but because these lines arise from high-lying levels, the inferred abundances are quite uncertain. Very recently, the 183 GHz line has also been detected by groundbased observations at much higher angular resolution (Cernicharo et al. 1990). More reliable estimates can be made from observations of the optically thin H_2^{18}O 203 GHz line, which lead to $\text{H}_2\text{O}/\text{H}_2 \approx 10^{-5}$ in the hot core (Phillips et al. 1978; Jacq et al. 1988, 1990). An unsuccessful search for the lowest 547 GHz transition of H_2^{18}O gives $\text{H}_2\text{O}/\text{CO} < 0.01$, but this limit probably applies to the extended ridge rather than the hot core (Wannier et al. 1991). Infrared absorption lines of gas-phase H_2O have probably been seen toward BN, leading to $\text{H}_2\text{O}/\text{CO} \approx 0.03 \pm 0.02$ (Knacke et al. 1988b; Knacke and Larson 1991). As mentioned in Sec. IV, HDO is readily detected in the hot core with an abundance $\text{HDO}/\text{H}_2 \approx 5 \times 10^{-8}$ (Blake et al. 1987; Plambeck and Wright 1987; Jacq et al. 1990), suggesting $\text{HDO}/\text{H}_2\text{O} \approx 0.004$. Thus, many lines of evidence indicate that the gas-phase H_2O abundance in Orion/KL is significantly less than that of CO, and accounts for at most a few % of the total oxygen budget. Indirect limits on the gas-phase O_2 abundance from searches for the $^{16}\text{O}^{18}\text{O}$ 234 GHz transition give $\text{O}_2/\text{CO} < 1$ for the Orion hot core (Blake et al. 1987), so that only a few % of the oxygen can be locked up in O_2 . Atomic oxygen can be observed by its fine-structure transitions at 63 and 145 μm from airborne platforms. Strong O I 63 μm emission in Orion has been observed by Werner et al. (1984), but the interpretation is complicated by the fact that it arises partly in the shocked plateau gas, and partly in the photodissociation region close to the Trapezium stars. Nevertheless, conservative estimates of the atomic oxygen abundance in the hot core region indicate $\text{O}/\text{CO} < 1$. Gas-phase CO itself takes up $< 10\%$ of the available oxygen. CO_2 could conceivably be an important oxygen-bearing molecule, but cannot be observed directly in the gas phase by millimeter transitions. The protonated version HOCO^+ has not been detected in Orion. In other molecular clouds, limits of $\text{CO}_2/\text{CO} < 0.01$ have been inferred, except for the galactic center where $\text{CO}_2/\text{CO} \approx 1$ (Minh et al. 1988).

In summary, at most 25% of the oxygen in the Orion hot core is detected in gas-phase species. As discussed above, another 20 to 25% may be locked up in known species in grains. This leaves more than 50% of the oxygen

TABLE IX
Observed Abundances X/H_2 in Orion

Species	Hot Core	Ref. ^a	Ext. Ridge/ BN	Ref. ^a	Other Clouds	Ref. ^a	Abundance
Gas phase:							
CO	1(-4)	1	5(-5)	1	(0.5-2)(-4)	2	15-40% of C; few % of O

budget unaccounted for, assuming solar abundances. If, however, the oxygen abundance in Orion is indeed significantly less than solar (cf. Sec. II.C), the major oxygen species may have been identified.

On the basis of the models, most of the gas-phase nitrogen is thought to reside in the form of N_2 , but observations of the N_2H^+ ion suggest that it takes up at most a few %. The ammonia abundance in the hot core is controversial, but may be as low as 10^{-7} (see Table IX), i.e., similar to that found in cold clouds. A few % of the nitrogen may be in the form of solid NH_3 . This leaves more than 90% of the nitrogen in unobserved species. It is likely that a significant fraction of this is in the form of gas-phase N and N_2 .

It is thus concluded that in spite of the fact that Orion/KL is one of the best studied sources in the sky, major uncertainties remain in the principal oxygen and nitrogen reservoirs in these clouds. Even less is known about the extent to which the abundances of these major species are influenced by the star formation process, and about the form in which they enter a solar nebula.

VI. CHEMICAL EVOLUTION OF THE SOLAR NEBULA

A. Chemical Processes

Gases and solids processed in the star-forming region in which the Sun was born eventually fall into the solar nebula where they undergo further chemical and physical transformations before incorporation in solid bodies. A general discussion of chemistry in protoplanetary nebulae is provided in the chapter by Prinn and Chang. Here, we outline the driving physical processes behind the chemistry and the implications for the fate of infalling cloud material, with particular emphasis on how the original chemical and physical mix has been altered. Gases and grains may experience, in rough order, the nebular accretion shock, drag heating of grains, transport of grains radially and consequent thermal chemistry, and energetic chemistry associated with lightning, nebular flares, and ultraviolet irradiation. Additionally, some material may find its way into the denser nebulae surrounding the forming giant planets, and be further altered there (see Chapter by Lunine and Tittlemore). Condensation of volatiles and/or trapping in a more refractory matrix are the final processing steps considered here. Figure 13 summarizes these processes graphically.

A wide range of solar nebula models exist in the literature (see Chapters by Morfill et al. and by Palme and Boynton). For our purposes, the following, somewhat generalized properties are invoked: (1) the nebula has a radial temperature which decreases with increasing distance; (2) the nebular gas is crudely of solar composition; (3) the nebula gains material in the form of gas and grains from the surrounding interstellar cloud which has a composition described in Secs. II–IV, and summarized in Tables V–IX. Thus, while specific models of chemical modification of infalling material require a very specific set of nebular physical processes, the following discussion is framed in a more general way to illustrate more clearly the principles involved. The inner nebula is crudely defined as the region up to 5 AU, whereas the outer

Figure 13. Schematic illustration of the physical and chemical processes in the solar nebula, illustrating the complex interplay between different parts of the nebula, between the nebula and the infalling interstellar cloud material, and between the solar nebula and sub-nebulae surrounding the giant planets. Two processes which further affect the material but which are not shown are an accretion shock, and drag heating of infalling grains (Lunine 1989c).

nebula extends to about 100 AU. In such a model, the density is roughly 10^{14} cm^{-3} and the temperature $T \approx 800 \text{ K}$ at 1 AU, decreasing to 10^{11} cm^{-3} and 80 K, respectively, at 15 AU. Thus, the densities are much higher than those found in the molecular cloud cores from which stars like the Sun formed, and three-body processes are important in the chemistry.

1. Thermal Chemistry in the Nebula. Prinn and Fegley (1989) computed the energy available for chemical processing of material by various nebular mechanisms, and concluded that, because of the high densities, thermal equilibrium chemistry (i.e., that driven at a sufficiently high rate by virtue of the gas temperature) was by far the most important. They also reviewed the important reaction schemes associated with interchange of carbon-, oxygen- and nitrogen-bearing species. As one proceeds radially outward in the nebula, the direction of the reactions is generally such as to increase the abundances of the reduced species in the gas. Thus, in thermodynamic equilibrium, methane would increase at the expense of carbon monoxide in the outer nebula, and ammonia at the expense of molecular nitrogen (Lewis and Prinn 1980). At lower temperatures, carbon dioxide is also produced at the expense of carbon

monoxide, though the compositional gradient is less steep than for methane. However, the reaction rates are strongly temperature dependent, and can be represented as an Arrhenius relationship for the rate-limiting step, and therefore the molecular abundances in a parcel of nebular gas depend rather sensitively on the length of time that parcel retains its identity and radial location. In other words, physical mixing time scales, and in their absence, the dynamic lifetime of the nebula, determine the gas-phase abundances radially outward from the chemically-active zone. Some of the key reaction rates, particularly those of the carbon species, are poorly known (Yung et al. 1988). A final complication is that the chemical-reaction rates can be greatly accelerated by catalyzing the processes on metal grains (Vannice 1975).

As a result of all these processes, the outer nebula is expected to contain less CH_4 and NH_3 than would be expected on the basis of equilibrium considerations, if the carbon arrives mostly in the form of CO and the nitrogen in the form of N_2 from the interstellar cloud. For example, using the graphs in Prinn and Fegley (1989), the recently determined interstellar value of CH_4/CO (gas plus grains) of 0.01 (Lacy et al. 1989b) would be reproduced thermochemically in the nebula at a temperature of roughly 750 K. However, this high a ratio could be achieved within reasonable nebular mixing times only if grain catalysis were efficient; in the absence of such catalysis, quenching would occur at a CH_4/CO ratio 5 orders of magnitude smaller. Conversely, significantly larger mixing ratios of methane in the outer nebula would require lower quench temperatures (i.e., the temperature at the nebular radius at which the chemical destruction time equals the radial mixing time), which are likely to have been unachievable during the astrophysical lifetime of the nebula (of order 1 Myr).

2. *Mixing of Inner and Outer Nebular Material.* In the absence of any radial mixing of nebular gases, two chemically distinct zones would occur: an inner zone in which material comes to chemical equilibrium, and an outer region whose composition reflects that of the "last" radial zone at which equilibrium could be achieved over the duration of the nebula. This is an oversimplification for several reasons, including the fact that different molecular species are interconverted by reaction networks with distinct limiting rates and hence quench temperatures. Thus, one must define quenched zones for each of the $\text{CO}-\text{CH}_4$, $\text{CO}-\text{CO}_2$ and N_2-NH_3 interconversions. Radial mixing of nebular material acts to bring chemically "unaltered" material inward to chemically active zones, and return partially processed material back to the inert, outer nebula. (Here again we are oversimplifying the picture for heuristic purposes; as discussed below, other chemical processes may be active in the outer parts of the nebular disk.) The degree to which material is mixed radially in the nebula is crucial to an understanding of the gas-phase composition of the nebula, yet current nebular physical models do a poor job of addressing this question. Stevenson (1990) and Prinn (1990) examined semi-analytic models of a viscously evolving solar nebula to set limits on the extent of radial mixing. While a viscously evolving disk will inevitably

transport some material radially, the amount cannot be determined based on a linearized treatment of momentum and mass transport terms, as such a treatment leaves the relative magnitudes of angular momentum and mass transport undetermined (Prinn 1990). More complex models of coupled momentum and mass transport in the solar nebula are required, which unavoidably will involve additional parameters and ambiguities. The implications of nebular transport for carbon- and nitrogen-bearing species are described below in Sec. VI.B.1. on comets.

Solar nebula thermochemistry will also act to reduce the enhancements of deuterated species in molecules heavier than hydrogen created in the interstellar medium. The higher temperatures and preponderance of neutral-neutral reactions in the solar nebula shift the abundances back toward higher-temperature equilibrium, in which HD is the preferred deuterated carrier. Constraints on D-to-H ratios in the outer solar nebula may therefore set limits on the amount of chemical processing in the inner nebula and subsequent outward mixing, although to date this has not been attempted quantitatively.

3. *Processing of Material in Giant Planet Subnebulae.* The formation of the giant planets apparently resulted in bound, gaseous disks which produced the regular satellite systems (see Chapters by Podolak et al., Bodenheimer et al. and Lunine and Tittlemore). Such disks were not necessarily of similar composition to the solar nebula, as they could have been spun-out from the atmospheres of the forming giant planets. In such a case, the rock and ice abundances may have been greatly enhanced relative to solar, with highly uncertain ratios. Quantitative chemical modeling of such disks, for an assumed solar abundance, has been conducted for Jupiter and Saturn by Prinn and Fegley (1989). By setting these disks to a minimum mass required to account for the regular satellites, and constructing simple models of disk energy balance, one can show that the pressures in the satellite-forming zone are as much as 6 orders of magnitude higher than in the surrounding solar nebula (Lunine and Stevenson 1982). Consequently, for a given temperature, the equilibria are strongly shifted toward the reduced nitrogen- and carbon-bearing species. Such nebulae are potentially significant sources for ammonia and methane, reprocessing solar nebula carbon monoxide and nitrogen and returning the products (Prinn and Fegley 1989). The difficulty is in estimating the amount of material which may plausibly escape these gravitationally bound disks into the solar nebula. Prinn and Fegley propose that ejection of circumplanetary planetesimals into solar orbit may be the most plausible process, but to date no detailed work on this or other dynamical mechanisms has been undertaken.

4. *Chemistry at the Nebular Accretion Shock.* Gas and grains, undergoing free-fall into a medium of increasing gas density, eventually encounter a shock front referred to as the accretion shock. Here material is heated to varying degrees permitting evaporation of volatiles and acceleration of chemical reaction rates. Astrophysical shocks and resulting chemistry have been extensively examined in the literature (see, e.g., Mitchell 1984; Shull and Draine 1987; Hollenbach and McKee 1989; Neufeld and Dalgarno 1989), but

generally have not been specialized to the case of the solar nebula. The chemical modification of the shocked material depends on (1) velocities through the shock; (2) grain size (and hence coupling to the gas); and (3) initial chemical state of the material. Mitchell (1984) shows that for a shocked interstellar cloud, the initial abundance of CO vs elemental carbon as well as the shock velocity critically affect the post-shock abundances. Substantial quantities of methane could only be produced in a high-velocity shock ($>10 \text{ km s}^{-1}$), again dependent upon the initial state of the carbon. One key difference for the case of the nebular shock is that much of the infalling material may be in the form of grains, which depending on their size may largely decouple from the shocked gas and be subject to relatively little processing. Initial results of models by Neufeld and Hollenbach (in preparation) indicate that most of the oxygen is converted into water, and that grains most likely survive, except at distances $<3 \text{ AU}$.

Figure 14. Temperature vs time for a water ice grain falling into the outer part of the solar nebula at two initial velocities. A gas density typical of the outer solar nebula, $10^{-11} \text{ g cm}^{-3}$, is used. The number in parentheses is the amount of mass remaining after the heating/sublimation episode (figure adapted from Engel et al. 1990).

5. Drag Heating of Grains. Grains which have undergone free-fall into the solar nebula and survived passage through the accretion shock are subjected to gas drag forces which bring the particles toward a state of Keplerian orbit. Interstellar grains, being small submicron-sized particles, will continue to be largely borne by the gas and hence not in true Keplerian rotation; however in terms of chemical modification, it is the decoupling of the grains from the gas during infall (probably not in the accretion shock) which

concerns us most. Wood (1984) postulated that meteorite chondrules might have been formed by drag heating, but required rather extreme conditions to melt refractory grains. Lunine (1989*b*) and Engel et al. (1990) showed that drag heating could raise the temperature of icy grains entering the outer part of the solar system to sufficient temperatures to cause significant mass loss. Figure 14 shows an example of the results, for a small ($0.05\ \mu\text{m}$) water ice interstellar grain falling in with two initial velocities. The percentages show the amount of grain material which survives infall. The results turn out to be highly sensitive to the ability of the grain to effectively radiate in the infrared, i.e., to the choice of emissivity, and only moderately sensitive to the nebular gas density. Lunine et al. (1991), in a follow-on study, used Mie-scattering theory to explicitly compute the radiating properties of the subliming grains, and examined the effects of other volatile species on the grain sublimation. While the more precise computation of thermal radiation results in higher temperatures and hence more mass loss, the presence of species more volatile than water ice acts as a thermostat and keeps temperatures lower, resulting in loss of less water. Temperatures become large enough to cause reactions in any unstable radical species which may be trapped in the grains, but little else occurs chemically during the short period of heating. Nonetheless, the results indicate that perhaps half of the icy grain mass entering the solar nebula is returned to the gas phase; for this material to be incorporated in icy outer solar system bodies, condensation and/or physical trapping must subsequently occur within the nebular environment. These processes are quantified in Lunine et al. (1991).

6. *Trapping of Volatiles in Ices.* Return of volatile molecular species to condensed phases requires that they be either condensed out or physically trapped in water ice. Examination of theoretical nebular temperature profiles indicate that water ice should be fully condensed beyond 5 AU; condensation of ammonia (either as a pure ice or stoichiometric ammonia hydrate) is uncertain because it is predicted to be highly underabundant based on nebular thermochemical models. However, one can argue that interstellar ammonia, delivered to the nebular gas by grain-drag evaporation, may not be destroyed by nebular thermochemistry if radial mixing is limited. We provide supporting evidence for this below. Under such circumstances ammonia condensation is assured at or beyond roughly 10 AU. Carbon dioxide may also condense in the outer solar system if it represents a significant sink of carbon. Beyond carbon dioxide, however, direct condensation of species such as methane, carbon monoxide, nitrogen are problematic, depending on the temperature-pressure dependence in the outer parts of the nebula which is poorly defined. The more likely mechanism by which such species find their way (back) into the condensed phase is by physico-chemical trapping in water ice. Trapping in other phases is possible too (e.g., in graphite), but the large abundance of water ice coupled with its high specific adsorption area make it a compelling reservoir. Two trapping mechanisms have been explored in detail: adsorption onto surface sites, and clathration, in which a structural phase change in the

water ice creates three-dimensional voids into which the volatile species are inserted (Stevenson and Lunine 1988).

The amount of material trapped by these processes is a strong function of temperature. Clathration, being a phase change, exhibits a well-defined onset for a given set of gas abundances, and can accommodate up to 13% by number of non-water-ice volatile species. However, efficient clathration requires good exposure of the gas and ice; clathration in the interior of ice grains is strongly kinetically inhibited (Lunine and Stevenson 1985). Adsorption into crystalline ice generally traps much less volatile material than does clathration, but this is not true of amorphous ice which can trap as much as clathrate at very low temperatures (Mayer and Pletzer 1986; Bar-Nun et al. 1987). Again, however, this efficient trapping requires that the trapped gas be available at the time of amorphous ice condensation, which has traditionally been considered unlikely for the solar nebula. However, more recent experiments (Bar-Nun et al. 1988) and theoretical models (Lunine et al. 1991) suggest mechanisms by which such efficient trapping may have taken place.

Of most interest to us here is the chemical fractionation effects associated with water ice trapping of more volatile species. Direct condensation, of course, is potentially the strongest form of what is essentially fractional distillation: if methane were to condense out but not carbon monoxide, icy objects in the outer solar system would exhibit large amounts of methane but little or no carbon monoxide. However, at temperatures above the condensation points of the pure ices, selective clathration or adsorption could produce fractionation effects with the same trends, though not of the same severity.

Figure 15, modified from Lunine (1989c), illustrates this effect for methane and carbon monoxide trapped in clathrate, and demonstrates that the degree of fractionation is a function of total gas uptake. Imagine having a cometary water-ice sample in the laboratory in which the ratio of CO to CH₄ were measured to be unity. Figure 15 then shows the ratio CO/CH₄ in the original nebular gas as a function of the total amount of gas trapped in the ice. An abscissa value of unity corresponds to the maximum clathration ratio of 1:6 volatile gas to ice. Smaller values physically represent kinetic inhibition of gas uptake, due to poor contact between the gas and ice, or limited time available for uptake. The figure is not general, for it assumes that the ice was present in a region of the nebula cold enough that both methane and carbon monoxide clathrates would be separately stable (Lunine and Stevenson 1985). Hence, for abscissa values toward the right-hand end, after all of the methane has been trapped, cage sites are available for carbon monoxide and will be readily filled by that gas. Had we picked a nebular region at which methane but not carbon monoxide clathrate hydrate was stable, the curve would not decrease so steeply to the right.

Based on volatility considerations (Miller 1961) and detailed models (Lunine and Stevenson 1985), CO₂, CH₄, CO and N₂ will incorporate in clathrate or adsorption sites in decreasing propensity. Ammonia strongly hydrogen bonds to water, hence forming a stoichiometric crystal much more

Figure 15. Carbon monoxide to methane ratio in the initial nebular gas from which a grain of clathrate has been recovered. The clathrate grain is assumed to have a measured CO/CH_4 ratio of unity. The ordinate is plotted as a function of the amount of gas taken up in the clathrate, where a value of $0 = \log(1)$ corresponds to the maximum possible gas uptake, one volatile molecule for every six molecules of water (figure based on Lunine 1989b).

readily than clathrate. Carbon dioxide, at low temperatures, tends to condense out as dry ice rather than be trapped in clathrate or adsorption sites. Finally, no detailed work has been done to date on the isotopic effects of nebular gas trapping, although vapor pressure effects on condensation can alter the mole fraction of deuterated species relative to the gas phase. Such alterations are not strong compared to interstellar enhancements but can be in either direction depending on the temperature (Bigeleisen 1961). In any event, it is clear that the composition of the condensed phases in nebular planetesimals is not identical to that of the gas phase, and requires an understanding of the mechanisms of trapping in order for the original gaseous mix to be inferred.

In these discussions, we assume that direct gravitational capture of nebular gas by objects up to the size of the largest satellites is not a plausible source of observed volatiles; this is certainly the case dynamically because plausible subsequent processes of atmospheric escape could not leave behind the small solar abundances of heavier species while removing all of the molecular hydrogen (see, e.g., Hunten et al. 1989).

7. *Energetic Chemistry in the Nebula.* In addition to the processes described above, special effects may alter the abundances of species in planet-forming bodies from that in the original interstellar cloud. These include photolysis driven by solar ultraviolet, radiochemistry powered by ^{26}Al , light-

ning and nebular flares. Prinn and Fegley (1989) have assessed the importance of the first three of these processes for solar nebula chemistry. They compared the energy flux from these processes, usable for chemistry, to the energy flux available for inner nebula thermochemistry. Assuming live ^{26}Al was available, they show that the energy flux available for radiochemistry was 7 orders of magnitude less than that from thermochemistry. As at least 10^{-3} of the thermochemically processed gas could have been transported to the outer nebula (~ 100 AU) by both the Prinn (1990) and Stevenson (1990) transport models, it is clear that the radiochemistry is unimportant relative to thermochemistry even if it acted locally in the outer part of the nebula. Solar and stellar ultraviolet radiation cannot penetrate very far into the gas and dust disk of the solar nebula; stellar photons are more efficient than solar because of the geometry. Prinn and Fegley estimate, based on the current observed stellar ultraviolet flux, that the usable energy flux for nebular chemistry is ~ 4 orders of magnitude lower than that due to thermochemistry. However, if the molecular cloud ultraviolet flux were enhanced, such photochemistry could have been predominant in parts of the outer nebula if surrounding gas and dust were patchy and radial mixing inhibited so that inner nebula thermochemistry were less important. It is difficult to estimate the energy flux available from lightning because the nebular mechanism is not well understood. Prinn and Fegley estimate a usable energy flux from lightning and thundershocks of 0.1 that of thermochemistry. Clearly this could be an important source of chemical reactions in the outer part of the nebula. Further work on the mechanisms, and radial dependence thereof, of lightning generation may alter this estimate (see Chapter by Morfill et al.).

Levy and Araki (1989) have proposed a mechanism for making meteorite chondrules by generation of nebular flares. The physics of the flares is entirely analogous to solar flares. Such flares will engender heating of the surrounding gas and are a potential source of energy. The minimum energy flux from such flares can be estimated by assuming that they are the primary means by which chondrules were created. Using the fraction of primitive meteorites in the form of chondrules, the required energy release of 10^{34} ergs/nebula corresponds to an average flux roughly 8 orders of magnitude lower than the energy available from thermochemistry estimated by Prinn and Fegley (1989). Although this is a lower limit, two other issues mitigate against the importance of nebular flares for altering the nebular chemistry: (1) flares occur high above the disk midplane, and (2) a value many orders of magnitude larger than the lower limit given would require large magnetic fields which may be incompatible with other aspects of nebular models. There is sufficient uncertainty here that a careful look at flares as a nebular chemistry source is required.

The net effect of the lightning and thundershock-induced chemistry described by Prinn and Fegley (1989) is to produce significant quantities of hydrogen cyanide. Maximum yields in the solar nebula correspond to 0.3% of the nitrogen locked up as HCN; for the Jovian nebula Prinn and Fegley estimate as much as 7%. Shock chemistry may also partially reset the D to

H ratio in molecules heavier than hydrogen, as well as have other isotopic effects which have not been investigated.

B. SOLAR SYSTEM OBSERVATIONAL DATA

1. Comets. Because comets are generally agreed to be the least evolved samples of water ice and more volatile species in the solar system, they may be the most valuable link between solar nebula and interstellar chemistry. A proper chemical inventory of cometary ices and volatiles requires either a laboratory or *in-situ* analysis of cometary nucleus samples, in which the molecular abundances, ice phases and mechanisms of trapping are assessed directly. A big step forward toward this goal will be the laboratory analysis of a comet sample returned to Earth, such as is planned for the Rosetta mission. The best currently available assay of cometary volatile species comes from the combined ground- and space-based measurements of comet Halley in 1986. It should be remembered that these analyses involved measurement of molecular fragments, or daughter products, in the comet coma; nucleus abundances were inferred from chemical models of the coma. No information on the physical modes of trapping of the molecules in the nucleus could be obtained. Nonetheless, consideration of these data sets along with those of other comets is illuminating for the issue of nebular modification of the original mix of gas and dust coming from the giant molecular cloud.

Table X is a current interpretation of the 1986 results for Halley abundances. Much of it is the same as that reviewed in Lunine (1989*b*) and Weaver (1989), and the discussion in those papers should be consulted for the uncertainties (see also Chapter by Mumma et al.). Changes include a decreased ammonia abundance based on the telescopic studies of Wyckoff et al. (1988;1991*a*). The methane abundance is particularly controversial. The value quoted here derives from the analysis of the spatial distribution of CH before perihelion, assuming that CH is a granddaughter product of CH₄ (Allen et al. 1989). Subsequent searches for the infrared lines of CH₄ at postperihelion were unsuccessful, yielding upper limits of CH₄/H₂O < 0.01 (Kawara et al. 1988). Also, Boice et al. (1990) argue for an upper limit CH₄/CO < 0.005, based on a re-interpretation of the Giotto Ion Mass Spectrometer data, although their arguments are not compelling. If the values listed in Table X apply, the ratio of methane to carbon monoxide in Halley is comparable to that found in some interstellar clouds (Lacy et al. 1991), and much higher than that predicted by standard solar nebula models. Similarly, the ammonia abundance relative to water is much higher than that given by the nebular models. Lunine (1989*b*) proposed that the methane abundance in Halley was an indication of more effective catalysis of nebular thermochemistry than had been previously assumed in published models, along with the fractionation effects associated with trapping of these species in water ice. Engel et al. (1990) quantified this, arguing that laboratory studies did not rule out the synthesis of methane in Fischer-Tropsch-type reactions on grains, and that therefore low nebula quench temperatures for the CO-CH₄ interconversions

TABLE X
Comparison of Abundances in Comets with Interstellar Clouds

Species	Halley ^a	Other Comets ^a	ISM (gas) ^b	ISM (grains) ^b
H ₂ O	1	1	1	1
CO	0.05 – 0.1	0.02 – 0.07	10	0 – 0.13
N ₂	<0.05	<0.001	0.1 – 10	—
CH ₄	0.05 ^c	—	0.01	0 – 0.05
NH ₃	0.001 – 0.01	0.001 – 0.02	0.01	< 0.1
CO ₂	0.02 – 0.04	—	< 0.1	0 – 0.03
H ₂ CO	0.01 – 0.1	0.005 ^d	0.002 – 0.01	—
CH ₃ OH	0.01	0.01 ^d	0.01 – 0.1	0.01
HCN	0.001	0.0002 – 0.002 ^d	0.02 ^e	—
H ₂ S	? ^f	0.002 ^d	0.5 ^g	< 0.01 ⁱ
¹² CN/ ¹³ CN	65 ± 9 ^h	—	45 – 90	—

^a Based on review of Weaver (1989), unless otherwise indicated.

^b Based on Table VIII; the gas-phase abundances refer mostly to the Orion hot core.

^c Boice et al. 1990 suggest an abundance less than 0.0005.

^d Bockelée-Morvan et al. 1990.

^e Mangum et al. 1991.

^f Probably detected, but abundance not known.

^g Minh et al. 1990.

^h See text.

ⁱ Smith 1991.

could not be ruled out. Under these conditions, 0.1 to 1% of the carbon might be in the form of methane at the edge of the chemically active region. This abundance is then diluted in the outer nebula because of inefficient radial mixing (and their low assumed methane abundance in the native gas of interstellar composition), but the methane fraction relative to carbon monoxide is then boosted in water ice by the effects of clathration or adsorption.

Figure 16. Ratio of carbon monoxide to methane in the solar nebula as a function of quench temperature for the grain catalysis process discussed in the text. The rough acceptable range based on the Halley data, corrected for the fractionation effects of ice trapping, is given by the shaded region. Thus, to be consistent with the Halley data, one must choose a quench temperature that puts the curve in the shaded region. It is assumed that nebular mixing is only moderately efficient, as discussed in the text (figure based on Engel et al. 1990).

Figure 16 shows the results from Engel et al. (1990) for the CO-CH₄ ratio. Quench temperatures from 600 to 1400 K are chosen, and the assumed amount of nebular radial mixing corresponds to a conservative case from Stevenson (1990), wherein 1% of the material in the outer solar nebula has been processed in the inner disk and remixed outwards. The figure assumes a C/O ratio of 0.6; while Anders and Grevesse (1989) and Grevesse et al. (1991) recently redetermined this ratio to be 0.45–0.5, consideration of cold trapping of water by condensation (Lunine and Stevenson 1988) argues in favor of a ratio closer to unity. In any event, the results are mostly sensitive to the quench temperature. All values correspond to some significant degree of catalysis of the interchange reactions on grains; if such catalysis is inhibited,

as argued by Prinn and Fegley (1989), then the CH_4 in comet Halley cannot be a product of solar nebula processing of CO. If, on the other hand, grain catalysis can be argued to have been operative in the nebula, Halley's methane abundance could indeed be a solar nebula product. Likewise, the carbon dioxide abundance measured in Halley could have been manufactured from CO in the solar nebula, though somewhat lower quench temperatures or higher efficiency of radial mixing are required. HCN, on the other hand, if a solar nebula origin were to be invoked, would best be explained as a product of energetic chemistry associated with lightning and thundershocks as described above.

Other species measured in Halley cannot be explained by thermochemistry in the solar nebula. Engel et al. (1990) concluded that no plausible model of solar nebula thermochemistry could manufacture the abundance of ammonia, relative to water, seen in comet Halley. They concluded that ammonia was evidence of preserved volatile species from the molecular cloud. Prinn and Fegley (1989) argue for an alternative explanation, that both methane and ammonia were manufactured in the high pressure nebulae surrounding the giant planets, and then transported outwards to form part of Halley. They propose that the most plausible delivery mechanism is in the form of solid bodies collisionally scattered from orbits around the giant planets into the solar nebula. Formaldehyde, on the other hand, is difficult to manufacture within solar or giant planet nebular environments, and if the abundance determined by Mumma and Reuter (1989) is correct, H_2CO may be of interstellar origin. Fegley (1992) offers an alternative interpretation: that formaldehyde is indicative of active photochemical processes in the solar nebula. This, and the possibility that nebular Fischer-Tropsch reactions provided large amounts of formaldehyde (Fegley 1992), require detailed modeling and laboratory studies for their validity to be evaluated.

Two isotopic ratios in Halley have been reasonably well-constrained: the D/H value and $^{12}\text{C}/^{13}\text{C}$, listed in the table (see also Table IV). When interpreting D/H ratios, it is essential to distinguish between the various deuterated species and the different histories they may have experienced. Halley's ratio is for water, and while it compares well with enhanced deuterium in methane in the outer solar system, methane and water had very different histories. Lutz et al. (1990) argue that the high D/H in Uranus, Neptune, Titan and Halley are the result of the presence of an interstellar component in each of these bodies. Alternatively, Yung et al. (1988) conclude that photochemical enhancement of deuterium in the solar nebula may have occurred for both methane and water. However, the fact that water condenses readily in most of the nebula, coupled with the need to bring these materials well above the midplane to enable exposure to stellar ultraviolet, suggests that these two molecules may have had very different photochemical histories and the respective deuterated fractions ought not necessarily to be similar. Also, Titan's deuterated methane component may have been further enhanced by atmospheric photochemistry after formation (Pinto et al. 1986), further decoupling the history of the two

molecules. In summary, the relationship of deuterated water in Halley to deuterated methane in the rest of the outer solar system is by no means clear, nor is the origin of the enrichment necessarily interstellar. A sample return mission to a comet would clearly be of great importance to settle this issue.

The carbon isotopic ratio $^{12}\text{C}/^{13}\text{C}$ of roughly 65 in Halley appears different from that measured in meteorites and other comets (Wyckoff et al. 1989). This might be used to argue for an interstellar origin for Halley, and perhaps even a special one for this comet. Such an invocation appears premature, on several grounds. First, only Halley has had a carbon isotope ratio reported in CN, published values for other comets are from C_2 , and chemical processes which produce the isotopic enhancement are different for the two. In fact, an analysis of the available $^{12}\text{C}^{13}\text{C}$ spectra of Halley yields $^{12}\text{C}/^{13}\text{C}$ around 90 (Gredel 1987). Second, Fegley (1992) points out that carbon isotopic measurements for the outer solar system range from roughly 20 to 160, illustrating not only the observational difficulties but the possibility that the history of this isotopic ratio is complex. The inner solar system value of 89 is derived from meteorites and may represent yet a different history and set of processes. Finally, the interstellar $^{12}\text{C}/^{13}\text{C}$ ratio has been the subject of considerable discussion, with values ranging from 43 ± 6 (Hawkins and Jura 1987) to 77 ± 3 (Stahler et al. 1989), although the most recent data appear to favor a value around 65 (Langer and Penzias 1992; Crane et al. 1991; Centuri3n and Vladilo 1991). It is therefore premature to argue that the Halley value must represent an interstellar origin distinct from the solar system.

Another clue to their origin may be provided by the ortho/para ratio of the cometary molecules. Mumma et al. (1988*b*) find an ortho/para ratio of H_2O in comet Halley that can be characterized by a nuclear spin temperature of ~ 25 K. Such a spin temperature is similar to that derived from the observed ortho/para ratios of H_2CO and H_2CS in cold interstellar clouds such as TMC-1, which in turn is thought to reflect the temperature of the grains on which the molecules formed (Kahane et al. 1984; Minh et al. 1991). However, gas-phase exchange reactions with ions can also establish ortho/para ratios which are characterized by a low spin temperature.

In summary, a purely interstellar origin for Halley cannot be ruled out; nonetheless, we do not know enough to dismiss substantial solar nebula processing either. The heating calculations of Engel et al. (1990) demonstrate that the fate of grains falling into the solar nebula is to be partially preserved in solid form and partially evaporated. The subsequent history of such grains is that they will later condense or adsorb partially processed solar nebula gases as a layer surrounding a core of relatively unaltered material. The result would be a comet comprised of an amalgam of chemistry reflecting the whole history of planetary system formation. Ultimately, detailed study of cometary samples is required to elucidate the rich history locked in the icy grains.

2. *Outer Planets and Satellites.* The origin and evolution of outer planet atmospheres is reviewed by Gautier and Owen (1989) and Lunine (1989*c*), and will not be repeated here. Because of the re-equilibration of gases throughout

their massive, hot envelopes, these bodies are not good indicators of early solar nebula processing of interstellar material. The exception, isotopic ratios involving deuterium and carbon, have been obliquely referred to above. The state of observations of the carbon isotope ratios is too primitive to be of help in the present discussion. The challenge with regard to deuterium is to understand the relationship between HD and CH₃D at present, as the deuterium re-equilibrates between these species. Progress is being made in this area (Fegley and Prinn 1988), to the point that Lutz et al. (1990) have begun constructing a history of deuterium reservoirs in the outer solar system. A stubborn and outstanding problem in ascribing enriched deuterium to a preserved, interstellar component is current inability to characterize and constrain the ultraviolet flux in the early solar nebula. How much material was transported high above the nebular disk, exposed to ultraviolet and chemically altered, must be quantified before one can evaluate the alternative that the enriched deuterium in methane was photochemically created (Yung et al. 1988). In Titan's atmosphere, which contains a deuterated methane enrichment nearly identical to the deuterated water enrichment on Earth (de Bergh et al. 1988), it is possible to show that atmospheric photochemistry could be responsible for a significant fraction of the enhancement (Pinto et al. 1986). It cannot be totally ruled out that an early epoch of enhanced photolysis or even impact-shock chemistry on Titan produced today's observed enrichment.

The large icy bodies of the outer solar system tell an interesting story with regard to carbon and nitrogen species, as covered in the Chapter by Lunine and Tittmore. Carbon monoxide is apparently a minor component of Triton's surface, based on Voyager UVS data (Broadfoot et al. 1989), and preliminary reduction of near-infrared spectroscopy (Cruikshank et al. 1991). This suggests chemical evolution of the component grains after contact was lost with the gas of the solar nebula or parent molecular cloud (Lunine et al. 1991), or processing after the formation of Triton itself (Shock and McKinnon 1992). Further refinement of the CO upper limit for Triton from Voyager data is critical, as is a more precise determination of Pluto's atmospheric composition. The surface has methane, nitrogen and carbon monoxide, based on spectroscopic detection of frosts (Owen et al. 1992). The relative abundance of these last two in the atmosphere is undetermined (Yelle and Lunine 1989), but obviously is of high interest. Finally, the inability to find ammonia on any surface in the outer solar system is curious, but should not be taken as a signal that it was absent from the solar nebula. Surface ultraviolet or charged-particle chemistry has undoubtedly transformed ammonia to hydrazine and perhaps even molecular nitrogen in the optical surfaces of icy satellites. Searches by Cassini for polar volatiles on the icy satellite Enceladus, and others, would be illuminating in this regard.

3. Isotopic Effects in Meteorites. The reader is referred here to the Chapters by Ott, and by Palme and Boynton, for a discussion of isotopes in meteorites. We mention here only the deuterium. Clearly the deuterium record in meteorites indicates processes for enhancing deuterium in interstel-

lar clouds (Yang and Epstein 1983). The relationship between the highly fractionated organic component and enhanced, deuterated methane awaits an understanding of the origin of methane in the outer solar system, but it is tempting to ask whether methane might not be the product of heavy organics in the hydrogen-rich environment of the solar nebula (Walker et al. 1970). While this is distinct from the origins of solar system methane described above, an outstanding uncertainty remains in how Fischer-Tropsch-type reactions operate in a system like the solar nebula, for which no real laboratory analog has been constructed. Clearly a severe test would be the measurement of the $\text{CH}_3\text{D}/\text{CH}_4$ ratio in a comet. While some might regard it as ironic if solar system methane turned out to be a product of heavier, interstellar organics, irony appears to be one of nature's strong suits.

VII. CONCLUDING REMARKS

The preceding sections have amply demonstrated that many different processes can modify the chemical composition of a cloud as it evolves from its initial quiescent state to protostellar and protoplanetary regions. Although systematic data on molecular abundances at the various stages of the star-formation process are still lacking, the observed chemical gradients within actively star-forming regions such as Orion/KL and IRAS 16293–2422 stress more and more the close interdependence between source dynamics, energy balance and chemical composition. No longer can the initial stages of star formation be studied ignoring these chemical changes, and vice versa.

In spite of the wealth of new observational data, many questions remain. For example, what are the primary oxygen- and nitrogen-bearing species in cold, dark clouds prior to star formation? How are they affected by the star formation process? Unfortunately, observational searches for H_2O , O_2 , O , N_2 and N in cold clouds will remain difficult to impossible for some time to come. Even in warm clouds, where H_2O can be observed, up to 50% of the oxygen may be unaccounted for, if the elemental abundances in these clouds are close to solar. Finding the missing source of oxygen, whether in the gas phase or on grains, will be one of the major challenges for the next decade. Another challenge will be to find a truly quiescent dark cloud core in which the chemistry has not yet been affected by star formation, to delineate the initial conditions and to test the "standard" interstellar chemistry models. Even in the classical test cases like TMC-1, the chemistry may be affected to some extent by the earliest stages of star formation, which may at least partly explain the chemical gradients observed in these clouds on scales of only a few tenths of a pc.

The example of Orion/KL demonstrates that star formation modifies the chemistry in at least two ways: by changing the molecular depletions and by creating energetic events. The observed high abundances of deuterated and even doubly deuterated molecules in the hot core in Orion/KL form perhaps the best evidence that molecular mantles are released from grains when heated

to temperatures in excess of 100 K. The distribution of NH_3 in IRAS 16293–2422 may be one of the first case studies of the depletion of molecules in the inner core, and return to the gas phase in the outer part. The extent to which grains actively form new molecules is still an open question, however, and the actual chemistry of NH_3 in interstellar clouds is still poorly understood. Observations of CS toward HL Tau also suggest large depletions of polar molecules in its circumstellar disk.

The two most obvious signposts of energetic phenomena associated with star formation are infrared emission from warm dust and large scale molecular outflows. The chemistry is expected to respond to these energetic events. Physically, the increased temperature opens up normally closed chemical channels for the destruction and creation of species such as H_2O . If strong enough, the shocks not only can vaporize the mantles, but also disrupt grain cores and return sulfur, silicon and perhaps oxygen to the gas phase. The large amounts of SO, SO_2 and SiO observed in star-forming regions like Orion/KL most likely result from the interaction of the surrounding molecular material with the outflow, although the details of the chemistry still need to be worked out. The enhancements may depend on the luminosity of the source, however, and on the evolutionary state, as demonstrated by the fact that the abundances in IRAS 16293–2422 are only little affected compared with cold clouds.

On scales appropriate to the solar nebula (<100 AU), many processes have been identified that can change the chemical composition of material entering even the outer part of the solar nebula. The relative importance of these processes as a function of position in the nebula is still poorly determined observationally. It must be understood that different material will be altered to different degrees, and the *whole* record obtained from refractory phases, volatiles, and isotopic enhancements must be considered in quantifying the history of interstellar material which became solar nebula and then planetary material. The clues that we currently have suggest that in the outer part of the nebula some original molecular cloud material was preserved to a significant degree. Desperately needed are *in situ* or sample return analyses of comet nucleus material, and further inventory of the isotopic and molecular record on other outer solar system bodies.

Observations of the distribution of molecules in circumstellar disks around other stars on scales of 5 to 50 AU would be very valuable as tests of the theories of our own solar system formation, but must await the development of higher-resolution interferometric techniques, such as might be provided by the millimeter array. Nevertheless, some insight into the extent to which interstellar material is modified can be obtained from the single dish molecular surveys on scales of a few 1000 AU combined with interferometric imaging on scales of 500 to 1000 AU. High-resolution infrared absorption line observations toward embedded sources will also be very valuable for the determination of abundances in both gas and solid phases close to the young stellar object, but additional laboratory measurements on infrared absorption in synthetic grain mantle analogs will be required to fully interpret the as-

tronomical spectra. By applying this array of observational techniques to a much wider range of objects with differing luminosities, we are hopefully in a position to unravel, for the first time, the driving chemical reactions and physical processes that steer the formation of stars and planets.

APPENDIX

INTERSTELLAR CHEMISTRY AND MODELS

This Appendix contains a more detailed description of the interstellar chemistry and models discussed in Sec. II. First, a brief introduction into the basic ion-molecule gas-phase chemistry scheme is given, and some recent developments regarding the models are discussed. This is followed by a description of chemical processes involving grains, and a summary of model results regarding grain mantles. Finally, a few remarks concerning shock chemistry are made. More details can be found in the reviews mentioned at the beginning of Sec. II.

A. Basic Processes

The thousands of reactions that enter all interstellar and protostellar chemical networks can be categorized in only a few different classes, as summarized in Table A1 (Dalgarno 1987; van Dishoeck 1988a). The two basic processes by which molecular bonds can be formed from atomic precursors in the low-density interstellar environment are radiative association, which is accompanied by the emission of a photon, and grain-surface formation, in which the grain carries off the energy released upon formation of the molecular bond. The major destruction process of neutral molecules in any environment in which ultraviolet photons are present is photodissociation, whereas molecular ions are usually most rapidly removed by dissociative recombination with electrons. In regions of very high temperature (>3000 K) and density, collisional dissociation can play a role. Chemical reactions can rearrange bonds, once diatomic species have been formed. In an ion-molecule exchange reaction, the bonds in the new molecule are formed at the expense of those of the reactant species. Another possible outcome of an ion-molecule reaction is charge-exchange. Ion molecule reactions are usually very fast at low temperatures if the reaction is exothermic, with rate coefficients close to those given by the simple Langevin theory ($\sim 10^{-9}$ cm³ s⁻¹). Neutral-neutral reactions are much slower than the ion-molecule reactions at low temperatures due to the weak long-range attraction and potential barriers along the reaction path. They become significant, however, at higher temperatures.

A key aspect of interstellar chemistry is the fact that H₂ is by far the most important constituent of the cloud. Thus, if the reaction of an ion or molecule with H₂ is exothermic, that process will be the dominant reaction path. Only if the ion does not react with H₂ can reactions with less abundant species effectively compete to produce other molecules. A second essential

TABLE A1
Classes of Chemical Reactions

Type	Process	Rate Coefficient
Formation Processes		
Radiative association	$X + Y \rightarrow XY + h\nu$	$10^{-16} - 10^{-9}$
Grain surface formation	$X + Y:g \rightarrow XY + g$	$\sim 10^{-18}$
Destruction Processes		
Photodissociation	$XY + h\nu \rightarrow X + Y$	$\sim 10^{-10} - 10^{-8} \text{ s}^{-1}$
Dissociative recombination	$XY^+ + e \rightarrow X + Y$	$\sim 10^{-6}$
Collisional dissociation	$XY + M \rightarrow X + Y + M$	—
Chemical Processes		
Ion-molecule exchange	$X^+ + YZ \rightarrow XY^+ + Z$	$\sim 10^{-9}$
Charge-transfer	$X^+ + YZ \rightarrow X + YZ^+$	$\sim 10^{-9}$
Neutral-neutral	$X + YZ \rightarrow XY + Z$	$\sim 10^{-12}$

^a Approximate rate coefficients appropriate for cold dark clouds. All rate coefficients are sensitive to temperature. For photodissociation, the rates in s^{-1} in the unattenuated interstellar radiation field are listed.

assumption in the chemistry networks is the presence of sufficient amounts of reactive ions to drive the ion-molecule reaction network. In diffuse and translucent interstellar clouds, these ions are created by the photoionization of elements with ionization potentials less than 13.6 eV, such as C, S and Si, but not O and N. Inside dense clouds, where the interstellar radiation field no longer penetrates, cosmic-ray ionization produces He^+ and H_2^+ ions, and H_2^+ subsequently reacts rapidly with H_2 to form H_3^+ . The rate at which cosmic rays ionize hydrogen is $\sim 10^{-17}$ to 10^{-16} s^{-1} , and it is usually assumed that they can penetrate dense clouds at least up to column densities of 10^{24} cm^{-2} , although their penetration deep into star-forming regions is still uncertain.

Consider as an example the first part of the oxygen network, illustrated in Fig. A1. The H_3^+ resulting from cosmic-ray ionization reacts with atomic oxygen to form OH^+ . Once OH^+ is formed, a sequence of rapid hydrogen abstraction reactions with H_2 follows, in which H_2O^+ and then H_3O^+ are made. This sequence stops when an ion is formed (H_3O^+ in this case) for which the reaction with H_2 is endothermic. H_3O^+ can thus react with other species in the cloud, and will most likely dissociatively recombine to form OH and H_2O , unless the electron abundance is very low, $n(e)/n(\text{H}_2) < 10^{-8}$. OH can subsequently react with neutral or ionized carbon to form CO, and with neutral atomic oxygen to form O_2 . Only at high temperatures can it react rapidly with H_2 to produce H_2O .

The carbon chemistry in dense clouds is initiated by a similar reaction

Figure A1. The most important interstellar chemical reactions involving oxygen-bearing molecules (figure from van Dishoeck 1988a).

between C and H_3^+ to form CH^+ . In more diffuse regions, C can be photoionized directly and the radiative association reaction between C^+ and H_2 then starts the carbon network. By contrast, the sequence of reactions that launches the nitrogen chemistry is more uncertain, because the reaction of N with H_3^+ to form NH^+ is endothermic, while that to form NH_2^+ has significant barriers. The only other possible initiating reaction is that between N^+ and H_2 to form NH^+ , which is slightly endothermic (by 19 meV), but which can proceed if either H_2 is rotationally excited, or if the N^+ atom has excess translational energy, e.g., as a result of its production by dissociative ionization of nitrogen-bearing molecules such as N_2 or CN. The latter scheme requires, of course, the prior presence of nitrogen molecules in the cloud. These can be formed through coupling of the oxygen, carbon and nitrogen chemistries. For example, the NO molecule can result from the neutral-neutral reaction of N with OH. Much more efficient are the reactions involving carbon, because C^+ is easily inserted into carbon chains, and relatively rapid condensation (e.g., $\text{CH}_3^+ + \text{C}_4\text{H}_2 \rightarrow \text{C}_5\text{H}_3^+ + \text{H}_2$) and radiative association (e.g., $\text{C}_3\text{H}^+ + \text{H}_2 \rightarrow \text{C}_3\text{H}_3^+ + h\nu$) reactions can occur, leading to the more complex hydrocarbon molecules.

An essential element of the chemical models is the availability of reliable reaction rates for these processes (see Millar et al. 1991b for a recent summary). Because the physical conditions in interstellar clouds are quite

different from those normally found in a laboratory on Earth, relatively few reaction rates have been measured at the relevant temperatures and densities. This often leads to major uncertainties in the predicted abundances, which need to be taken into account in comparison with observations. Although educated guesses can be made for the majority of the unmeasured cases, important gaps remain for some crucial reactions. In fact, one of the most important aspects of the modeling efforts is to identify the key reactions in the networks for which accurate rates are essential. This, in turn, stimulates complementary laboratory or theoretical efforts to determine these rates, and often unexpected results are obtained, not only for individual reactions, but even for whole categories of reactions. Some recent developments in this area are summarized below:

1. *Ion-polar molecule reactions*: Until a few years ago, most ion-molecule reactions were measured either at room temperature or at 80 K, and it was assumed that if the reaction is fast at those temperatures, it remains equally fast at lower temperatures. It is now possible to measure ion-molecule reactions at temperatures as low as 10 K (Rowe 1988), and several exceptions to this simple rule have been found. In particular, reactions of ions with molecules that have a sizable permanent dipole moment (e.g., C^+ with H_2O) have been found to proceed 1 to 2 orders of magnitude more rapidly than the Langevin rate at the lowest temperatures, owing to the enhanced long-range attraction.
2. *Dissociative recombination branching ratios*: There has been considerable theoretical debate concerning the products that arise from the dissociative recombination of polyatomic ions (Bates and Herbst 1988b; Adams and Smith 1988). For example, does the dissociative recombination of H_3O^+ produce mainly H_2O or OH ?

The theoretical values for f have fluctuated between 0 and 0.85 over the last few years. Such variations directly affect the amounts of H_2O and OH , and consequently O_2 , in the models. Recently, the first experimental determination of this branching ratio has been reported, $f \approx 0.65$ (Herd et al. 1990), which results in less H_2O and more O_2 in the models than if f were 0. Note also that dissociative recombination is usually a very fast process, but that some exceptionally slow cases have been found. In particular, the dissociative recombination of H_3^+ may be extremely slow under interstellar conditions, although this issue has not yet been settled (Mitchell 1990).

3. *Radiative association*: Rates for radiative association reactions continue to be uncertain by 1 to 2 orders of magnitude (Bates and Herbst 1988a).

Because a photon has to be emitted during the formation of the molecular bond, the process is extremely slow and difficult to measure in the laboratory. The theoretical rates have increased considerably over the last few years, when it was realized that excited electronic states may play a significant role in the process. However, for the one reaction which has been studied in the laboratory,

the experiments give a rate that is a factor of 20 lower than the theoretical estimates (Gerlich and Kaefer 1989).

4. *Photodissociation:* Most photodissociation rates have increased up to an order of magnitude over the last decade, as more laboratory data and better calculations become available (van Dishoeck 1988*b*).

B. Gas-Phase Models

The models presented in Table V of Sec. II are the simplest “standard” models, in the sense that they are homogeneous and consider only gas-phase reactions at fixed temperature and density. They also compute only relative abundances at one position in the cloud, and equate abundance ratios with column density ratios. Several recent improvements to this standard model are listed below. Most of them have been stimulated by the large observed abundances of atomic carbon and complex molecules in the clouds, which are not readily explained in the standard models.

1. *Clumpy Models.* There is growing observational evidence that interstellar clouds are far from homogeneous, but that they have a very clumpy structure (Falgarone and Péroult 1987). In particular, the large measured column densities of C and C⁺ and their widespread abundance throughout clouds such as M 17 suggest an inhomogeneous structure through which the ultraviolet radiation can penetrate deeper into the cloud and dissociate CO (Keene et al. 1985; Stutzki et al. 1988; White and Padman 1991). Detailed models of such clumpy clouds are in the process of being developed. They can no longer be restricted to relative abundances, but need to compute actual column densities and line intensities which include the contributions from the edges of the clumps.

2. *Cosmic-Ray-Induced Photons.* A dilute flux of ultraviolet photons can also be maintained inside the densest clumps through the interaction of cosmic rays with hydrogen (Prasad and Tarafdar 1983):

The electrons e^{*} produced in the cosmic-ray ionization of H and H₂ have sufficient energy to excite H₂ to H₂^{*} electronically. The excitations are followed

by spontaneous emission of photons in the wavelength range between 800 and 2000 Å. The resulting photodissociation rates of molecules due to the photons produced by this process have been computed by Gredel et al. (1989), and are, in the case of CO, sufficient to maintain a significant fraction of atomic carbon inside the cloud. Note that ionizations by X-ray emission from embedded young stars can have similar effects at comparable rates (Krolik and Kallman 1983).

3. *Large Molecules.* The presence of very small grains or large molecules such as the PAH can influence the chemistry as well as the ionization balance (Omont 1986; Lepp and Dalgarno 1988; Draine and Sutin 1987). Their most important effect is to neutralize atomic and molecular ions without destroying them, so that the abundances of complex molecules are enhanced. Also, the free electrons can attach to the PAH to form PAH^- ions, which may carry most of the negative charge in the cloud. In that case, the limits on the fractional ionization $x(e)$ are lowered substantially. Finally, the inclusion of large molecules in the chemistry removes the dependence of cloud-model results on metal abundance, which was found in earlier studies.

4. *Photodissociation Models.* Models of clouds exposed to intense ultraviolet radiation due to a nearby young star have been developed, e.g., by Tielens and Hollenbach (1985) and van Dishoeck and Black (1988*b*). Such models treat the depth dependence of the concentrations and photodissociation rates in detail and calculate column densities, which can be compared directly with observations. Large amounts of atomic carbon are readily formed in these models, although those of complex molecules have not yet been investigated in detail. Attempts to include the observed clumpy structure into the models have been made, e.g., by Burton et al. (1990).

5. *Evolutionary Models.* Models in which the physical parameters are no longer fixed, but in which density and temperature evolve with time from a diffuse to a dense state according to the equations of motion for gravitational collapse have been developed by Tarafdar et al. (1985) and Prasad et al. (1987). Because the clouds spend most of their lifetime as diffuse clouds where the amount of atomic carbon relative to CO is high, they produce significant amounts of complex molecules. One difficulty with these models is that they may lead to star-formation rates that are too large compared with observations, unless some arbitrary mechanism is introduced that slows down the evolution or prevents stars from forming. Dynamical models in which material is repeatedly cycled between clumps and the tenuous interclump medium by ablation of material from the clumps by newly formed stars have been investigated by Charnley et al. (1988,1990).

One problem with the new models is that they often include only one or two of these new developments, but ignore others. Such studies are useful to investigate their influence on the computed abundances compared with the standard model (see, e.g., Millar 1990). However, the effects sometimes go in opposite directions, so that the overall result is not clear, and comparison with observations less meaningful.

An important parameter in the chemistry, and also in the star-formation process, is the fractional ionization in the cloud, $x(e) = n(e)/n(H_2)$, which determines the efficiency with which the magnetic field couples to the cloud. In diffuse and translucent clouds, the electrons are produced primarily by photoionization of atomic carbon, and the resulting ionization is high, $x(e) \approx 10^{-4}$. Such a high fractional ionization probably prevents star formation in these clouds (McKee 1989). Inside dense clouds, the ionization fraction is determined by the cosmic-ray ionization rate ζ , and the rate at which ions recombine either with electrons or with negatively charged grains: $x(e) \propto (\zeta/n)^{1/2}$. Upper limits on the fractional ionization in dense clouds can be derived from the observed DCO^+/HCO^+ abundance ratio, and values of $x(e) \lesssim 10^{-6}$ are found if $\zeta \approx 10^{-17}$ to 10^{-16} s^{-1} (Dalgarno and Lepp 1984).

C. Grain Chemistry

Quite aside from being the largest “molecules” present, dust grains also play an intimate role in interstellar chemistry. Their importance is based on three distinct functions: they serve to shield molecular regions from the dissociating interstellar radiation; they catalyze the formation of molecules, particularly the most important molecule, H_2 ; and they remove (perhaps selectively) molecules from the gas phase. Good summaries of the various chemical processes involving grains have been given by Tielens and Allamandola (1987*a, b*) and Turner (1989*c*).

1. *Ultraviolet Opacity.* The ultraviolet extinction law is well determined for diffuse interstellar gas in the solar neighborhood to wavelengths as short as 1000 Å. Considerable variations in the ultraviolet extinction are seen from one line of sight to another (see, e.g., Cardelli, et al. 1989), but on average the dust provides an extinction cross section per H nucleon which is given to within $\pm 20\%$ by $\sigma \approx 2.5 \times 10^{-21} (1000 \text{ Å}/\lambda) \text{ cm}^2$ for $2500 > \lambda > 1000 \text{ Å}$. In dense regions the extinction per H nucleon may be smaller than in diffuse clouds by a factor of 2 or more. This reduction in extinction per H nucleon is presumed to be due to coagulation of small grains (Jura 1980).

The ultraviolet albedo ω and scattering asymmetry parameter g remain somewhat uncertain (Witt 1989), but for diffuse regions both observations and models (see, e.g., Draine and Lee 1984) are consistent with $\omega \approx 0.5 \pm 0.1$ and $g = \langle \cos \theta \rangle \approx 0.5 \pm 0.1$ over the 1000 to 2000 Å region. Unfortunately, the ultraviolet scattering parameters g and ω are essentially unknown in dense clouds. Because photodissociation and photoionization play a major role in gas-phase chemistry in diffuse and translucent regions with $A_V < 2 \text{ mag}$, models of such clouds will remain uncertain until the ultraviolet scattering properties of the dust therein are better characterized.

2. *Gas-Grain Interactions.* Dust grains play a primary role in interstellar chemistry by catalyzing the formation of H_2 . If Σ is the projected grain surface area per H nucleon, and $n_H = n(H) + 2n(H_2)$ the density of H nucleons, then the time scale for a neutral X to collide with a dust grain is $\tau^{-1} = R_{\text{coll}} n_H$, where the “rate coefficient” for collision with a grain surface is given in

$\text{cm}^3 \text{s}^{-1}$ by

$$R_{\text{coll}} = (8kT/\pi m_X)^{1/2} \Sigma = 6.5 \times 10^{-17} (T/20 \text{ K})^{1/2} A_X^{-1/2} \Sigma_{21} \quad (\text{A4})$$

where A_X is the molecular weight, and $\Sigma_{21} \equiv \Sigma/10^{-21} \text{ cm}^2$. For a graphite-silicate grain model designed to reproduce the observed interstellar extinction, $\Sigma_{21} \approx 1.1$ (Mathis et al. 1977; Draine and Lee 1984).

The rate of formation of H_2 on dust grains is given by $R_{\text{H}_2} = 0.5\epsilon R_{\text{coll}} \approx 3.2 \times 10^{-17} \epsilon (T/20 \text{ K})^{1/2} \Sigma_{21} \text{ cm}^3 \text{s}^{-1}$, where ϵ is the fraction of the H atoms arriving at a grain surface that are converted to H_2 . In $T \approx 80 \text{ K}$ diffuse clouds, ultraviolet absorption-line observations have been used to estimate $R \approx 3 \times 10^{-17} \text{ cm}^3 \text{s}^{-1}$ (Jura 1975), seemingly confirming the original theoretical analyses of H_2 catalysis by grains (Hollenbach and Salpeter 1971) which concluded that the efficiency ϵ should be of order unity. The situation is, however, not so simple, because of the presence of the ultra-small grains. The surface area provided by these particles would be considerable: e.g., $\Sigma_{21} \approx 9$ for a size distribution favored by Draine and Anderson (1985). Such an enhanced population of ultra-small grains could play a major role in both surface chemistry and recombination of free charges (Draine and Sutin 1987). The fact that the H_2 formation rate coefficient deduced from observations is $R_{\text{H}_2} \approx 3 \times 10^{-17} \text{ cm}^3 \text{s}^{-1}$ indicates that these particles, if actually present, do *not* efficiently catalyze the formation of H_2 in diffuse clouds. This reduced efficiency may be a consequence of frequent thermal “spikes” which may result in desorption of adsorbed H atoms before another H arrives with which to recombine.

Unfortunately, we have little direct information on the values of R appropriate in denser regions; the observed decrease in the extinction per H nucleon in going from diffuse to dense regions, and the corresponding decrease in inferred grain surface area, would suggest that R will follow a similar reduction. However, in regions where the atomic density is increased and the ultraviolet radiation field is attenuated, thermal spikes may be less effective at preventing H_2 formation on the ultra-small grains, if they are in fact present in dense regions, so that the effective R may remain similar.

In addition to acting as a source of H_2 , grains may catalyze the formation of other species. The time scale in years for a species X to be deposited on a grain surface is only

$$\tau = (R n_{\text{H}})^{-1} = 2 \times 10^6 \alpha^{-1} (10^3 \text{ cm}^{-3}/n_{\text{H}}) (A_X/20)^{1/2} (T/20 \text{ K})^{-1/2} \Sigma_{21}^{-1} \quad (\text{A5})$$

where α is the probability that species X will stick to the grain, which is thought to lie between 0.1 and 1 for most species. Thus, the grains may act as very effective cold traps, especially if numerous small grains are present. A major question in grain chemistry is the extent to which the grains act only as *passive* sinks, and the extent to which surface catalytic reactions can *actively* produce new molecules. Jones and Williams (1984), e.g., have argued that

the observed H_2O ice mantles in the Taurus molecular cloud cannot have been formed by accretion of H_2O , and therefore must be due to formation of H_2O on the grain surface itself. Additional observational evidence for active grain chemistry has been presented in Sec. IV.A. Note that trapping of H_2 itself is not possible; while there may be a surface monolayer of H_2 adsorbed on the grain substrate, this is a negligible fraction of the total H_2 reservoir. The vapor pressure of solid H_2 is too high for more than a monolayer to accumulate.

As noted in Sec. II and Fig. 2, the accretion process by itself would quickly remove heavy species such as C and CO from the gas phase on a time scale that is short compared with the estimated lifetime of the clouds, or even the time scale to reach chemical equilibrium in the gas phase. As no opaque clouds void of gas-phase molecules like CO have yet been found, this raises the question of how the trapping process is circumvented. Various transient processes which may act to return adsorbed species to the gas have been discussed by Leger et al. (1985), including grain-grain collisions triggering "chemical explosions" (d'Hendecourt et al. 1982), and thermal spikes due to ultraviolet and X-ray photons and cosmic rays. Transient increases in the radiation field due to, e.g., FU Ori outbursts could conceivably be important (Draine 1985a). Duley et al. (1989) have recently argued that "spot heating" of amorphous carbon grains by photons can result in effective desorption of volatiles, whereas Boland and de Jong (1982) suggested that material is continuously recycled from the dense part to the more diffuse edge of the cloud by turbulent mixing. Some combination of these processes is apparently effective in quiescent clouds, but it is not yet clear which are the most important.

In regions of star formation, the higher temperatures resulting from the radiation of embedded stars or shocks can evaporate the grain mantles and return species to the gas phase. The temperature required for thermal evaporation of pure CO ice is only 17 K, whereas that for pure H_2O ice is 90 K. "Dirty ice" mixtures probably have sublimation temperatures in between these values. If the clouds are subjected to strong shocks ($v_s > 200 \text{ km s}^{-1}$), not only the volatile mantles, but also the refractory cores can be destroyed, returning silicon, iron, carbon and other species to the gas phase (Seab 1987).

3. *Grain Mantle Models.* Detailed theoretical models of the composition of icy grain mantles have been developed, e.g., by Tielens and Hagen (1982) and d'Hendecourt et al. (1985). The results depend sensitively on the physical conditions in the cloud, and in particular on the corresponding gas-phase composition. This can be understood by realizing that at low temperatures ($T \approx 10 \text{ K}$), only lightly bound species such as H, H_2 , C, N, O and S can migrate over the surface, whereas molecules such as CO, N_2 , O_2 , NH_3 and H_2O are trapped in both physis- and chemisorbed sites. Thus, only reactions among the mobile species themselves, or between a mobile atom and a trapped molecule can occur, with the result that the mantle composition depends sensitively on the relative amounts of H, C, O and N in the gas phase. Three different chemical regimes can be distinguished, which have been illustrated in Fig. 3 in Sec. II (Tielens 1989): at low densities ($n < 10^4 \text{ cm}^{-3}$), atomic H is more

abundant in the gas phase than heavy species, and dominates the grain surface reactions. Under such reducing conditions, most of the accreted gas-phase species such as CO and O₂ are transformed into hydrides like H₂O and H₂CO. Subsequent reactions of H with H₂CO may form CH₃OH. Note, however, that the predicted mantle abundance of NH₃ is quite low in these particular models, in which the reaction of N₂ with H is inhibited by a large barrier. Only a large fraction of gas-phase atomic N can lead to a substantial amount of NH₃. CH₄ is also not predicted to be significant in these steady-state models, although it reaches a fractional abundance of more than 10% at early times.

At higher densities ($n > 5 \times 10^4 \text{ cm}^{-3}$), the gas-phase abundances of CO, O, O₂ and N₂ are larger than those of H, so that O becomes the most mobile atom on the surfaces. If the O/O₂ ratio in the gas phase is low, few surface reactions occur, resulting in an inert grain mantle whose composition reflects that of the gas phase. For high O/O₂ abundance ratios, the reaction $\text{O} + \text{CO} \rightarrow \text{CO}_2$ makes CO₂ a major constituent.

The grain surface processes can also result in large deuteration effects, because the gas-phase atomic D to H ratio ($\approx 10^{-2}$) is much larger than the overall deuterium abundance ratio ($\approx 10^{-5}$). Most of the gas-phase deuterium is locked up in HD, but the sequence of reactions $\text{HD} + \text{H}_3^+ \rightarrow \text{H}_2\text{D}^+ + \text{H}_2$; $\text{H}_2\text{D}^+ + \text{CO} \rightarrow \text{DCO}^+ + \text{H}_2$; $\text{DCO}^+ + \text{e} \rightarrow \text{D} + \text{CO}$ can enhance D relative to H (Tielens 1983; Dalgarno and Lepp 1984). Because D is nearly as mobile as H on the surface, molecules like HDO, NH₂D and CH₃OD are readily formed in the grain mantles. Doubly deuterated molecules such as NHD₂ and D₂CO probably arise exclusively from grain mantles (Brown and Millar 1989b; Turner 1990).

In summary, different types of grain mantles can occur under different conditions in molecular clouds. Because most grain mantles observed so far are dominated by H₂O and possibly CH₃OH (see Table VIII), it appears that the first scenario, in which grain mantles are formed at relatively low densities in a hydrogen-rich atmosphere, prevails. However, it should be stressed again that the model grain mantles primarily reflect the gas-phase composition, which, as discussed in Sec. II.B (see also Sec. III.C and Sec. V), is highly uncertain. In particular, the recent controversies surrounding some crucial gas-phase reaction rates result in ill-determined O/O₂, N/N₂ and C/CO gas-phase abundance ratios. Also, the actual amount of atomic H inside dense clouds is not well known. The effects of these uncertainties on the grain mantle composition have not yet been explored in detail. In addition, subsequent processing of mantle material by ultraviolet photons and/or cosmic rays can occur. More laboratory work is needed on the basic chemical processes that can take place on the grains, as well as on basic solid-state spectroscopy.

4. Shock Chemistry. Models of shocked regions may be divided into several classes (see Dalgarno 1984; Shull and Draine 1987; Hollenbach et al. 1989 for reviews). First, there are the classical *J*-type shocks with or without magnetic precursors. *J*-type shocks are characterized by the pres-

ence of an abrupt transition layer where the hydrodynamic variables jump discontinuously. The chemistry in *J*-type shocks has been discussed, e.g., by Hollenbach and McKee (1979), Hartquist et al. (1980), Mitchell (1984) and Graff and Dalgarno (1987). If the shock is fast enough, the molecules are dissociated and they reform in different configurations as the post-shock gas cools. Sophisticated dissociative shock models have recently been presented by Neufeld and Dalgarno (1989) and Hollenbach and McKee (1989).

The second class of shocks, called *C*-type, occurs if the fractional ionization is low and the magnetic field sufficiently strong. Here the hydrodynamic parameters vary smoothly from pre-shock to post-shock values, and the peak temperature is generally lower than in *J* shocks. Detailed calculations of the physical structure of such a shock in a dense cloud have been performed by Draine et al. (1983), but these models include only a limited chemistry.

The results of the models depend, of course, on whether the shock is of *J* or *C* type, and whether it passes through a diffuse or dense cloud. Nevertheless, some general features emerge. In particular, the formation of molecules no longer occurs by ion-molecule reactions, but proceeds mostly through neutral-neutral reactions of the type

A good example is provided by the oxygen chemistry, where both OH and H₂O are formed efficiently through the reactions

Compared with cold quiescent clouds, the shock models thus predict enhancements of OH and H₂O, of sulfur-bearing molecules like H₂S for which the reactions are endothermic, and of molecules such as SiO and HCN.

Star Formation

ENVIRONMENTS OF STAR FORMATION: RELATIONSHIP BETWEEN MOLECULAR CLOUDS, DENSE CORES AND YOUNG STARS

ELIZABETH A. LADA

Harvard-Smithsonian Center for Astrophysics

KAREN M. STROM

University of Massachusetts

and

PHILIP C. MYERS

Harvard-Smithsonian Center for Astrophysics

In this chapter, the star-forming properties of three molecular cloud complexes, Taurus-Auriga, Ophiuchus and Orion, are discussed. In particular, recent observational knowledge of the distribution and properties of dense molecular gas and young stellar objects within each complex is reviewed. Studies of the two nearest molecular cloud complexes, Taurus and Ophiuchus, have shown that at least two modes or environments of star formation exist: isolated and clustered. Studies of the nearest giant molecular clouds in the Orion complex also show evidence for both modes. However, the recent and extensive census for dense cores and young stellar objects in the L1630 (Orion B) cloud has clearly shown that the clustered mode of star formation is dominant in this region. Existing observations of the L1641 GMC (Orion A) suggest that the clustered mode of star formation may also dominate in this cloud. If star formation in L1630 is representative of star formation in other giant molecular clouds, then the clustered mode of star formation may be the dominant mode of star formation in our Galaxy.

I. INTRODUCTION

Understanding how stars form is one of the major goals of modern astrophysics. In order to fully understand star formation, one must study both the prenatal material and the recent products of star formation. Over the last two decades, radio and infrared observations have revealed that stars in our Galaxy form from the densest, dust-enshrouded regions of molecular clouds. It is therefore important for star formation studies to acquire a knowledge of the distribution and properties of dense gas within molecular clouds and the distribution and properties of the young stellar objects (YSOs) formed within molecular clouds. Such knowledge not only helps to determine the conditions

and mechanisms necessary to produce stars but also provides valuable insights into the relationship between young stars and their environments.

In this chapter, we will discuss recent observations of the dense gas and associated YSOs in three star forming complexes: Taurus-Auriga, Ophiuchus, and Orion. These are regions for which both the molecular gas content and young stellar content have been the most extensively studied.

II. STAR FORMATION IN NEARBY CLOUDS

A. Taurus-Auriga Molecular Complex

Nearby molecular cloud complexes provide excellent laboratories for investigations of the star forming process because they have the advantage of being studied with high angular resolution and high sensitivity. One of the best-studied examples of a nearby region forming predominantly low-mass stars is the Taurus-Auriga complex. It is located at ~ 140 pc (Elias 1978*b*), towards $l = 170^\circ$ and $b = -15^\circ$, and extends over several tens of parsecs. The complex contains $\sim 10^4 M_\odot$ of material (Wouterloot and Habing 1985; Cernicharo et al. 1985; Ungerechts and Thaddeus 1987) and is composed of several well known dark clouds (Barnard 1919; Lynds 1962). Figure 1 presents a visual photograph of the central region of the Taurus-Auriga complex. The dark clouds L1495 (right center) and L1534 or TMC1 (lower left corner) are easily seen in this picture as regions of visual obscuration. The large-scale structure of Taurus-Auriga has been studied using ^{13}CO (Kleiner and Dickman 1984, 1985), star counts (Cernicharo et al. 1985), OH (Wouterloot and Habing 1985), CO (Baran 1982; Ungerechts and Thaddeus 1987) and IRAS $100 \mu\text{m}$ column density measurements (Scalo 1990). These studies have all revealed very complex, irregular and filamentary structures, typical of molecular cloud complexes in our Galaxy (see Chapter by Blitz).

In addition to the diffuse, filamentary structures, small dense cores have been found within Taurus-Auriga by molecular line surveys of regions of optical obscuration (Myers et al. 1983; Myers and Benson 1983). The cores are well-defined structures and their physical properties are determined from molecular line maps of molecules sensitive to gas densities $\geq 10^4 \text{ cm}^{-3}$, such as NH_3 (Myers and Benson 1983; Benson and Myers 1989), CS (Zhou et al. 1989), HC_3N (Sorochenko et al. 1986) and DCO^+ (Butner et al. 1992). The most extensive studies of the properties of cores in Taurus have been carried out using NH_3 (Myers and Benson 1983; Benson and Myers 1989). Examples of NH_3 cores are shown in Figs. 2 and 3. These cores are found in regions of high visual obscuration as is evident from the Palomar Sky Survey plates. The NH_3 observations reveal that the cores are small, having sizes on the order of 0.1 pc and masses on the order of a few solar masses. In addition, the cores exhibit kinetic temperatures of ~ 10 K and densities $\sim 10^4 \text{ cm}^{-3}$. One of the most notable characteristics of the cores is their very narrow NH_3 line widths $\sim 0.3 \text{ km s}^{-1}$ (FWHM). Analysis of the NH_3 line profiles have revealed that thermal motions dominate the line broadening and that nonthermal motions

Figure 1. A visual photograph of the central regions on the Taurus complex (figure from Barnard 1927).

may be due to subsonic microturbulence. Similarly, narrow line widths are also evident in lines of HC_3N (Sorochenko et al. 1986), C_3H_2 (Cox et al. 1989).

The core properties described above are not restricted to Taurus cores. They also apply to most nearby dark cloud cores such as those found in Ophiuchus and Cygnus, but the Taurus complex is the best studied complex: 14 of the 41 dense core maps in Benson and Myers (1989) are in Taurus. It is important to note however, that the properties derived for the cores can vary with the molecular line observed (Myers 1985). For example, CS observations of a sample of nearby " NH_3 cores" in Taurus and other nearby clouds (Zhou et al. 1989; Fuller 1989) have revealed that the core properties determined from CS differ with those determined from previous NH_3 observations. Core sizes measured in CS are on average 1.5 times larger than sizes measured in NH_3 and the CS line widths are \sim a factor of 2 wider than the NH_3 line widths. In addition, estimates of core mass and density are also larger by 1 to

Figure 2. An example of a typical NH_3 core in the Taurus molecular cloud complex. An enlargement of the PSS Print is compared with an NH_3 map for TMC1-1C. The NH_3 contour levels are 0.10, 0.30, 0.50 and 0.70 K (figure from Benson and Myers 1989).

Figure 3. An example of a nearby dense core and its associated IRAS source. A reproduction of the PSS Print is compared with NH_3 maps for B35. The NH_3 contour levels equal 0.15, 0.20, 0.25 and 0.30. IRAS sources associated with the cores are represented by asterisks. (figure from Benson and Myers 1989).

2 orders of magnitude. The differences in size and line width are perplexing because the CS transitions are expected to trace densities comparable to or higher than NH_3 (Zhou et al. 1989). In particular, if the NH_3 and CS emission originate from similar regions and thermal motions dominate, then one would expect the CS lines to be narrower than the NH_3 lines, because CS is a heavier molecule. Yet, the widths of the CS lines are substantially larger than those of the NH_3 lines suggesting that nonthermal (e.g., turbulent) motions are significant. Fuller (1989) has suggested that the CS observations trace

somewhat lower densities than the NH_3 due to high optical depth and radiative trapping in the CS line. However, Zhou et al. (1989), have ruled out optical depth effects as the sole cause of CS line broadening in at least two sources based on C^{34}S observations. They suggest that chemical differentiation in the cores (e.g., underabundance of NH_3 relative to CS) may be responsible for the differences in the CS and NH_3 properties.

Butner et al. (1992) have surveyed the Myers and Benson (1983) sample of 27 NH_3 cores for $\text{DCO}^+(J=1\rightarrow 0, J=2\rightarrow 1 \text{ and } J=3\rightarrow 2)$ emission and have mapped 9 cores in $\text{DCO}^+(J=1\rightarrow 0)$. The DCO^+ molecule is expected to be abundant in cold, dense gas. The critical densities of the DCO^+ transitions are $\sim 10^5 \text{ cm}^{-3}$, similar to the critical densities for the CS transitions. Therefore the DCO^+ observations provide an independent measurement of the properties of the dense cores. Core sizes and shapes measured in $\text{DCO}^+(J=1\rightarrow 0)$ are similar to those measured in NH_3 . However, core densities derived from the DCO^+ multi-transition observations are 3 to 10 times higher than densities estimated from NH_3 observations. In addition, the DCO^+ line widths are found to be significantly broader than the NH_3 line widths, although somewhat narrower than the CS line widths. Butner et al. (1992) conclude that many of the broad DCO^+ line widths do not arise from optical depth effects, scattering or foreground absorption. On the other hand, it is difficult to identify any mechanism, other than maser emission, which would make the widths of NH_3 , C_3H_2 , and HC_3N significantly narrower than the true distribution of molecular velocities. Furthermore, the relative intensities of NH_3 lines in dark clouds are inconsistent with maser emission. The reason why line width differences among various molecular species exist is still a puzzle and may be due to effects of interstellar chemistry (Zhou et al. 1989; Butner et al. 1992). However, it appears that the dynamical states of dense cores can not be simply characterized as either thermal or turbulent. Clearly further studies are needed to resolve the apparent inconsistencies among dense core line widths.

One core property that appears to be independent of the choice of molecular line tracer is core shape. An NH_3 survey for nearby dense cores has shown that cores are significantly elongated, having aspect ratios between 1.4 to 2.3. (Benson and Myers 1989). Butner et al. (1992) compare DCO^+ and NH_3 maps for 9 cores and find that the maps have similar shapes. Myers et al. (1991a) compare NH_3 (Benson and Myers 1989), C^{18}O and CS (Fuller 1989) maps of 16 nearby cores. They find that the maps for each core are similar in position, elongation and orientation and therefore suggest that elongation is a common characteristic of dense cores. This elongation probably corresponds to a prolate, rather than oblate shape in at least six cores (Myers et al. 1991a). This has important consequences for theories of star formation, for it implies that cores cannot be simply modeled as isolated, self-gravitating regions of quasi-stable equilibrium.

Dense cores, such as those found in Taurus, are sites of star formation. This is demonstrated by the observations that many dense cores are associated

with known T Tauri stars (Myers and Benson 1983), bipolar outflows (Fuller and Myers 1987; Myers et al. 1988) and low luminosity IRAS sources (Beichman et al. 1986; Myers et al. 1987). In fact, IRAS sources were detected in approximately half of the known ~ 100 nearby cores (Benson and Myers 1989). Furthermore, IRAS sources having spectral energy distributions with positive slopes (Class I or steep spectrum sources) are found in closest proximity to dense core centers. Typically one to a few stars are found per core. Figure 3 compares the position of the dense core, B35 A with its associated IRAS source. In this example, the IRAS source is located near the peak of the NH_3 emission.

To fully characterize the star-forming activity within a given complex requires knowledge of both the dense gas and the population of YSOs within the cloud. Knowledge of the distribution of YSOs is of particular interest. The first large-scale survey of the embedded stellar population in the Taurus complex was obtained at $2\,\mu\text{m}$ using a single detector (Elias 1978*c*). The spatial resolution ($1''$ – $2''$) and the sensitivity ($m_K \geq 7.5$) of this survey were poor by current standards but nonetheless, Elias was able to detect ~ 200 sources. Most of these sources were found to be field stars. The sources associated with the cloud appeared to be distributed in small groups, scattered throughout the cloud. Jones and Herbig (1979) and Larson (1982) arrived at similar conclusions based on optical studies of the distribution of young stars in this complex.

Recently, Kenyon et al. (1990) have completed a survey of the young stellar population in the Taurus-Auriga region, using the IRAS data base. Their survey is complete for luminosities $L > 0.5\,L_\odot$, making it one of the most sensitive surveys for YSOs. They have identified ~ 105 objects clearly associated with the Taurus complex. Only 7 of these objects are newly identified pre-main-sequence stars (i.e., optically visible T Tauri stars). Six are new deeply embedded objects (i.e., optically invisible IRAS sources with red spectra). The distribution of YSOs in the Taurus complex is shown in Figs. 4 and 5 superimposed on maps of CO emission (Ungerechts and Thaddeus 1987; Kenyon et al. 1990) and IRAS $100\,\mu\text{m}$ column density, respectively. Examining the distribution of YSOs, we find that the YSOs in Taurus are located over a large area of the molecular cloud. Roughly 100 YSOs are found in a $15\,\text{pc} \times 20\,\text{pc}$ region. Although the sources for the most part are scattered throughout the cloud in agreement with earlier studies, some weak clustering of sources is also apparent in Figs. 4 and 5.

Although studies of dense cores in Taurus and other nearby regions suggest that cores are frequently associated with star formation, they do not address the question of whether star formation occurs exclusively in dense molecular cores. Answering this question requires comparing the surveys for embedded YSOs with surveys of the molecular gas content in a given cloud complex. Comparing the distribution of YSOs with the distribution of CO in Taurus (Fig. 4), we find that the YSOs are all located within the molecular cloud boundaries, illustrating that stars do form in molecular clouds.

Figure 4. The distribution of young stellar objects in Taurus-Auriga is shown superimposed on a map of CO integrated intensity (figure from Kenyon et al. 1990). The CO contours are presented for integrated intensities equal to 5, 10, 25, and 40 K km s⁻¹.

Furthermore, most of the YSOs in Taurus are located in regions of relatively high column density (Fig. 5). While high column densities do not necessarily imply high volume density, recent work on clumping in molecular clouds has found that regions of high column density are usually also regions of high volume density (Stutzki and Gusten 1990). Finally, since IRAS surveys for embedded objects have not found a significantly large number of new sources (Kenyon et al. 1990), and since previously identified embedded sources in Taurus are known to be associated with dense molecular gas (Beichman et al. 1986; Myers et al. 1987), it appears that star formation in Taurus is restricted to the dense gas. However, unbiased studies of the distribution of the dense gas in Taurus are needed to quantify this observation.

Determining the natures and evolutionary states of YSOs is essential for investigating the star-forming history of a molecular cloud complex. Because stars appear to form from the densest regions of molecular clouds, it is expected that YSOs will be associated with large amounts of gas and dust.

Figure 5. The distribution of young stellar objects in Taurus-Auriga is shown superimposed on a map of IRAS 100 μm column density (figure courtesy of S. Kenyon).

Consequently, they will radiate a significant fraction of their energy at infrared wavelengths and their infrared spectral energy distributions should reflect the nature and distribution of the material surrounding them and their evolutionary state (Lada 1987; Adams et al. 1987). In fact, YSOs can be meaningfully classified into three distinct morphological classes based on the shapes of their broad band (1–100 μm) energy distributions (Lada and Wilking 1984; Adams et al. 1987; Myers et al. 1987). These are illustrated in Fig. 6. Class I sources have strong “infrared excesses” (i.e., infrared energy distributions that are broader than a blackbody distribution) and their spectral energy distributions are characterized by positive slopes at wavelengths longer than 2 μm . In addition, many of these sources are difficult to detect at wavelengths short-

ward of $12\ \mu\text{m}$. Class I sources are likely protostellar in nature (Adams and Shu 1986; Adams et al. 1987). Class II sources also have infrared excesses, but their energy distributions are characterized by flat or decreasing slopes at wavelengths longer than $2\ \mu\text{m}$. They are surrounded by considerably less circumstellar material than protostellar objects. Class II sources are optically visible and have emission-line characteristics of classical T Tauri stars. The infrared excess in Class II sources is thought to arise in circumstellar disks (Rucinski 1985; Adams et al. 1987; Kenyon and Hartmann 1987; Rydgren and Zak 1987; Strom et al. 1988). Class III objects have little or no infrared excess emission and their energy distributions are characterized by reddened blackbody functions. These sources are also optically visible and include young main-sequence stars and also younger pre-main-sequence stars that no longer have optically thick circumstellar disks such as the weak-lined or naked T Tauri stars (see, e.g., Walter 1987*a*). The classifications described above are thought to represent phases in an evolutionary sequence of YSOs from protostar to young main-sequence star (Lada 1987; Adams et al. 1987).

Broadband infrared energy distributions have been constructed for the IRAS population in Taurus (Beichman et al. 1986; Myers et al. 1987; Kenyon et al. 1990). As a result, 26 IRAS sources known to be associated with the cloud have been classified as Class I sources and 59 as Class II sources (Kenyon et al. 1990). In addition, there are about 20 Class III sources in Taurus (Walter et al. 1988; Strom et al. 1989*b*). One should note that the sample of Class III sources is most likely incomplete and the total number of these sources may be comparable to the number of Class II sources (Walter et al. 1988; Kenyon and Hartmann 1990; Kenyon et al. 1990; Strom et al. 1990). Kenyon et al. (1990) estimate that Taurus-Auriga contains ~ 100 to 140 pre-main-sequence stars and consequently the ratio of embedded sources to pre-main-sequence sources is small. These statistics are consistent with the idea that most sources have an optically invisible "embedded" phase of a $(1-2) \times 10^5$ yr, comparable to the free-fall time of a dense core, followed by a visible T Tauri phase of a few $\times 10^6$ yr.

Using the infrared energy distributions, Kenyon et al. (1990) have constructed a luminosity function for the Taurus complex (see Chapter by Zinnecker et al.). Surprisingly, the luminosities of the embedded (Class I) sources do not obviously differ from the luminosities of the optically visible T Tauri stars. This fact is inconsistent with the protostellar collapse calculations, where the protostellar luminosity must be considerably greater than that of the resulting star if the collapse time is short relative to the T Tauri star lifetime. Kenyon et al. (1990) construct models for the luminosity functions of accreting protostars, examining the sensitivity of the resultant luminosity functions to the input conditions, in order to place constraints on the model parameters from the observations. They find that, if the assumed age of the T Tauri population is correct and the time scale for the embedded phase $\sim (1-2) \times 10^5$ yr, the mass accretion rate onto the stellar photosphere for the embedded objects cannot be steady; it must be much lower than previously

Figure 6. Classification scheme for young stellar object energy distributions (figure from Lada 1987a).

assumed for most of the time in order that the luminosity of the embedded sources be as low as observed. This might indicate that most of the infalling material is stored in a circumstellar disk to be accreted over a longer period

of time or in bursts such as FU Ori outbursts. Hartmann and Kenyon (1990) have estimated that as much as 0.1 of the final stellar mass is accreted from the disk during the T Tauri phase of evolution. If the true ages of the T Tauri stars have been underestimated by a factor of ~ 3 and material is accreted slowly from the disk during that time, the models agree within a factor of 2 with the observed luminosity function.

B. Ophiuchus Molecular Complex

Another example of a nearby star forming region is the Ophiuchus molecular cloud complex (see Wilking 1992 for a review). The Ophiuchus complex is located near the Scorpius-Centaurus OB association. Distance estimates to the molecular complex range from the traditional value of 160 pc (Bertiau 1958; Whittet 1974; Chini 1981) to a more recent value of 125 ± 25 pc (de Geus et al. 1990). Many similarities exist between the Ophiuchus and Taurus complexes. Like Taurus, the Ophiuchus complex is a region of low-mass star formation. It contains a number of dark clouds (Lynds 1962), and the total mass of the complex, measured in CO, is $\sim 10^4 M_{\odot}$ (de Geus et al. 1990). Figure 7 presents an optical photograph of the L1688 cloud, located in the western part of the Ophiuchus complex (Barnard 1927). Large-scale molecular line surveys of Ophiuchus using CO (de Geus et al. 1990) and ^{13}CO (Loren 1989*a, b*) have revealed filamentary or clumpy structures. In fact 89 distinct ^{13}CO structures have been identified by Loren (1989*a, b*). In addition, several dense NH_3 cores, having properties similar to cores found in Taurus, have been identified in this complex (Myers and Benson 1983; Benson and Myers 1989).

The Ophiuchus star-forming region is distinguished by the presence of a large centrally condensed core with active star formation (Wilking and Lada 1983). This core is located near the star Rho Oph, in the dark cloud L1688 (Rho Ophiuchi), the westernmost cloud of the complex. It is a region of high visual extinction, with A_v as high as ~ 50 – 100 mag (Vrba et al. 1975, 1976; Chini et al. 1977, 1981; Wilking and Lada 1983). Wilking and Lada (1983) have mapped the core in C^{18}O , which is expected to be a good indicator of column density. They find the core to be $1 \text{ pc} \times 2 \text{ pc}$ in size and to contain $\sim 600 M_{\odot}$.

In addition to being a region of high visual extinction and high column density, high-density gas is also concentrated in the Rho Ophiuchi cloud core. Early observations of the density sensitive molecules, SO (Gottlieb et al. 1978) and H_2CO (Loren et al. 1983) identified two concentrations of dense gas, Rho Oph A and B within the cloud core. Density estimates of these concentrations indicate peak densities of $\sim 10^5 \text{ cm}^{-3}$ for Rho Oph A and $\sim 10^6 \text{ cm}^{-3}$ for Rho Oph B (Loren et al. 1983). Recently, an extensive survey for DCO^+ emission has been completed in the Ophiuchus complex (Loren et al. 1990). As a result, 12 cold, dense condensations were identified. These DCO^+ cores have masses ranging from 8 to $44 M_{\odot}$ and densities ranging from $10^{4.5}$ to 10^5 cm^{-3} . In addition, DCO^+ line widths range from 0.4 to

Figure 7. A visual photograph of the dark cloud of ρ Ophiuchi (figure from Barnard 1927).

1.1 km s^{-1} . Of the 12 dense condensations identified, 8 are located within the Rho Ophiuchi cloud core as defined by C^{18}O . Moreover, the distribution of these 8 DCO^+ cores appears to be highly clustered (Loren et al. 1990), indicating that the dense gas is localized in the Rho Ophiuchi cloud core.

The Ophiuchus complex is further distinguished by the localized concentration of YSOs in the Rho Ophiuchi cloud. $\text{H}\alpha$ objective prism surveys of the Ophiuchus complex (Haro 1949; Dolidze and Arakelyan 1959; Wilking et al. 1987) have shown that the majority of young T-Tauri like objects are associated with the western half of Rho Ophiuchi (Fig. 8). IRAS based studies of the embedded stellar population (Ichikawa and Nishida 1989) have also found a concentration of sources in this cloud. Furthermore, near-infrared

observations of the Rho Ophiuchi cloud core have revealed the presence of a dense stellar cluster (Grasdalen et al. 1973; Vrba et al. 1975; Elias 1978a; Wilking and Lada 1983).

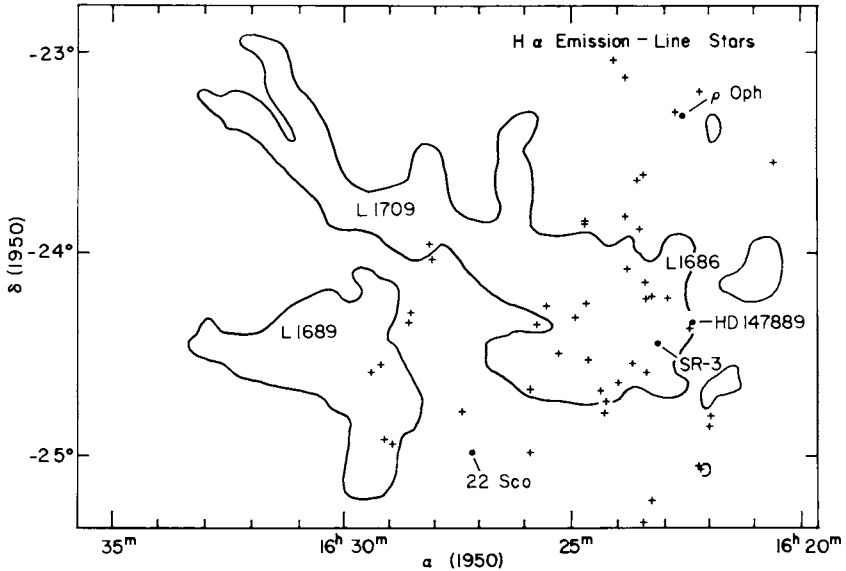

Figure 8. The distribution of $H\alpha$ stars is shown (figure from Wilking et al. 1987a). The molecular clouds are outlined by contours of ^{13}CO emission. The contour level represents $T_A^* = 3$ K (Loren and Wootten 1986).

The young stellar population in the Rho Ophiuchi cloud core has been carefully studied using both near-infrared and IRAS observations (Wilking and Lada 1983; Lada and Wilking 1984; Young et al. 1986; Wilking et al. 1989a). The distribution of YSOs is shown in Fig. 9. A total of 78 YSOs have been identified as members of the cluster and 39 additional infrared sources lie within the core boundary, but remain unclassified (Wilking et al. 1989a). Spectral energy distributions have been used to classify the majority of these sources. As a result, 24 YSOs have been identified as Class I sources and 27 as Class II sources. The nearly equal number of Class I and II sources suggests that the lifetimes of the stars in the embedded state (Class I) may be comparable to the average lifetime of the T Tauri (Class II) stars in the cloud, approximately 4×10^5 years (Wilking et al. 1989a). This would imply that the lifetime of the embedded phase in Rho Ophiuchi is somewhat longer than that in Taurus. However, one should note that the survey for Class II sources in the Rho Ophiuchi cloud is incomplete due to IRAS insensitivity and that Class III sources are not considered in this estimate. Accounting for the incompleteness of Class II and Class III sources, Wilking et al. (1989a)

estimate the lifetime of the embedded phase to be $(1-4) \times 10^5$ yr, consistent with the estimates for Taurus.

Figure 9. The distribution of young stellar objects associated with the ρ Ophiuchi molecular cloud (figure from Wilking et al. 1989a). The YSOs associated with the molecular cloud core are displayed as open circles, superposed on the red photograph of the Palomar Sky Survey. The boundaries of the molecular gas (^{13}CO ; Loren 1989a) are presented by a solid contour).

Wilking et al. (1989a) construct a luminosity function for the Rho Oph core and find that the YSO luminosities are segregated according to the shapes of their spectral energy distributions. Class I sources appear to dominate at intermediate luminosities while Class II sources dominate at lower luminosities. For example, 82% of the YSOs having luminosities in the range of $5.6 L_{\odot}$ to $56 L_{\odot}$, are Class I sources whereas 67% of the sources with $0.5 L_{\odot} < L < 5.6 L_{\odot}$, are Class II objects. This result implies that stars in Rho Oph undergo luminosity evolution as they progress from Class I to Class II objects, consistent with theoretical expectations (see, e.g., Stahler et al. 1980; Adams and Shu 1986; Adams et al. 1987). However this is quite different

TABLE I
Star-Forming Properties of Nearby Clouds

Regions containing 100 stars	Area (pc ²)	Stellar Density (number/pc ²)	Gas Mass (M _☉)	Mode of Star Formation
Taurus	300	0.3	10 ⁴	isolated
ρ Oph Core	2	50	600	clustered

than the situation in Taurus as described earlier in this review, where Class I sources have comparable and even lower luminosities than Class II sources. An alternate interpretation of the luminosity segregation is that stars in the Rho Oph cloud core are being produced sequentially in mass, with the most recent episode of star formation producing mostly intermediate mass stars. In addition, the observations suggest that a deficiency of intermediate mass stars relative to the initial luminosity function exists in the Rho Oph cloud.

Finally, estimates of the star formation efficiency (SFE) of the Rho Oph core reveal a SFE > 20% (Wilking and Lada 1983; Wilking et al. 1989*a*). Such high star formation efficiencies suggest that the embedded cluster may survive as an gravitationally bound open cluster when it emerges from its core (Wilking and Lada 1983; Lada et al. 1984).

III. CLUSTERED VERSUS ISOLATED STAR FORMATION

From studies of nearby molecular cloud complexes, two different pictures of the star-forming process have emerged (see, e.g., Lada 1987; Shu et al. 1987*a*). Observations of low-mass cores in Taurus and Ophiuchus (Myers 1985) have presented us with one picture in which individual stars form from small, isolated dense cores distributed throughout a molecular cloud. These observations have led to the development of the first detailed theory of star formation (Shu et al. 1987; Lada and Shu 1990). In this theory, a dense core, supported primarily by thermal and magnetic pressures, slowly contracts, via ambipolar diffusion, to form a density structure similar to that of an isothermal sphere. At this point, gravitational collapse begins, first in the center of the core and then propagating outward (inside-out collapse). The inner regions form a protostar and if the dense core is slowly rotating initially, a disk will also form within the centrifugal radius, R_c . Material continues to fall onto the star-disk system from the surrounding envelope of dust and gas. At some point during the evolution of this system, a strong wind or outflow develops. The outflow reverses the infall of the outer envelope and eventually reveals the young star and its circumstellar disk.

A very different picture of star formation is presented by observations of the Rho Ophiuchi molecular cloud core. Here, a rich cluster of stars is forming from a single massive concentration of dense gas. In this case, star formation is not occurring in an isolated environment but rather in a densely packed one. To illustrate this point, we can compare the surface density of

YSOs in the Rho Ophiuchus cloud core with that of YSOs in regions of Taurus (Table I). We have learned from the previous discussions that approximately 100 YSOs are located in a 2-pc^2 area of the Rho Ophiuchi cloud core. In Taurus, an equal number of YSOs are found in a much larger area, covering roughly 300 pc^2 . Consequently, the stellar surface density in Rho Ophiuchi (50 stars/pc^2) is much higher than the corresponding density (0.3 stars/pc^2) in Taurus. Although some weak clustering is also apparent in Taurus (see Figs. 4 and 5), the surface density of stars, even in the clustered regions is still an order of magnitude lower than in the Rho Ophiuchi cluster (Lada and Myers, in preparation).

The physical conditions within massive cores producing rich clusters of stars are expected to be quite different from those of isolated cores forming single stars. Consequently, the physics governing star-formation in these two environments may differ in some fundamental way not accounted for in present theoretical models. For example, the star-formation efficiency of the Rho Ophiuchi cloud core is higher than the efficiency of regions in Taurus which are producing an equal number of YSOs. In the Rho Oph core, ~ 100 stars are forming from $\sim 600\text{ M}_\odot$ of gas, whereas ~ 100 stars are forming from $\sim 10^4\text{ M}_\odot$ of gas in Taurus.

The differences observed in star-forming environments suggest that two distinct modes of star formation may exist, (1) an isolated or distributed mode and (2) a clustered mode. Isolated star formation can be characterized by low stellar density and low overall star-formation efficiency. In this mode, 1 to a few stars form from small, well-defined dense cores *distributed* through a molecular cloud. Clustered star formation can be characterized by high stellar densities and relatively high star-formation efficiency. In this case, groups of many stars form from single massive concentrations of gas. At the present time, it is unclear whether current theoretical models can account for the differences in these modes of star formation.

IV. STAR FORMATION IN GIANT MOLECULAR CLOUDS: ORION COMPLEX

While studies of nearby clouds reveal much about the star-formation process, they do not necessarily tell us how the majority of the stars in the Galaxy form. Most stars in our Galaxy form in giant molecular clouds (GMCs) (Roberts 1957; Miller and Scalo 1978; Blitz 1980). GMCs are large, massive collections of gas and dust, extending over 100s of parsecs and having masses on the order of 10^5 M_\odot (see Chapter by Blitz). They are notable for being the sites of OB star formation but produce stars of both high and low mass (Lada et al. 1991b). It is important to study the properties of these clouds and to determine how GMCs produce stars. For example, how do the properties of the star-forming cores in GMCs compare to those in nearby dark clouds, and does star formation in GMCs occur in the clustered or isolated mode or by some combination of both modes?

The Orion molecular cloud complex is the nearest giant star-forming complex to the Sun. Distance estimates to the Orion clouds have traditionally ranged from ~ 400 to 500 pc. The best estimates, ranging from 390 to 415 pc, result from a study of the distances to B stars in the Orion association (Anthony-Twarog 1982). A recent review of the star-forming properties of this region is given by Genzel and Stutzki (1989). The large-scale gas distribution of the complex has been mapped in CO (Maddalena et al. 1986). Most of the molecular material is concentrated in two large clouds, Orion A and Orion B. Both are elongated structures. Orion A or L1641 extends southward from the Orion Nebula for about 6 deg. The Orion B or L1630 cloud extends northward from the Horsehead Nebula for about 4 degrees. Both clouds contain $\sim 10^5 M_{\odot}$ of material, respectively, and are associated with regions of active star formation such as M42, NGC 1977, NGC 2023, NGC 2024, NGC 2068 and NGC 2071. The L1641 and L1630 clouds have also been extensively mapped in ^{13}CO (Bally et al. 1987, 1992; see Chapter by Blitz). Both clouds have very clumpy and filamentary structures. In this sense, these massive clouds are very similar to the nearby Taurus and Ophiuchus clouds.

A. The L1641 Molecular Cloud

Recently, the properties of dense cores and young stellar objects in the L1641 molecular cloud have been examined. A survey of the NH_3 emission toward IRAS sources in the Orion region (Wouterloot et al. 1988) has revealed the presence of dense gas. This survey detected NH_3 emission towards 18 IRAS sources. Subsequently many of these sources have been mapped in NH_3 (Harju et al. 1991) with a linear resolution comparable to that used to study NH_3 cores in Taurus (Myers and Benson 1983). As a result, 24 dense cores have been found in the Orion complex, 18 of these located in L1641. The cores have significantly larger NH_3 sizes, having median core diameters twice as large as the Taurus cores (Fig. 10). NH_3 line widths are also substantially larger in Orion (Fig. 10). However, the Orion cores are not as large as would be expected from the correlation between line width and size for other cores (Myers 1983). Harju et al. (1991) suggest that CO outflows associated with many of these IRAS sources (Wouterloot et al. 1989) may cause the observed line widths to increase, leading to the observed deviations from the predicted relationships. Finally, the L1641 cores also have higher kinetic temperatures and larger masses and are associated with IRAS sources that are much more luminous than those in the cores found in Taurus. It is important to note, however, that the comparison between Orion and Taurus cores may be somewhat misleading. The NH_3 cores studied in Orion were IRAS selected and consequently the sensitivity to sources in Orion is lower than that in Taurus (see discussion that follows). It is therefore possible that the L1641 molecular cloud also contains cores similar to those found in Taurus, but that these cores were not detected.

Studies of the IRAS selected young stellar population have also been carried out in the L1641 molecular cloud (Strom et al. 1989*a, b, c*). Strom

Figure 10. A comparison of NH_3 core (a) line widths and (b) diameters in Taurus and Orion (figure from Harju et al. 1991).

et al. (1989c) found 93 sources from the IRAS Point Source Catalog (PSC) to be associated with this cloud. Figure 11 shows the distribution of these sources superimposed on the ^{13}CO map of Bally et al. (1987). The IRAS sources are generally found in regions of high column density. In addition, the sources appear to be scattered throughout the cloud. This is reminiscent of the distribution of sources seen in Taurus.

In the Taurus-Auriga clouds, due to their proximity, we can assemble virtually the entire stellar population of the clouds, while in L1641 we are much more restricted. The IRAS selected sample in L1641 is only complete to $\sim 6 L_{\odot}$ (Strom et al. 1989c). This completeness limit is much higher than the corresponding limit ($0.5 L_{\odot}$) for the Taurus-Auriga clouds. It is therefore difficult to compare the stellar populations of these two regions directly. Some useful comparisons can be made however, but one should keep in mind the completeness differences of the two samples. In Taurus-Auriga over 80% of the IRAS PSC sources have optical identifications while, in L1641, only 53% of the IRAS sources have such identifications even though we are observing sources that are intrinsically more luminous sources. The reason for this difference can be found in the fact that L1641 contains a larger percentage of sources with spectra which are flat or rising into the far-infrared (Strom et al. 1989a) than does Taurus (Fig. 12). Specifically, only 29% of the IRAS sources in Taurus have Class I type spectral energy distributions and only 2% of the sample is detected only at wavelengths longward of $12 \mu\text{m}$. In contrast,

Figure 11. The distribution of IRAS sources associated with the L1641 molecular cloud (figure from Strom et al. 1989a). The associated IRAS sources are shown superposed on a ^{13}CO map (Bally et al. 1987).

76% of the sources in L1641 are classified as Class I sources and 32% are detected only at $\lambda > 12\mu\text{m}$.

Comparison of dense cores and YSOs in L1641 reveals that 8 of 12 steep spectrum sources (i.e., with slope of their spectral energy distribution $n > 1$) are associated with NH_3 emission while only 1 of 8 sources with $n \leq 1$ has detectable NH_3 emission (note that here, $n = d(\log \lambda F_\lambda)/d(\log \lambda)$ evaluated at $2.2\mu\text{m}$ and $25\mu\text{m}$) (Strom et al. 1989b). Thus, in L1641 the steep spectrum or Class I IRAS sources are preferentially associated with the dense molecular cores as they are in Taurus, Ophiuchus and other nearby molecular clouds (Myers et al. 1987).

Figure 12. A comparison of the frequency distribution of the slope of the spectral energy distribution n for sources in L1641 and Taurus (figure from Strom et al. 1989b). For L1641, the distribution is incomplete below $n = 1$.

Myers et al. (1987), Strom et al. (1989c) and Hughes (1989) find that the slope of the spectral energy distribution n is correlated with A_V , the visual extinction of the circumstellar dust. Sources located within cores with high extinction show large values of n because: (a) extinction at $2.2 \mu\text{m}$ depresses the near-infrared flux, and (b) the core material reprocesses the optical and near-infrared radiation from the embedded sources and re-emits these absorbed photons in the mid- and far-infrared, thus increasing the observed flux at $\lambda \geq 25 \mu\text{m}$. The higher proportion of IRAS sources with steep spectral energy distributions in L1641, compared to Taurus-Auriga, suggests that star-forming dense cores have greater optical depths in L1641 than in Taurus. Strom et al. (1989a) have used deep $2.2 \mu\text{m}$ searches to locate and image 10 of 11 IRAS selected cores and have obtained near-infrared fluxes for 10 and colors for 6 of the associated YSOs. Estimates of A_V were obtained for these core sources from the (H-K) color index, assuming that the spectral energy distributions of the YSOs were similar to that of a typical T Tauri star in Taurus. The derived values range from 40 to 80 mag.

The studies discussed above have mainly emphasized the differences in the star-forming properties of the Taurus and L1641 regions, namely that the cores in L1641 appear to be larger and more massive and are producing more luminous, and hence presumably more massive stars than those in Taurus. This is consistent with the observation that the L1641 cloud as a whole contains about ten times more molecular mass than do the Taurus clouds. If we compare the distribution of IRAS sources, however, we see that the

two regions are morphologically similar. As in Taurus, the IRAS sources in L1641 are spread over a large region of the cloud. Star formation is also occurring in well-defined dense cores. Sensitive $2.2\text{ }\mu\text{m}$ observations of 9 Class I IRAS sources reveal that the majority of the sources are single and pointlike (Strom et al. 1989a), indicating that only small number of stars form per core. (However, the magnitudes of many of these objects were not far above the detection threshold and it is possible that many fainter objects in these fields remain undetected.) These characteristics suggest that the isolated or distributed mode of star formation is occurring in L1641. However, we know from optical studies that clusters are also present in this cloud. One well-known cluster is the Trapezium (M42, Orion A) cluster (Trumpler 1931; Herbig and Terndrup 1986). Recently, McCaughrean et al. (1989) has surveyed this cluster in the near infrared and has found a total of 480 sources. The properties of this cluster are discussed in the Chapter by Zinnecker et al. In addition to this cluster, Strom et al. (1989b) have discovered a possible dense, but much smaller cluster associated with the IRAS source, 05338-0624 (Fig. 13). This IRAS source has the highest luminosity of the steep spectrum sources in L1641 and is associated with the bipolar outflow, L1641-N (Fukui et al. 1986; Wilking et al. 1990). Harju et al. (1991) estimate a clump mass of $\sim 64\text{ }M_{\odot}$ from their NH_3 map of the region. The cluster contains at least 20 stellar or semi-stellar objects located within $35''$ (0.08 pc.) radius. The resulting stellar density is therefore very high. The star-formation efficiency must lie between 4% (if all objects are assumed to be $0.1\text{ }M_{\odot}$, a least likely case) and 40% (if all objects are assumed to be $1\text{ }M_{\odot}$, a more likely case) (Strom et al. 1989b).

Both the clustered and isolated modes of star formation seem to occur in the L1641 molecular cloud. But what fraction of stars form in clusters vs isolated regions? If we add up all the embedded sources associated with clusters, we find that $\sim 85\%$ of the YSOs known to be associated with L1641 are located in clusters. This number is uncertain and may be an overestimate, because the IRAS survey is not sensitive to the entire stellar mass spectrum and hence more low-mass stars may be distributed throughout the cloud.

B. The L1630 Molecular Cloud

In order to more confidently determine the nature of star formation within a GMC, an accurate census of the dense cores and embedded YSOs within the cloud is required. To date only one GMC, the L1630 molecular cloud, has been systematically and extensively surveyed for both dense gas and embedded infrared sources (Lada 1990; Lada et al. 1991a, b; Lada et al. 1992). The goals of these surveys were to determine the distribution and properties of the dense cores and young stellar objects within L1630 and most importantly to systematically investigate the relationship between the dense cores and the YSOs.

To identify the dense cores the L1630 molecular cloud was surveyed in the $J=2\rightarrow 1$ transition of CS (Lada et al. 1991a). The total area covered

H

K

Figure 13. Near-infrared images of a small, dense cluster associated with IRAS source 05338-0624 (figure from Strom et al. 1989c). The left panel presents the H (1.65 μm) image, while the right panel shows the K (2.2 μm) image of the same region.

by the survey was ~ 3.6 square degrees or $\sim 20\%$ of the molecular cloud as measured in CO (Maddalena et al. 1986). The results of the CS($2 \rightarrow 1$) survey are presented in Fig. 14 in the form of an integrated intensity map. Emission was detected, at a 3σ level over approximately 10% of the area surveyed, revealing very clumpy structures. The CS emission was found to be bright in all previously known star-forming regions (e.g., NGC 2071, NGC 2068, M78, NGC 2024, NGC 2023 and the Horsehead Nebula). In addition to these well known sources, many previously unknown dense condensations were found. In fact, 42 individual dense clumps or cores were identified at a 5σ level above the noise. The spatial distribution of these cores is shown in Fig. 14. Most of the cores appear to be distributed about a line extending southwest to northeast, corresponding to a ridge of strong CO emission (Maddalena et al. 1986).

The dense cores identified by the CS survey exhibit a range of properties. Core sizes range from < 0.10 pc to 0.53 pc and the distribution of sizes is such that there exist many more small cores than large ones. Most cores were found to be elongated, having aspect ratios between 1.0 and 3.3. The average aspect ratio for all the cores equals 1.8, similar to the ratios found for cores in Taurus (Benson and Myers 1989), Ophiuchus (Loren 1989a) and other nearby clouds (Clemens and Barvanis 1988). CS line widths, measured from composite core spectra, range from 0.73 to 2.24 km s $^{-1}$. In addition, virial masses range from ≤ 8 to 500 M_{\odot} . Most cores have masses $<$ than 100 M_{\odot} and only 5 cores have masses > 200 M_{\odot} . The spectrum of core masses is presented in Fig. 15. For $M > 20 M_{\odot}$, the distribution can be described by the power law, $dN/dM \propto M^{-1.6}$, where N equals the number of cores per solar mass interval. It is interesting to note that all clump mass spectra determined to date (for several different molecular clouds) have a similar spectral index (see Chapter by Blitz). Furthermore, this spectral index, $\alpha = -1.6$, implies that *a significant amount of the mass of the dense gas within a GMC is contained in the most massive cores*. Indeed $\sim 50\%$ of the total core mass in L1630 is contained within the 5 most massive cores, having masses > 200 M_{\odot} . These 5 massive cores cover approximately 1% of the total area surveyed, indicating that the dense gas in the surveyed region is confined to a small area. Moreover, the cores appear to be spatially distributed in groups with the small cores clustered around the most massive ones (Fig. 14). This further indicates that the dense gas is highly localized or clustered within this cloud.

In order to study the population of YSOs, a significant portion of the L1630 molecular cloud was surveyed at near infrared wavelengths using an infrared array camera (Lada et al. 1991b). Three thousand $1' \times 1'$ fields were surveyed at $2.2 \mu\text{m}$ covering an area of approximately 0.8 square degrees. Fifty percent of the area surveyed contained CS($2 \rightarrow 1$) emission above a 3σ level. The survey is estimated to be complete to a K magnitude of 13 which at the distance to L1630, corresponds to a 0.6 M_{\odot} main-sequence dwarf. Therefore the observations were sensitive enough to detect both high- and low-mass YSOs in the cloud.

Figure 14. The distribution of dense gas in the L1630 molecular cloud (figure from Lada 1992). The contours represent CS ($2 \rightarrow 1$) integrated intensity emission. The lowest contour level equals a 3σ detection above the noise. In addition, dense cores, identified by Lada et al. (1991a) are shown as crosses with the most massive cores represented by large crosses.

As a result of this survey, 912 sources having $m_K < 13$ were identified. The distribution of these sources is shown in Fig. 16. Using statistical arguments, Lada et al. (1991b) estimate that $\sim 50\%$ of the sources having $m_K < 13$ are associated with the molecular cloud. Even with this large contribution from

Figure 15. The mass spectrum for dense cores in the L1630 cloud is plotted (figure from Lada et al. 1991a). For $M > 20 M_{\odot}$, the mass spectrum is fit by the power law: $dN/dM \propto M^{-1.6}$. The turnover in the mass spectrum may be due to incomplete sampling.

a uniform background distribution, the observed sources appear grouped or clustered. In fact, four spatially distinct, embedded clusters were identified, where an embedded cluster is defined as a region in the sky where the source density significantly increases over the background star density (see, e.g., Lada and Lada 1991). Figure 17 presents the surface density distribution of the $2.2 \mu\text{m}$ sources, showing the locations of the four embedded clusters. These clusters are associated with the well-known star-formation regions, NGC 2071, 2068, 2024 and 2023.

The basic physical properties of these and other young embedded clusters are reviewed by Lada and Lada (1991). The L1630 embedded clusters exhibit a range in size ($r = 0.3 \text{ pc}$ to 0.9 pc) and associated number of sources (~ 20 to 300). The smallest cluster is associated with the reflection nebula NGC 2023. The largest and most spectacular of the four clusters is associated with the H II region NGC 2024. Optical images of this region are noted for the presence of a dark, obscuring dust lane (Fig. 18). Early infrared studies of the H II region (Grasdalen 1974) identified a bright embedded infrared source in the middle of the dust lane. More recently, studies using single beam photometers have discovered ~ 30 near-infrared sources in this region (Barnes et al. 1989). Figure 19 presents K band image obtained by Lada et

Figure 16. The distribution of $2.2\ \mu\text{m}$ sources ($m_K < 13$) towards the L1630 cloud. The solid lines correspond to the regions surveyed (figure from Lada et al. 1991*b*).

al. (1991*b*). This image illustrates the advantage of high-resolution imaging cameras.

The most striking result of the $2.2\ \mu\text{m}$ survey is that the vast majority of the sources detected are concentrated in the four embedded clusters. Lada et al. (1991*b*) find that 58% of the sources detected by the survey are contained within the four clusters. After correction for the presence of background/foreground field stars, Lada et al. (1991*b*) estimate that $\sim 96\%$ of the sources associated with the molecular cloud are contained within the four

Figure 17. The surface density of $2.2\mu\text{m}$ sources ($m_K < 12$) toward the L1630 molecular cloud is shown in the form of a contour map. The lowest contour level corresponds to 5 times the background/foreground density of stars and subsequent levels are multiples of this value. Four embedded clusters were identified by Lada et al. (1991*b*) from this map at 10 times the background density. These clusters are associated with the well-known star formation regions NGC 2071, NGC 2068, NGC 2024 and NGC 2023. (figure from Lada et al. 1991*b*).

clusters. Furthermore, the total area covered by the four embedded clusters equals only 18% of the total region surveyed. From these results, Lada et al. (1991*b*) conclude that star formation in L1630 is a highly localized process even for stars whose masses are as low as the mass of the Sun.

Figure 18. CCD I-band image of NGC 2024 (figure courtesy of R. Probst). The well-known dust lane is prominent in this figure.

The CS and $2.2\,\mu\text{m}$ surveys have revealed that both the distribution of the dense gas and the distribution of embedded infrared sources are highly localized within the L1630 molecular cloud. Comparison of these two surveys shows that the embedded clusters are coincident or nearly coincident with 4 of the 5 most massive CS cores (Lada 1992). These findings are summarized in Fig. 20 which displays the locations and extents of the embedded clusters and the dense gas in the L1630 molecular cloud. As the embedded clusters contain the majority of YSOs associated with L1630, these results clearly show that star formation in L1630 occurs almost exclusively in dense gas. Furthermore, it appears that star formation in L1630 not only requires high densities but is also strongly favored in regions having substantial amounts of mass.

Surprisingly, even though star formation is confined to the dense regions of the L1630 molecular cloud, it is not occurring uniformly throughout the

Figure 19. Distribution of $2.2\ \mu\text{m}$ sources in NGC 2024. The K-band image (figure from Lada et al. 1991b) reveals the presence of a rich embedded cluster. The image is a mosaic of $64\ 1' \times 1'$ fields. The sensitivity limit of this image is estimated to be $m_K < 14$.

dense gas (Lada 1992). In fact, $\sim 97\%$ of the embedded sources found in clusters are associated with only 3 massive CS cores. These 3 cores have a combined mass of $\sim 1200\ M_\odot$ which corresponds to only 30% of the total core mass of the molecular cloud. This result is quite striking for it implies that the 3 massive cores may be distinct in their star-forming properties from the remainder of the dense gas. If all the cores had the same star-formation efficiency, one would expect the three most massive cores to have only 30% of the embedded sources rather than the 97 % observed. Furthermore, the L1630 cloud was found to contain a massive core (LBS 23) that is not associated with a recognizable cluster and another massive core (NGC 2023) which is associated with only a very poor cluster. The level of star-formation activity in these two massive cores is considerably lower than that in the three other comparable mass cores which are producing rich clusters. This is reflected in

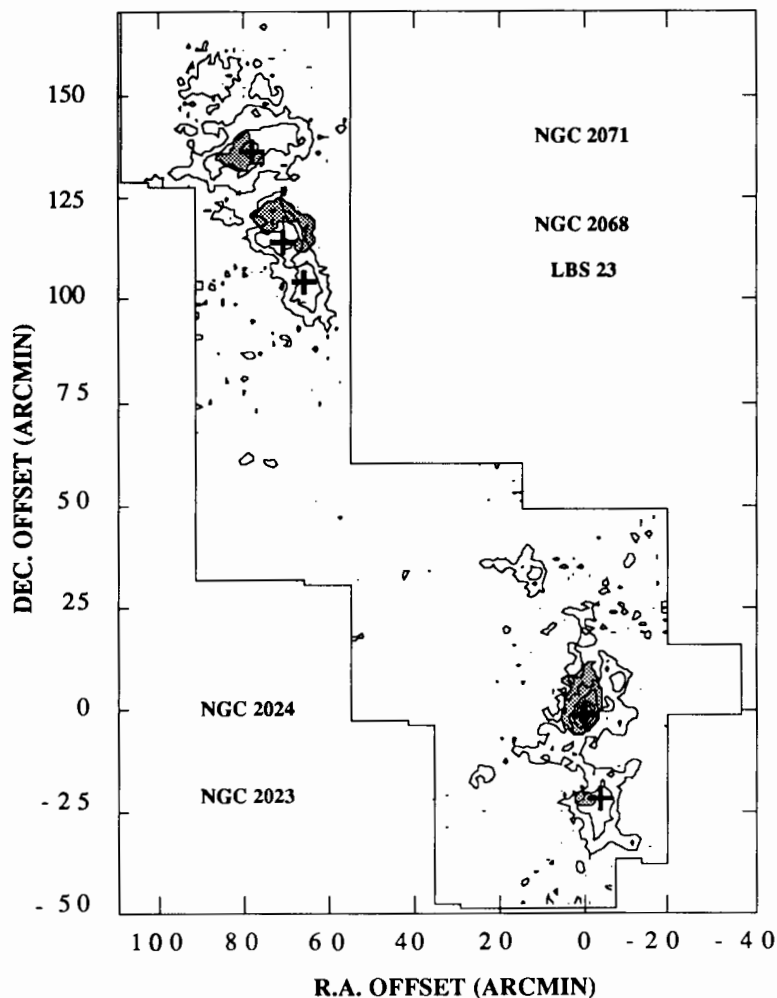

Figure 20. Locations of the embedded stellar clusters and dense cores in the L1630 molecular cloud (figure from Lada 1992). The shaded regions represent the location and extent of the embedded clusters. The distribution of dense gas is presented as intensity contours of CS(2→1) emission. In addition, the peak intensity positions of the 5 most massive CS cores ($M > 200 M_{\odot}$) are represented by crosses.

the derived star-formation efficiencies (Table II). The cores NGC 2024 and NGC 2071 contain 0.7 stars per M_{\odot} of dense gas, while the cores, NGC 2023 and LBS 23 contain only 0.07 stars per M_{\odot} of dense gas (Lada 1992). It therefore appears that high gas density and high gas mass may be necessary, but not sufficient conditions for formation of star clusters.

TABLE II
Star-Formation Efficiencies in L1630

Core	Number of Cluster Sources	Core Mass (M_{\odot})	Number of YSOs per Core Mass (M_{\odot}^{-1})
LBS 23 ^a	18	230	0.08
NGC 2023	21	294	0.07
NGC 2071	105	456	0.23
NGC 2068	192	266	0.72
NGC 2024	309	430	0.72

^a Not identified as associated with a cluster by the criteria of Lada et al. (1991b) due to low surface density of sources.

The surveys for dense cores and embedded infrared sources in L1630 have revealed that the vast majority of the stars, located in the surveyed regions, were formed in three rich embedded clusters which in turn, formed from three of the largest and most massive dense cores in the cloud, at relatively high star-formation efficiency. It therefore appears that star formation in these regions of L1630 is occurring in the clustered mode of star formation, resembling the star-forming process in the Ophiuchus molecular cloud core and L1641 clusters. In addition, there is no evidence for any significant star-formation activity of either high- or low-mass stars occurring outside these clusters. This implies that isolated or distributed star formation, similar to what is occurring in regions of the Taurus, Ophiuchus and L1641 molecular clouds, does not *significantly* contribute to the star-forming process in the L1630 cloud. Apparently, clustered star formation is the dominant mode of star formation in the L1630 molecular cloud (Lada et al. 1991b; Lada 1992). This leads to the astonishing conclusion that if L1630 is a typical GMC, most star formation in GMCs and therefore in the Galaxy may occur in the environment of dense clusters and not in isolated protostellar systems.

In order to understand how the vast majority of stars in L1630 (and possibly the Galaxy) formed, we must understand how a massive dense core with high star-forming efficiency is produced. In this regard, it is interesting to consider the five massive dense cores found in L1630. As we have already learned, these cores exhibit a range of star-forming efficiencies with three cores having high efficiencies compared to the remaining two. The origin of these differences could be due to differences in the fundamental physical properties of the cores such as density or magnetic fields or could be due to evolutionary effects. Comparison of the physical conditions in cores with different star-formation efficiencies should provide important insights into the nature of the star-formation processes in molecular clouds.

Clouds with embedded clusters appear to differ from clouds without embedded clusters in one respect which may be significant for understanding the role of magnetic fields in their evolution. The position angles of optical

polarization, measured toward background stars near in projection to a cloud, generally have a number distribution with a single local maximum, and a width greater than that due to measurement uncertainty. The width of the distribution is significantly broader in regions with embedded clusters in Ophiuchus, Perseus, Corona Australis and Lupus than in associated clouds with less mass and fewer stars (Myers and Goodman 1991). This increased dispersion in polarization direction might arise if the cluster gas has accumulated with infall speed greater than the Alfvén speed so that the associated field lines bend due to gravity faster than they can straighten by radiating Alfvén waves.

Finally, observations of GMCs indicate that their overall star-formation efficiency (SFE) is low, on the order of a few percent (Duerr et al. 1982). The question arises, why is the SFE so small? A key to answering this question may be found by considering the volumes within which the SFEs are measured (Lada 1987). The overall SFE for the entire region surveyed in the L1630 molecular cloud is only 3 to 4%. In contrast, the SFE of the 3 massive cores responsible for the bulk of the star-forming activity in this cloud is ~ 30 to 40% (Lada 1992). It therefore appears that only a small fraction of the mass of a GMC is suitable for star formation.

V. CONCLUSION

Observations of dense gas and associated YSOs are powerful probes of the star-formation processes in molecular clouds. Such studies in the nearest molecular cloud complexes have revealed that at least two modes or environments of star formation exist. For example, in Taurus, stars appear to be forming in an isolated or distributed mode of star formation, characterized by low stellar densities and low overall star-formation efficiency. In this mode, one to a few stars form in small, isolated dense cores distributed throughout the complex. In contrast, clustered star formation, characterized by high stellar densities and high star formation efficiency is occurring in the Rho Ophiuchus cloud. Here a relatively rich cluster of stars (~ 100) is forming from a single massive concentration of dense gas. The relative importance of these two modes in the production of stars in our Galaxy is still unclear. Indeed, these two examples may represent the extremes in a spectrum of a cluster forming process which ranges from the formation of isolated protostars, to small protostellar groups, to rich clusters. However, recent unbiased studies of the dense gas and associated young stellar content of the L1630 molecular cloud have revealed that the clustered mode of star formation is clearly dominant in this GMC. In addition, existing observations suggest that the clustered mode of star formation may also dominate in the L1641 cloud. If star formation in L1630 is representative of star formation in other giant molecular clouds, then clustered star formation may be the dominant mode of star formation in our Galaxy.

Most present day theories of star formation deal with the formation of stars within individual cores. While this is important, the results discussed

in this chapter suggest that in order to understand how most stars form in the L1630 molecular cloud and possibly throughout the Galaxy, one must understand how massive cores form and produce rich clusters of stars with high efficiencies.

Acknowledgments. We would like to thank L. Blitz, H. Butner, C. Lada and B. Wilking for their thoughtful comments on earlier versions of this chapter. We are also grateful to H. Butner, G. Fuller and C. Lada for many enlightening discussions on the subject matter presented here. Finally, we thank S. Kenyon, C. Lada and B. Wilking for assistance in preparation of the figures.

MAGNETIC FIELDS IN STAR-FORMING REGIONS: OBSERVATIONS

CARL HEILES, ALYSSA A. GOODMAN, CHRISTOPHER F. McKEE
University of California, Berkeley

and

ELLEN G. ZWEIBEL
University of Colorado, Boulder

We review the observational aspects of magnetic fields in dense, star-forming regions. First we discuss ways to observe the field. These include direct methods, which consist of the measurement of both linear and circular polarization of spectral line and continuum radiation; and indirect methods, consisting of the angular distribution of H₂O masers on the sky and the measurement of ambipolar diffusion. Next we discuss selected observational results, focusing on detailed discussions of a small number of points rather than a generalized discussion that covers the waterfront. First we discuss the Orion/BN-KL region in detail, both on the small and large scales. Next we discuss the derivation of the complete magnetic vector, including both the systematic and fluctuating component, from a large sample of Zeeman and linear polarization measurements for the L204 dark cloud. Third we discuss the virial theorem as it applies to dark clouds in general and one dark cloud, Barnard 1, in particular. Finally we critically discuss the numerous claims for alignment of cloud structural features with the plane-of-the-sky component of the magnetic field, and find that many of these have not been definitively established.

This is the first of two chapters in this book on magnetic fields in star-forming regions, and deals with the observations; the second chapter by McKee et al. deals with theory.

Magnetic fields reveal themselves by polarizing radiation. The first observational indication of interstellar magnetism was linear polarization of optical starlight, produced by extinction of aligned interstellar dust grains. During the past few years, such polarization has also been observed in the infrared, and even in the thermal radiation emitted by the grains. A second indication, the Zeeman effect, produces circular polarization, and the first detections in dense regions have occurred during the past few years. In addition, magnetic fields should reveal themselves in ways not yet observed, and we expect that people will soon attempt to detect these different effects.

Here we review both the observational manifestations of magnetic fields and some aspects of the current observational knowledge. Previous reviews (Crutcher 1988; Troland 1990) summarize all existing observational results;

here we cover results for only a few objects, but discuss them extensively. Section I covers the observational manifestations of magnetic fields. These include the direct mechanisms that produce both linear and circular polarization of spectral lines and radiation emitted or attenuated by dust, and indirect indications such as ambipolar diffusion and the distribution of masers in the sky. The remaining sections cover the observations and their interpretation, usually employing particular examples. Section II covers the Orion region, the nearest and best-studied hotbed of young, massive stars. Section III discusses a technique by which the three-dimensional magnetic field can be described, and applies this technique to the dark cloud L204. Section IV discusses the virial theorem and its application to, first, the dark cloud Barnard 1, and second, to statistical ensembles of clouds. Section V discusses alignments of cloud structure, rotation, and magnetic field. Finally, Sec. VI presents our perspective and summary discussion.

To begin with, a word on notation is in order. We use \mathbf{B} to designate the full vector (magnitude and direction) magnetic field, \hat{B} to designate the direction alone (within the two-fold ambiguity of “which way the vector points”), and B to designate the magnitude alone. The subscripts \parallel and \perp designate the line-of-sight and the plane-of-the-sky components, respectively.

I. MANIFESTATIONS OF MAGNETIC FIELDS IN DENSE CLOUDS

A. Zeeman Splitting

The Zeeman effect arises from the coupling of an atom’s or a molecule’s magnetic moment with an external magnetic field. The magnetic field removes the degeneracy in states with nonzero angular momentum, which splits a transition into a number of π and σ components. The σ components are elliptically polarized, and the circularly-polarized portions are used to detect the splitting. Individual σ transitions appear at $\pm\Delta\nu_Z$ where ν is frequency, and the circularly polarized portion of their amplitudes $\propto \cos^2 \gamma$, where γ is the angle between \hat{B} and the line of sight.

For any species with an electronic orbital angular momentum or spin

$$\Delta\nu_Z = \frac{g\mu_o}{h}B = \frac{b}{2}B \quad (1)$$

where g is the Landé g -factor appropriate to the transition, μ_o is the Bohr magneton, h is Planck’s constant, and b is a convenient coefficient for calculating the splitting. For species with no unpaired electron spin, but nonzero nuclear magnetic moment, such as H_2O , the Bohr magneton is replaced with the nuclear magneton in calculating the Zeeman splitting, which reduces the order of magnitude of the effect by a factor $m_e/m_p = 1/1836$. Table I provides b -values for many astrophysically important species; these values are either weighted over sublevels by opacity or are for the strongest subcomponent, which is proper in the optically thin case but not necessarily in any other

case. Calculation of a g -factor is often not a trivial undertaking, and some of the b -values in Table I may yet be revised. Often, a g -factor is not considered known until it has been measured in the laboratory.

Under essentially all interstellar conditions except in OH masers, $\Delta\nu_Z \ll \Delta\nu$, where $\Delta\nu$ is the full line width at half-intensity (FWHM). This makes Zeeman splitting very difficult to detect. Success requires either a species with a large magnetic moment and/or a region of very high field strength. To date, detections of Zeeman splitting have been reported for only four species in the interstellar medium: H I (emission, absorption and self-absorption); OH (emission, absorption and stimulated emission); C₂S (emission, but the result is probably spurious [see, e.g., Güsten and Fiebig 1990 and personal communication]); and H₂O (stimulated emission [see Fiebig and Güsten 1989], but this may be “fake Zeeman splitting” [see Sec. I.B.1c]). H I traces low-density atomic regions and the outer portions of molecular clouds. OH traces molecular clouds of moderate density, $n_H \lesssim 2500 \text{ cm}^{-3}$ (or perhaps greater; Sec. I.A.2) and C₂S probably traces somewhat higher densities than OH, perhaps $n_H \sim 10^3$ to 10^5 cm^{-3} . OH masers trace $n \sim 10^7 \text{ cm}^{-3}$. H₂O masers trace $n \sim 10^9 \text{ cm}^{-3}$; H₂O has no unpaired electron spin, and Zeeman splitting is detectable only because the field strength increases with density. B ranges from a few μG in H I to perhaps over 40 mG in H₂O masers (see Sec. I.B.4a).

In the usual case in which $\Delta\nu_Z \ll \Delta\nu$, Zeeman splitting is best observed by subtracting the left from the right circular polarization to produce the Stokes V spectrum. This exhibits a scaled derivative of the line profile, known as a “Zeeman pattern.” (See Fig. 2 in Sec. IV, for an example.) The amplitude of this pattern depends not only on splitting itself, but also the amplitude of the circularly polarized portion of the σ component; the net result is that the amplitude depends on the line-of-sight component $B_{\parallel} = B \cos \gamma$. Unfortunately, there is no way to separate $\cos \gamma$ from B . In contrast, if $\Delta\nu_Z > \Delta\nu$, the splitting is directly measurable and provides B itself, not B_{\parallel} ; this is the case for OH masers.

For the usual case $\Delta\nu_Z \ll \Delta\nu$,

$$V(\nu) = \frac{dT(\nu)}{d\nu} bB_{\parallel} \quad (2)$$

where $T(\nu)$ is the total intensity. For a Gaussian line profile having central intensity T_A and FWHM $\Delta\nu$, $|V(\max)| = 1.43 T_A b|B_{\parallel}| / \Delta\nu$. Detectability increases with the ratio of splitting to line width $bB_{\parallel} / \Delta\nu^{1/2}$; this favors low frequencies because $\Delta\nu$ arises from Doppler broadening and is proportional to the line frequency. Compared to the splitting factor and the field strength, velocity width is relatively unimportant, both because the sensitivity varies only as $\Delta\nu^{1/2}$ and because widths usually lie within the fairly narrow range of 1 to 10 km s^{-1} . Table I provides estimates of $|V(\max)|/T_A$ for a field strength derived from the empirical relation $B_{\mu\text{G}} = 0.51 \Delta\nu_{\text{km s}^{-1}} n_{\text{H, cm}^{-3}}^{1/2}$ (Myers and Goodman 1988a); here n_H is the volume density of hydrogen nuclei. As Table I illustrates, detecting the Zeeman effect is difficult. As

Notes: (a) approximate transition frequency; (b) references for columns (a) and (c); (c) *b*, the Zeeman splitting factor in Hz μG⁻¹; (d) approximate highest density traced by this transition, in LTE for the species with splitting determined by an electronic magnetic moment, or maser emission for the species with splitting is determined by a nuclear magnetic moment; (e) typical observed line width of this transition for LTE cases, or of an LTE transition tracing the same density in the case of simulated emission; (f) estimated $B[\mu\text{G}] = 0.51(\Delta\nu[\text{km s}^{-1}](\eta[\text{cm}^{-3}])^{1/2})$ (Myers and Goodman 1988a), and we assumed $B_{\parallel} = B/2$; (g) see Eq. (2); (h) recombination lines occur in a wide variety of environments and can even show maser emission (Martin-Pintado et al. 1990); (i) the *b*-value is quoted by the authors as uncertain to within a factor of 2; (m) the *b*-value listed is an average of the values listed by the authors for the transitions all very close to this frequency—it should be noted that Bel and Leroy 1989 present a different value; (n) although simulated emission has been observed in NH₃ transitions, (Madden, personal communication) the transition listed is hypothetical; (p) these transitions are mostly observed as masers; (q) it is not feasible to observe these transitions from the ground. (r) these are LTE line strengths, presumably the transition would be much stronger in simulated emission. Other species: Zeeman candidates suggested to date, but not included in the table above, are transitions of: NS, CP, HCO and CH₂CN which have been detected in the interstellar medium in states with nonzero electronic magnetic moment (Turner, personal communication); and CS, SiO, and SiS, which have been detected in states with no electronic magnetic moment, but finite nuclear magnetic moment.

expected, HI and OH appear among the best candidates. Less expected, perhaps, is the predicted feasibility of CH Zeeman experiments at 0.7 GHz, which occurs both because the transition is in an excited rotation level, which requires high density for its excitation, and because of the low frequency of the line.

Astronomical convention defines a magnetic field that points toward the observer as negative in sign. In Zeeman experiments, this means that if the right circularly polarized (RCP) component (defined according to the IEEE convention as a wave that rotates clockwise as seen by the source) is observed at higher frequency than the LCP component, then the field points toward the observer and is given a negative sign.

1. *Zeeman Splitting of HI.* H_2 dominates HI in molecular clouds by definition. Nevertheless, sometimes HI is observed to be associated with dark clouds. This takes two forms: one, cold HI in the cloud produces “self-absorption” of the 21-cm line against warmer background 21-cm line emission (see, e.g., Knapp 1974); and two, warm HI on the outside of a cloud tends to produce excess 21-cm line emission (Andersson et al. 1991). Zeeman splitting has been seen from both forms (near Orion in one single spectrum; Heiles and Troland 1982).

Astrochemical theory indicates that in the ultraviolet-free centers of dense clouds the volume density $n_{HI} \sim 1.2 \text{ cm}^{-3}$, almost independent of n_{H_2} (Leung et al. 1984). As a representative example, consider the “medium” size of cloud Barnard 1 (B1), as defined in Table III, and discussed in Sec. IV.B. Although the B1 HI profile as observed at Arecibo does not exhibit self-absorption, the cloud should be representative in its physical properties. The central portion should have an HI column density $N_{HI} \sim 4 \times 10^{18} \text{ cm}^{-2}$ at temperature $\sim 15 \text{ K}$, which would provide a 21-cm line opacity of ~ 0.15 . This is too small to produce the self-absorption that is observed in some clouds.

This indicates that most of the HI responsible for self-absorption lies near the edge of the cloud where UV is more active in dissociating H_2 (van Dishoeck and Black 1986). Thus HI should probe the outer portions of molecular clouds, although this has yet to be observationally verified. In contrast, OH is a better high-density probe, so comparing HI with OH should provide information on magnetic structure within the cloud. However, if a cloud is sufficiently patchy then UV can dissociate H_2 throughout the cloud volume, and HI results could be equivalent to OH.

Zeeman splitting of HI in self-absorption has been measured for two clouds, L204 (Heiles 1988) and Ophiuchus (Troland et al. 1991). Only for Ophiuchus do there exist OH Zeeman splitting data for comparison. The HI and OH lines differ in velocity by $\sim 1 \text{ km s}^{-1}$, and the measured field strengths B_{\parallel} are nearly identical. This single result does not permit much interpretation, so we are currently surveying a large portion of the Ophiuchus dark cloud complex and several other known self-absorption regions for Zeeman splitting.

2. *Zeeman Splitting of OH in Emission.* The OH molecule is detected

in most molecular clouds that have extinction $\gtrsim 1$ mag. The lowest rotational level, $^2\Pi_{3/2}$, $J = 3/2$, is always populated and exhibits Λ -doubling and hyperfine splitting, which produces transitions near 1612, 1665, 1667 and 1720 MHz. In addition to the weak emission from molecular clouds, OH often produces maser emission from very high-density regions located near H II regions and from circumstellar ejecta from cool stars (Sec. I.B.4). The unpaired electron and low transition frequencies make OH the most sensitive tracer of magnetic fields in molecular regions.

The transition probabilities of the 1665 and 1667 MHz lines are 5 and 9 times, respectively, those of 1612 and 1720 MHz lines, and their g -factors are also larger (Table I). For these reasons, it is the 1665 and 1667 MHz lines which are observed, usually simultaneously, in observations of molecular clouds. However, if the 1665 and 1667 lines are opaque, it may be wise to observe the 1612 and 1720 MHz lines in order to see into the more dense portion of a cloud.

Although OH is the best tracer of magnetic fields in molecular regions, it may not be a good tracer of H_2 . In clouds that are not too dense, both observations and theory imply that OH is a good tracer of H_2 . However, in cold dense clouds there are no observational indications, and theory implies that OH is *not* a good tracer of H_2 . The primary question is, up to how large a density does OH remain a good tracer of H_2 ?

Observationally, for moderate extinctions of < 7 mag the fractional abundance of OH with respect to H (total H, $HI + 2H_2$) X_{OH} is constant and $\sim 4 \times 10^{-8}$ (Crutcher 1979). The major observational work that extends the range of *column* density as high as 7 mag is the detailed study of the ρ Oph dark cloud by Myers et al. (1978); this study finds the corresponding *volume* density to be $n_H \sim 2500 \text{ cm}^{-3}$. Crutcher (1988) argues that OH traces n_H up to $\sim 3 \times 10^4 \text{ cm}^{-3}$ in TMC-1, but in our opinion this argument needs to be better substantiated and to be made quantitative.

Theoretically, in clouds that are not too dense, starlight dominates the ionization and is involved both in the production and destruction of many molecules. Under these conditions X_{OH} is predicted to be roughly independent of n_H for the range $250 < n_H < 1000 \text{ cm}^{-3}$, although X_{OH} does depend on temperature, particularly for $T \gtrsim 50 \text{ K}$ (van Dishoeck and Black 1986). However, the theoretical estimate of these density limits is inaccurate because of uncertainty regarding the exact process responsible for the formation of OH (Lepp et al. 1987; Gredel et al. 1989; Herd et al. 1990). Thus it seems reasonable to use the observations as a guide and extend the upper limit of the range of n_H from 1000 to at least 2500 cm^{-3} .

At higher densities, we must rely exclusively on theoretical astrochemical calculations. The question of what constitutes a “high” density depends on the degree to which starlight is excluded, which in turn depends on the degree of nonuniformity of a cloud, and in particular its porosity. The absence of starlight makes a big difference because the sequence of reactions that form OH involves ion-molecule reactions, whose rate is limited by the ionization

rate. Without starlight, ionization results from cosmic rays and OH destruction from reactions with neutral atoms, which to first order makes X_{OH} far from constant; instead, n_{OH} is almost independent of n_{H_2} (Herbst and Klemperer 1973). Calculations that include a more complete set of reactions (see, e.g., Leung et al. 1984) indicate X_{OH} approximately $\propto n_{\text{H}_2}^{-0.8}$.

This near-independence of n_{OH} with respect to n_{H_2} is definitely not universally true at very high densities. Theoretically, high-temperature regions should produce copious amounts of OH. High temperatures can be produced by shocks, either with magnetic fields (Draine and Katz 1986) or without (Mitchell and Watt 1985); X_{OH} can be much higher than usual with shock velocities of somewhat less than 10 km s^{-1} . Such production has presumably occurred in OH masers, where X_{OH} is high and $n_{\text{H}} \sim 10^7 \text{ cm}^{-3}$; the high OH abundance can be understood only if these regions have been subjected to high temperatures.

3. Aperture-Synthesis Techniques. Observationally, understanding the role of magnetic fields in star formation requires obtaining information on small angular scales. This, in turn, requires use of aperture synthesis arrays such as the Very Large Array (VLA). However, as the telescopes are spread farther apart to obtain better angular resolution, the sensitivity to surface brightness is decreased. The major limitation of most Zeeman measurements on emission lines is sensitivity to brightness temperature. To obtain sufficient sensitivity with an array, the telescopes must be placed as close together as possible. At no existing array can the telescopes be clustered tightly enough to obtain useful surface-brightness sensitivity for most Zeeman measurements of emission lines.

This sensitivity problem can be circumvented by observing opaque lines in absorption against a continuum source having high surface brightness. Compact H II regions are the prime sources, both because they are bright and because they are the very places where star formation has recently occurred. The only other type of bright continuum source is supernova remnants such as Cas A, which can provide information on molecular regions, but these regions are not necessarily characterized by star formation (Schwarz et al. 1986; Heiles and Stevens 1986).

Zeeman observations of OH lines in absorption against compact H II regions are usually (but not always) contaminated by highly polarized OH maser emission. This leaves the 21-cm HI line, which is unfortunate because it does not highlight the dense molecular gas.

H II regions are special: part of the photodissociation region, which is the interface between the ionized and molecular gas, contains primarily HI, not H₂ (Tielens and Hollenbach 1985). If the exciting stars are early O stars then the HI is predicted to be warm, $\sim 1000 \text{ K}$, but to have high column density, $\sim 4 \times 10^{21} \text{ cm}^{-2}$, so its 21-cm line opacity should be reasonably high, ~ 1 ; if the exciting stars are cooler, then the HI should be cooler. Unfortunately, no HI absorption line has ever been interpreted as being associated with a photodissociation region. To be in such a region, the HI velocity should be

more negative than the H II velocity by amounts ranging up to $\sim 10 \text{ km s}^{-1}$ for a young H II region. Instead, all currently observed H I absorption lines seem to result from foreground H I that may lie close to the H II region but has not yet been dynamically perturbed by the ionization front. Much of this H I should lie preferentially in the outer layers of the parent molecular cloud. It should reflect the magnetic field in the outer, less dense portions of the cloud (Sec. I.A.1).

There are currently only two H II regions, W3 and Orion A, for which aperture synthesis Zeeman observations exist; they are discussed in Sec. II below. Orion A has a strong, easily detected field; for W3 there are two independent studies, and they do not agree.

B. Polarization of Radio Spectral Lines Arising From Radiative Transfer Effects

Both linear and circular polarization resulting from radiative transfer effects of radio lines have been predicted in many environments, but observed only in masers. In our discussion below, we will conclude that, apart from masers, both linear and circular polarization will be difficult to detect. In both masers and nonmasers, circular polarization can falsely mimic the Zeeman effect in some cases.

1. Physical Principles

a. Linear polarization. If an external magnetic field orients the quantization axis of a molecule, then anisotropic radiative excitation can produce differing populations of the magnetic substates, which leads to different optical depths for the π and σ components. These components are orthogonally polarized. Thus, if a background source suffers absorption that differs in the two polarizations, the observed absorption line will be polarized. This phenomenon is called “linear dichroism” (Kylafis and Shapiro 1983). Emission lines from the cloud can be similarly linearly polarized.

b. Circular polarization. Circular polarization can also occur. The production of linear polarization relies on differing opacities for the polarizations that are parallel and perpendicular to \hat{B}_\perp (the optical axes). These opacities are the imaginary part of the index of refraction. According to the Kramers-Kronig dispersion relation, this inevitably leads to different phase velocities for orthogonal linear polarizations that are aligned along the optical axes. This turns linear polarization into circular polarization by a process that is similar to Faraday rotation, which occurs when the phase velocities are different for the orthogonal circular polarizations.

First, consider absorption of a linearly polarized background source. If the polarization direction is *not* parallel to either optical axis, then the wave can be decomposed into two waves in both axes. The differing phase velocities then produce elliptical polarization; the intensity of the circular component varies sinusoidally with distance along the direction of propagation. The polarization always changes sign across the line center, and looks similar to signature of the Zeeman effect. This is known as “linear birefringence.” The

fractional circular polarization p_c is maximum when the polarization of the background is oriented at 45° with respect to the optical axes. In this case, for a Maxwellian velocity distribution and to first order in $\delta\tau_0$, the difference in line center opacities for the two optical axes, the maximum Stokes parameter V occurs at the 0.43 intensity point and is about $0.61 \delta\tau_0$. Thus, V can be comparable to the change in linear polarization.

Next, consider either absorption of an unpolarized background source or the line emission itself. Here, the differing opacities produce linear polarization within the cloud. This polarization lies along one of the optical axes, so there is no possibility for circular polarization. However, if the direction of \hat{B}_\perp changes along the line of sight (the field twists along the line of sight), then the optical axes follow the twist and linear birefringence can occur. The circular polarization depends on the amount of twist. For typical cases, we expect $p_c \lesssim p_l^2$ because the circular polarization is a second-order effect. Two illustrative examples, in which the field twists uniformly with distance along the line of sight, are given by Deguchi and Watson (1985). Our expectation is borne out in the first example in their paper, but not in the second. The explanation is simple: in the second example, the twist is so severe (5 radians) that the linear polarization “interferes with itself” and is thereby decreased in intensity. In the real Universe such a large twist might be produced by a large-amplitude circularly polarized Alfvén wave. Such severe twists in a static field may be rare.

c. Fake Zeeman splitting. In the latter “unpolarized background source” or line emission case, p_c should be typically so small that it would be very difficult to detect, and we would thereby recommend that observers concentrate on other, less difficult observations. Nevertheless, the effect may loom large in importance because it mimics—and can easily be mistaken for—the Zeeman effect (Deguchi and Watson 1985). The Zeeman effect produces small p_c , about $1.5\Delta\nu_Z/\Delta\nu$, where $\Delta\nu_Z$ is the Zeeman splitting and $\Delta\nu$ the line width. This amounts to one percent or less in many cases, which is small enough to be produced by linear birefringence. If so, linear polarization near the level $p_l \sim p_c^{1/2}$ should also be present.

d. Excitation considerations. The physical mechanism that produces differing populations of the magnetic substates rests on the fact that π and σ components, which are orthogonally polarized, have different directional dependencies on their interaction with radiation. If an external magnetic field orients the quantization axis, and if the molecule is subject to an anisotropic radiation field, then the populations of the associated states are affected differently by absorption and stimulated emission of the radiation, and the π and σ components have different intensities. To obtain a significant population difference, the collisional rate must not be too high. In addition, the Zeeman splitting must be larger than the collisional and the spontaneous emission rates, but small compared to the line width. These conditions are easily satisfied for many transitions.

For a two-level system, only the line radiation itself can produce an effect,

and we can easily get a feel for the direction of polarization. The cross section for the π component $\propto \sin^2 \gamma$ and that for the σ components $\propto 1 + \cos^2 \gamma$, where γ is the angle between the propagation direction and the magnetic field. If the intensity of radiation I is larger along the axis defined by the magnetic field ($\gamma = 0^\circ$), then the π state does not interact as strongly with the external radiation field. Photon trapping is less effective for the π component, so it has a smaller excitation temperature than the σ component. The π component has a smaller intensity than the σ component, so the emission is polarized perpendicular to the magnetic field.

A real molecule has multiple rotational levels and, in addition, vibrational levels that can be excited by an external source of infrared radiation. Infrared radiation is likely to be directional. This anisotropic radiation can affect the level populations to a greater degree than other local physical conditions if the source is strong, differentially populating the magnetic substates and leading to polarization. An extreme example is circumstellar material, in particular SiO masers; even in interstellar masers the radiative excitation is almost inherently anisotropic (see, e.g., Western and Watson 1984). In molecular clouds, infrared significantly affects the excitation of levels involved in the 18- and 5-cm transitions of OH (Burdyuzha and Varshalovich 1972; Crutcher 1977; Sec. I.B.3 below).

Calculating the polarization requires the full solution of radiative transfer and level population equations, and as such depends on the physical geometry and the velocity field. It is far from a trivial exercise, and solutions have only been calculated for simple geometries or using the large velocity gradient approximation for simple velocity fields. These have large anisotropies and produce quite large polarizations. Realistic velocity fields should be more complicated, resulting in significantly smaller polarization.

2. Emission Lines: Model Calculations. To discuss the predicted observables we consider two illustrative examples introduced by Kylafis (1983a) in which the anisotropy is provided by the velocity field. Even though these examples use simple geometries and velocity fields, their solution is complicated and requires numerical techniques. The symmetry axis (z axis) is perpendicular to the line of sight at position angle $\theta = 0^\circ$. The magnetic field is also perpendicular to the line of sight, but can have arbitrary position angle θ_B . The velocity field is symmetric with respect to the z axis. In the one-dimensional example, the cloud expands in the z direction with uniform velocity gradient. In the two-dimensional example, the cloud expands axisymmetrically with no motion in the z direction.

a. Intensity. Kylafis (1983a) provided solutions over the full range of physical parameters for his two examples, but restricted the treatment to a two-level system. Deguchi and Watson (1984) extended the treatment to the full rotational ladder for CO and CS, and found that the polarization was smaller than for the two-level case by a factor ~ 2 . We use results from their figures here, for which the magnetic field is parallel to the symmetry (z) axis ($\theta_B = 0^\circ$).

The *fractional* linear polarization, denoted as $p_l = (U^2 + V^2)^{1/2}/I$, depends sensitively on C/A , the ratio of collisional rate to Einstein A , and also on the optical depth. As $C/A \rightarrow 0$, p_l becomes large (~ 0.10)—but as $C/A \rightarrow 0$ the *line intensity* also $\rightarrow 0$, so the high fractional polarization is unobservable. As C/A increases, the line intensity increases, but p_l decreases significantly. The linearly *polarized intensity* $P_l = (U^2 + V^2)^{1/2}$ peaks at $C/A \sim 1$, at which point p_l is only ~ 0.01 for the two-dimensional and 0.03 to 0.12 (depending on the viewing angle) for the one-dimensional case. For gas temperature 30 K, the maximum polarized brightness temperature is about 0.3 K in the two-dimensional and 3 K in the one-dimensional case.

These two simple examples of Kylafis show that p_l depends extremely sensitively on the velocity field. Simply going from one dimensional to two dimensional reduces the polarization to the point of being observable only with difficulty. It seems reasonable to conclude that for more realistic velocity fields the polarization will be very small indeed.

b. Direction. The polarization is either parallel or perpendicular to \hat{B}_\perp , but it is not so easy to determine which. Again we consider the two examples of Kylafis (1983a).

First consider the behavior of the position angle of the linear polarization θ_{pol} as a function of the position angle of the magnetic field θ_B . In the one-dimensional case, the polarization is perpendicular to the magnetic field for $54^\circ < \theta_B < 125^\circ$, and parallel otherwise. In contrast, the two-dimensional case is *precisely opposite*. This behavior can be understood from the basic description given at the beginning of Sec. I.B.1d because the radiation intensity is larger along directions having no velocity gradient. Surprisingly, as a function of θ_{pol} , this dependence translates into the field being *either* parallel or perpendicular to the observed polarization (i.e., $\theta_B = \theta_{pol}$ or $\theta_B = \theta_{pol} + 90^\circ$) for a large range of θ_{pol} .

Next consider a three-dimensional case with isotropic velocity field; this has not been treated in the literature, so we must extrapolate the above one- and two-dimensional treatments to this case. Suppose that the magnetic field is either uniform, along the z axis, or a dipole field oriented along the z axis; in either case, the field direction $\theta_B = 0^\circ$ at both the “poles” and the “equator.” It would seem that the one-dimensional example should apply at the poles, while the two-dimensional example should apply at the equator. If so, then at the poles the observed polarization would be parallel to the field, i.e., $\delta = 0^\circ$, while at the equator it should be perpendicular with $\delta = 90^\circ$. Thus, as we move around a circle in the sky centered on the source, the observed polarization direction would change four times, from $\delta = 0^\circ$ to 90° to 0° to 90° . If one were observing with a single dish that was unable to resolve these changes the net polarization would be very small. If one used an array with adequate angular resolution, how would one interpret the observations?

Lis et al. (1988) relaxed the large velocity gradient assumption and considered a spherically symmetric cloud with a dense core and a radial magnetic field. They calculated $p_l \lesssim 0.02$, with 0.02 occurring only in the most op-

timistic case. Polarization increases with decreasing C/A , which favors molecules with high dipole moments; increasing complexity of hyperfine structure also decreases polarization.

In the absence of calculations for other, more realistic situations, we can only speculate. The direction of polarization is a sensitive function of the details of the velocity field. It seems likely that in more complicated cases the polarization direction might change direction rapidly with position, both on the sky and along the line of sight, and this should lead to much smaller p_l than is predicted for the simple situations. In this spirit, the negative results of attempts to observe polarization by Wannier et al. (1983) and by Lis et al. (1988) come as no surprise.

3. *Absorption Lines.* To discuss radiative excitation in the absorption-line case we first consider anisotropic radiation at the frequency of the absorption line. The source can be either a spectral line emitter, such as a warm CO cloud affecting a colder foreground CO cloud, or a continuum source such as a bright H II region. An example of each interstellar case was given by Kylafis (1983b). His examples used a three-dimensional isotropic velocity field, which presumably is less efficient than one- or two-dimensional cases in producing large polarization, and were geometrically optimized to produce large polarizations. Apart from these geometrical attributes, the three most important parameters are C/A , the solid angle of the source Ω_0 , and the brightness temperature of the source T_s .

The former example, with a warm CO cloud ($T_s = 20$ K) having angular diameter $\sim 45^\circ$ as seen by the colder foreground ($T = 10$ K) CO cloud, produces $p_l \sim 0.06$ for $n_{\text{H}_2} = 3000 \text{ cm}^{-3}$. The latter example applies mainly at cm wavelengths, where continuum sources are bright enough to matter. For the H_2CO 6-cm transition absorbing a bright H II region ($T_s = 1000$ K) with angular diameter 20° as seen by the cloud, $p_l \sim 0.09$ for $n_{\text{H}_2} = 3000 \text{ cm}^{-3}$. In both cases, 3000 cm^{-3} is the density for which the induced radiative and the collisional rates are roughly equal; p_l increases with smaller C/A (smaller n_{H_2}).

These examples seem reasonably realistic, and it seems worth making a serious observational effort to detect the linear polarization of absorption lines. Of course, anisotropic excitation at frequencies other than the line frequency, for example infrared radiation, can indirectly excite the line. Interpretation of results will not be without ambiguity, because as in the case of polarized emission lines, the polarization is either parallel or perpendicular to \hat{B}_\perp , depending on geometry. The requirement that the background source subtend a large solid angle is crucial to the mechanism, and observers should select clouds for which other evidence favors this geometry.

In particular, we believe that the 1665 and 1667 MHz lines of OH provide an interesting test case, although one for which the excitation arises from infrared radiation instead of from radiation at the line frequency itself. The b -factors from Table I have the ratio 1.67. If the polarization results from Zeeman splitting, then the ratio $p_{c,1665}/p_{c,1667}$ should equal 1.67, while if the

polarization results from linear birefringence the ratio should equal unity. For all observed cases (except one) the ratio is close to 1.67. For the lines in absorption against W22, a ratio of 1.67 lies quite far from the limits allowed by observational uncertainty; instead, the ratio is nearly unity (Kazès and Crutcher 1986), with both lines having $p_c \sim 0.015$. W22 is an H II region, so it is unpolarized. Therefore, if the circular polarization does indeed result from linear birefringence, then linear polarization should exist at the level of $\gtrsim 0.12$. This would require an intense source of anisotropic far-infrared radiation; independent evidence for this exists in the form of a strongly anomalous 1665/1667 intensity ratio (Crutcher 1979). W22 itself cannot be responsible, because the absorbing cloud lies far from W22.

4. *Polarization in Masers.* Both the circular and linear polarization of masers can provide information on the magnetic field.

a. *Zeeman splitting, fake Zeeman splitting.* Zeeman splitting of OH masers is often very easy to observe. First, the maser regions have high densities, which usually means high field strengths. Second, the OH molecule has a high b resulting from electronic angular momentum. As a result, the splitting is often larger than the line width, and OH masers often exhibit a classical, well-separated Zeeman pair, with each component almost 100% circularly polarized, in which case the splitting provides the total field strength B instead of line-of-sight component B_{\parallel} . A sufficiently large velocity gradient can cause selective maser amplification of only one of these components, leading to a single component with high circular polarization; in this case, the field strength cannot be derived. The position angle of linear polarization of OH masers provides no information on \hat{B}_{\perp} (Nedoluha and Watson 1990a).

An important selection effect is implied for OH masers. Field strengths can only be derived when both σ components are observed, which requires that the Zeeman splitting be larger than about 3 times the total velocity difference through the maser (Nedoluha and Watson 1990a). Thus, magnetic fields derived from OH masers emphasize regions that have either small velocity gradients or large magnetic fields. Thus, in a region with large velocity gradients (i.e., any region in which some of the OH masers exhibit only a single component with high circular polarization), the field strengths sampled by those OH masers that exhibit both σ components are larger than average for the region.

In masers, there is a problem for lines having more than one subtransition with different b -values. For example, the 1612 MHz line of OH has three σ components, and the 22-GHz line of H_2O has six hyperfine components (each of which has many σ components). The maser process can amplify transitions from some sublevels at the expense of others, so it is not clear which value of b to adopt; Nedoluha and Watson (1991) find that a single hyperfine component is rarely dominant for H_2O masers. Furthermore, observers of OH masers have not consistently used proper values of b when interpreting their data, and some of the quoted magnetic fields are simply wrong.

Fiebig and Güsten (1989) have detected weak circular polarization in H_2O

masers for one maser in each of four H II regions, with typical $B_{\parallel} \sim 35$ mG; H₂O masers sample densities of 10^8 to 10^{10} cm⁻³ (Elitzur et al. 1989). The circular polarization $p_c \sim 0.001$, which is extremely small. If linear polarization is present at the level of a few percent, then the circular polarization could be a result of linear birefringence (Sec. I.B.1b,c). Nedoluha and Watson (1990b) have made calculations of this effect for H₂O masers and find that this fake Zeeman splitting (which results only from radiative transfer effects) is in fact likely to occur. Future observations should include all Stokes parameters, which makes the task more difficult.

For OH masers associated with H II regions, Reid and Silverstein (1990) have compiled and assessed many measurements. Field strengths range up to 7 mG and average 3.6 mG. OH masers sample densities of 10^6 to 10^8 cm⁻³ (Reid and Moran 1981). If we ignore the possibility that the H₂O and OH field strengths are biased towards high values because of observational selection effects, then comparison of their field strengths and probable densities suggests that very roughly, $B \propto n^{1/2}$ in this regime. Unfortunately, no OH and H₂O masers for which Zeeman measurements exist have identical velocities and positions, so we cannot as yet use maser observations to study the detailed dependence of B on n in a given region.

Reid and Silverstein come to a remarkable conclusion: the *directions* of the fields in OH masers are systematically aligned over large segments of the Galaxy. This indicates that the field direction in a maser is related to the direction of the galactic field in its immediate vicinity. This, in turn, indicates that the field direction is largely preserved during the contraction of clouds to high volume densities. This is surprising, because during this contraction process one would expect the competing effects of gravitation, angular momentum and shocks to randomize the field in the dense cloud with respect to the surroundings. We discuss a particular example, Orion, below in Sec. II.A, and conclude that Orion seems, on the surface, to be preserving field direction over a large range of density, but that a deeper look brings cause for skepticism.

b. Linear polarization. Linear polarization can provide useful information on \hat{B}_{\perp} under some circumstances for masers in which the Zeeman splitting is much smaller than the line width. Most discussions are based on the theoretical analysis of $J = 1 - 0$ transitions, for which the production of linear polarization requires that several constraints on ratios of pumping rates, decay rates and Zeeman splitting be satisfied (Goldreich et al. 1973).

However, recent theoretical calculations for higher- J transitions and realistic ratios (Deguchi and Watson 1990; Nedoluha and Watson 1990c) show that observations of H₂O masers have been misinterpreted by using the earlier theory. Garay et al. (1989) provide a convenient observationally-oriented summary of the results for $J = 1 - 0$ transitions, which have been generally assumed to apply also to higher- J transitions; this summary must now be modified. The details are beyond the scope of this chapter, but we present some brief highlights.

Two particularly important parameters (among others) are (1) $g\Omega/R$, the ratio of Zeeman splitting to the stimulated emission rate of the maser, and (2) R/Γ , the degree of maser saturation. In previous treatments, $g\Omega/R$ was usually taken to be very large, but in reality it is expected to be of order unity. When $g\Omega/R \gg 1$ and $(g\Omega)^2/R\Gamma \gg 1$, the linear polarization is either parallel or perpendicular to \hat{B}_\perp , depending on γ , the angle between the magnetic field and the line of sight. However, the highest linear polarization occurs when the two parameters are roughly equal, i.e., $g\Omega/R \sim R/\Gamma$, and in this case the position angle of polarization is *not* either parallel or perpendicular to \hat{B}_\perp (see Nedoluha and Watson 1990c, Sec. III). Thus, when the polarization is largest (and thus easiest to observe), its direction bears no simple relation to \hat{B}_\perp .

The existence of large linear polarization in H_2O masers has been used to derive magnetic field strengths in the masers. For example, Garay et al. (1989) suggested that the $\sim 60\%$ polarization of the Orion "supermaser" implies that it has $B \sim 30$ mG. However, the new theory indicates that anisotropic pumping can produce large polarizations even without strong fields, and in particular, it is required for very strong fractional polarization ($\gtrsim 1/3$). Therefore, one should be skeptical of all field strengths derived from nothing more than the existence of large linear polarization.

C. Polarization Caused by Aligned Grains

Optical starlight is almost universally linearly polarized, to a degree that increases with extinction. The polarization arises from extinction by systematically oriented dust grains. As with spectral lines (Sec. I.B.1b), weak circular polarization can result from a twisted field.

Only magnetic orientation is sufficiently general and powerful to provide the universality, although in individual circumstances other agents, such as gas streaming or photons, may dominate. But *even if these other agents operate*, the polarization must be either parallel or perpendicular to the magnetic field under all reasonable interstellar conditions. The reason is that the Barnett effect, combined with suprathermal grain rotation, causes the grains to precess about the magnetic field on a very short time scale (Purcell 1979). (Such precession is also produced, albeit less strongly, by purely electromagnetic forces on a charged grain.) Thus the time-averaged image of the grain, seen in projection against the sky by the observer, is always symmetric with respect to the magnetic field. If other, stronger agents compete with magnetic alignment, then they can either reverse the sense of or reduce the magnitude of the net polarization compared to what would be obtained with pure magnetic alignment. However, they cannot cause the polarization to depart from being either parallel or perpendicular to \hat{B}_\perp .

In magnetic alignment, a needle-like grain spins primarily end-over-end or an oblate grain spins as tossed pizza dough (Lee and Draine 1985) around axes that are parallel to \hat{B} . The polarization that is most strongly attenuated by this field of systematically aligned grains lies along the longest projected

grain area, which is perpendicular to \hat{B}_\perp . Therefore, the observed linear polarization of absorbed light is parallel to \hat{B}_\perp . The alignment also produces linear polarization of far-infrared and sub-mm emission from the grains (Sec. I.C.2), which is perpendicular to \hat{B}_\perp . These relations between field direction and polarization often provide a satisfying interpretive picture concerning the *direction* of the field. For example, the many-thousand sample of stars of Mathewson and Ford (1970) shows that the large-scale galactic field lies predominantly in the galactic plane.

The *percentage polarization* provides no useful information on field strength. The polarization/extinction ratio depends on the degree of alignment. Suprathermal rotation increases the effectiveness of magnetic alignment against the randomization caused by gas-grain collisions. This allows good alignment even in weak fields, in contrast to the pure thermal rotation case treated by Davis and Greenstein (1951). However, the alignment occurs on a non-negligible time scale. The predicted time required to align the grains' spin axes τ_g depends on grain properties and, roughly, $\tau_g \sim 4 \times 10^5 \text{ yr}/(B/30 \mu\text{G})^2$; it can be of order the lifetime of the cloud under study (Purcell 1979; Goodman 1989). Thus the grains may not be very well aligned and the polarization may be small, even with a strong field.

1. *Interpretive Aspects of Polarization of Starlight by Extinction.* The anisotropy of magnetic forces creates the potential for magnetically related asymmetries of interstellar structures. But one cannot automatically assume that an alignment between structures and magnetic field means that the field is responsible, because there exist several other anisotropic influences. For example, a shock sweeps up everything and tends to align everything perpendicular to the shock velocity. Furthermore, the magnetic field can only directly affect the ionized component of the interstellar gas, and all effects on the neutral component are due to collisions, causing a time lag (Sec. I.D.3; Chapter by McKee et al., Sec. V). Therefore, in cold regions with very low fractional ionization, even an "energetically significant" magnetic field may not dominate the dynamics on short time scales.

The literature is replete with reports of alignments of objects, such as elongated clouds and bipolar flows, with \hat{B}_\perp (Sec. V contains an incomplete review). The emerging bank of observational data and theoretical results has made magnetic fields astrophysically fashionable, and the temptation to assign observed effects to magnetism is strong. We suspect that some of these assignments are misplaced. There are several cautions that must be considered before such assignments can reliably be made:

1. Correlations or alignments found within a cloud might not be peculiar to the cloud itself. Instead, they might characterize not only the cloud but also the region within which it is imbedded. Observers must map regions on both small and large scales so that the conditions within an individual object can be separated from those of the ambient medium.
2. The direction of \hat{B}_\perp is difficult to measure *within* a dense cloud because of

the large extinction. Optical polarization probes the $A_V \lesssim 3$ mag gas at the periphery of the clouds. In contrast, more difficult infrared polarization probes the denser portions. For example, $2.2 \mu\text{m}$ can probe regions where $A_V = 20$ mag ($n \sim 10^5 \text{ cm}^{-3}$ for size 0.05 pc). In compensation for the more difficult observations, the interpretation is simpler; virtually all of the dust that polarizes the infrared polarization must be associated with dense gas in the cloud of interest.

3. Sources observed in near-infrared polarization studies are often not true background stars, but are instead embedded deeply within the clouds. Such objects are often intrinsically polarized, and must be dealt with appropriately; they include sources associated with extended infrared emission and young (e.g., T Tauri) stars with disks. They can be identified by obtaining appropriate spectrophotometry.
4. Alignments between objects located within a dense cloud, such as bipolar flows, and the ambient magnetic field as measured by optical polarization of starlight near the cloud have been reported and seem to be common. However, the polarization near the cloud is produced by dust grains along the *entire* line of sight and may not reflect \hat{B}_\perp in the ambient medium near the cloud. This can be investigated only by the tedious procedure of observing a large sample of stars at different distances and in a large area surrounding the cloud.
5. It is imperative to make the distinction between cloud features aligned with each other from those that are aligned with the field. The mere existence of aligned features does not imply magnetic dominance.
6. "Alignments" can only be observed on the plane of the sky. The distribution of three-dimensional angles that produce a given two-dimensional angle in projection is only very weakly peaked at the observed value. Thus, large samples are required to relate three-dimensional orientations to the observed two-dimensional orientations.

2. Polarization of Grain Thermal Emission. According to Kirchoff's law, aligned grains that produce polarization by absorption of background radiation must also produce polarization of their own emitted thermal radiation. Thus the direction of polarization of the emitted radiation is the same as that in which the absorption is more effective. Normally, the magnetic field is perpendicular to the polarization of the emitted radiation. For details, we refer the reader to the excellent review by Hildebrand (1988), and here emphasize two of his most important points.

First, the ability to trace the magnetic field by making observations in emission is extremely important, because it allows one to map the magnetic field at will, without requiring a background source of radiation. The emission is detectable both at far-infrared and mm wavelengths. mm-wavelength observations have the advantage of higher attainable angular resolution by using interferometric techniques.

Second, if one is to interpret the polarization of diffuse radiation as

resulting from aligned grains, then one must ensure that scattered radiation, which is intrinsically highly polarized, is negligible. For realistic grains, the ratio of scattering to absorption decreases as λ^{-3} and is about 4×10^{-6} at $\lambda = 100 \mu\text{m}$ (Novak et al. 1989). Thus, at far-infrared and sub-mm wavelengths, polarized diffuse radiation can reliably be assumed to be produced by thermal emission from aligned grains. At such long wavelengths, grains have no resonant absorption features, and if the Rayleigh-Jeans limit also applies, then the fractional polarization of the thermal radiation (but not that of the extinction) should be independent of wavelength. For well-aligned, highly elongated grains the fractional polarization can exceed 10%, but with realistic grain models will be $\lesssim 4\%$ (Novak 1991, personal communication).

However, two simple circumstances can produce a wavelength dependence. If there is a mixture of cool and sufficiently warm grains along the line of sight, as may easily happen in molecular clouds containing protostars, then far-infrared wavelengths might lie on the Wien side of the thermal peak for the cool grains and on the Rayleigh-Jeans side for the warm grains, so the infrared observations would emphasize the warm grains. And far-infrared observations taken from the Kuiper Airborne Observatory have worse angular resolution than mm-wave observations, which may have produced the differences in angle of linear polarization that are probably observed in the BN-KL region of Orion (Novak et al. 1990; Sec. II.A.1 below).

In the mid-infrared ($\sim 10 \mu\text{m}$), scattering may contribute to producing some of the observed polarization. The spectra of many deeply embedded mid-infrared sources are best fit by models that include both emission and absorption by the same grain material. These embedded sources are often seen at least partly in scattered light, which is itself highly polarized. The polarization of thermal emission varies rapidly with wavelength in the vicinity of grain absorption resonances, which can be used to infer the properties of both the grains and the magnetic field (see, e.g. Lee and Draine 1985; Sec. II.A.1 below). If spectropolarimetry shows that the mid-infrared polarization angle is independent of wavelength (although in the vicinity of grain absorption features, the position angle can flip by 90° [Draine and Lee 1984]), and if the fractional polarization depends properly on wavelength, then it is reasonable to conclude that the polarization results not from scattering but from aligned grains. Even in this case, however, it is difficult to interpret the observations, because emission and absorption by the same grains give orthogonal positional angles.

D. Some Indirect Indications of Magnetic Fields

1. The Angular Distribution of H₂O Masers. The angular distribution on the sky of H₂O masers may indicate the direction of the plane-of-the-sky field \hat{B}_\perp and conceivably even the ratio of field strengths B_\perp/B_\parallel . Elitzur et al. (1989) have presented a comprehensive model for the H₂O masers observed in star-forming regions in which the masers occur behind shocks. The model is in reasonable agreement with observations and is reasonably efficient from

the energy standpoint. Magnetic fields dominate the post-shock pressure, leading to the expectation that $B \propto n_H^{1/2}$, which is reasonably accurate, at least in Orion (Sec. II.A).

The model makes the very important prediction that the maser luminosity $\propto B_{\perp, shock}^4$, where $B_{\perp, shock}$ is the strength of the preshock magnetic field component that is perpendicular to the shock velocity. Suppose a protostar emits an isotropic wind that produces a spherical shock in the ambient medium, which is threaded by a uniform magnetic field. Then the theory predicts the masers located in a ring around the "magnetic equator" to be very much brighter than those located toward the "magnetic poles." Thus, an observer should see this ring in projection as an ellipse on the plane of the sky. The major axis would be perpendicular to B_{\perp} and the ratio of minor to major axes would be equal to B_{\parallel}/B_{\perp} . The ring should exhibit the expansion of the shock, and may also exhibit rotation of the ambient pre-shocked gas. The masers are velocity-coherent filaments and emit along their axes, which could conceivably produce a geometrical preference for observability that varies systematically around the ring. In Sec. II.A.3 below we find that the positional distribution of masers in Orion is consistent with the Elitzur et al. theory.

2. *Faraday Rotation.* Faraday rotation of the direction of linear polarization is $\propto \lambda^2 \int n_e B_{\parallel} dl$ and is usually considered to be the domain of galactic structure (long path lengths) and of low-frequency radio astronomy. However, with the possibility for high volume densities and magnetic fields in star forming regions, measurable Faraday rotation can occur.

Simonetti and Cordes (1986) used the VLA at dm wavelengths to observe small sets of extragalactic sources fortuitously located behind the bipolar flows Cep A and L1551. They detected significant changes of Faraday rotation measures amounting to 150 and 30 rad m^{-2} , respectively, and ascribed these changes to conditions within the outflows. For a path length of 0.1 pc, 30 rad m^{-2} corresponds to $n_e B_{\parallel} = 400 \text{ cm}^{-3} \mu\text{G}$. Unfortunately, there are no independent estimates of n_e , but the absence of radio bremsstrahlung emission sets an upper limit to the emission measure $n_e^2 l$, which in turn specifies a minimum field strength of $\sim 1 \mu\text{G}$.

Novak et al. (1990) detected a 18° difference for the position angle of linear polarization between the far-infrared and 1.3-mm wavelengths in the BN-KL region of Orion (Sec. II.A.1 below); the difference was confirmed by Flett and Murray (1991). The most likely explanation involves the differing angular resolutions, but Faraday rotation is not ruled out. The required rotation measure of $\sim 2 \times 10^5 \text{ rad m}^{-2}$ could be produced by $n_e \sim 2000 \text{ cm}^{-3}$ and $B_{\parallel} \sim 300 \mu\text{G}$, parameters which could conceivably describe the ionized gas that lies in front of BN. If Faraday rotation is responsible, the definitive observation would be a measurement at 3-mm wavelength.

3. *Ambipolar Diffusion.* Ambipolar diffusion is a motion of charged particles, which are directly tied to the magnetic field, with respect to the neutrals, which are not (Chapter by McKee et al., Sec. V). If the density of charged

particles is high enough, the collisional drag makes the relative velocity very small. However, in the ultraviolet-free interiors of molecular clouds, charged particles can be sufficiently rare that the velocity is measurable. Thus, if charged species such as HCO^+ have systematically different velocities from neutral species, one might conclude that one has measured the drift velocity v_D (see Chapter by McKee et al. [hereafter McK], their Eq. 55):

$$v_D \sim 3 \frac{B_{\mu G}^2}{n_H^{3/2} \ell_{pc}} \text{ km s}^{-1} \quad (4)$$

where n_H is the volume density of H-nuclei ($n_{\text{HI}} + 2n_{\text{H}_2}$) in units of cm^{-3} and ℓ_{pc} is the length scale for variation in \mathbf{B} in pc. If ℓ is 0.1 of the subcore diameter in cloud B1 (Sec. IV.B), $v_D \sim 0.05 \text{ km s}^{-1}$, which might be measurable. However, if the ambipolar diffusion is similar on both the front and back side of the cloud, then the observable effect would be a small increase in line width instead of a velocity difference, which would be undetectable.

II. OBSERVATIONAL EXAMPLES: H II REGIONS

A. Orion: Zeeman Studies, Masers, Linear Polarization and Structural Alignments

The Orion region occupies a place of central importance because it is the nearest region of massive star formation. Genzel and Stutzki (1989) present a comprehensive review of the morphology and physical conditions, and here we extract the major points. These authors also review the large-scale properties of the magnetic field in the L1641 dark cloud. We concentrate here on the properties of the field in the Orion A region, the most massive concentration in L1641.

Orion A is a “blister” H II region protruding from the near side of a small (~ 6 arcmin), very dense north-south ridge about 1 pc in length known as Orion Molecular Cloud 1, or OMC-1. These are imbedded within a much larger (several degrees) elongated ($\sim 40 \times 2$ pc) giant molecular cloud known as the Orion A Molecular Ridge, which is in turn imbedded in a much larger and lower-density H I cloud (Chromey et al. 1989). There are other large molecular clouds immediately adjacent.

Within OMC-1 exist the famous Becklin-Neugebauer point source (the BN object) and the Kleinmann-Low nebula (the KL nebula); this smaller region is known simply as BN-KL. BN-KL contains a cornucopia of interesting objects. The two most luminous sources are IR compact source number 2 (IRc2) and BN itself. IRc2 is the brightest, with a luminosity of 2 to $10 \times 10^4 L_\odot$, and is also the center of a powerful bipolar outflow which is highlighted by esoteric and energetic phenomena such as OH masers, SiO masers, H_2O masers, Herbig-Haro objects, and vibrationally excited H_2 lines.

Information on magnetic fields in the Orion region has been obtained from linear polarization of optical, mid-infrared, far-infrared, and mm-wave

radiation, from Zeeman splitting of HI and OH in absorption against the H II region, from Zeeman splitting of OH and H₂O masers, and from linear polarization of H₂O masers. The OH and HI absorption measurements refer to gas on the near side of the H II region, and the infrared sources and masers are on the far side.

1. The Becklin-Neugebauer (BN) Point Source: A Magnetic Gold Mine.

The BN object in Orion is a very bright, easily identifiable (nowadays) infrared point source in the Orion region. It is embedded in the dense molecular cloud OMC-1, heavily attenuated by dust, and has been the subject of extensive spectrophotometric and spectropolarimetric observations in the infrared. The analysis is complicated by the fact that the intrinsic spectrum of the BN object is unknown. However, by assuming that BN is intrinsically unpolarized, the spectropolarimetric data allowed Lee and Draine (1985) to deduce the polarization caused by aligned dust grains and, consequently, to infer a great deal about the magnetic field and the details of grain composition and shape in front of BN, and even the intrinsic spectrum of BN.

High linear polarization ($\sim 15\%$) that varies rapidly with wavelength is observed in the vicinities of the $3.1\text{ }\mu\text{m}$ "ice" (H₂O and NH₃) and $9.7\text{ }\mu\text{m}$ "silicate" absorption features, and weak ($\sim 1\%$) circular polarization is observed near $3\text{ }\mu\text{m}$. In Lee and Draine's model, these data are best fit with a combination of graphite and silicate grains with ice mantles. The graphite grains are large enough so that scattering is negligible but magnetic dipole absorption is not. The graphite grains are oblate with the *c*-axis of the graphite parallel to the symmetry axis ("pancakes" of graphite flakes). The silicate grains are also oblate and have poorly constrained sizes, but they must have mantle volume larger than half the core volume or else they produce too much polarization near $10\text{ }\mu\text{m}$.

Of more interest for the current review is the magnetic field. The position angle of the linear polarization is $118^\circ \pm 0.4^\circ$ in the mid-infrared (Aitken et al. 1985), which gives the direction of \hat{B}_\perp because the polarization results from extinction, not thermal emission. Lee and Draine cannot reproduce the observed high linear polarizations unless the grain alignment is nearly perfect. Even so, the field must be not only well ordered, but also lie nearly in the plane of the sky. For a uniform field, the observed polarization varies as $\sin^2 \gamma$, where γ is the angle between the magnetic field and the line of sight (our definition of γ is orthogonal to that of the Lee and Draine model). Formally, Lee and Draine require $\gamma \gtrsim 40^\circ$, but in reality other effects (imperfect alignment and field nonuniformities) force an even higher limit on γ . The corollary is, of course, that the high polarization also implies a highly ordered field near BN. However, the field is not perfectly uniform: the observed circular polarization near $3\text{ }\mu\text{m}$ requires that the field "twist" by $\sim 30^\circ$ along the line of sight near BN. A similar twist is seen directly in \hat{B}_\perp by Burton et al. (1991; also Sec. II.A.3 below).

Chernoff et al. (1982) use shock models for BN-KL to estimate theoretically that $n_{\text{H}} \approx 2 \times 10^5\text{ cm}^{-3}$ and $B \approx 0.45\text{ mG}$ in this region, similar to

values derived in a similar model by Draine and Roberge (1982). Such field strengths are also required by the Lee and Draine model to align the grains. We regard these estimates as sufficiently secure to insert in Table II, which summarizes field strengths in the Orion region.

2. *The Orion Region: The Field Strength B.* The field strength is most reliably derived from Zeeman splitting. This has been measured on several size and density scales: for the large-scale environment with HI and OH in absorption against the H II region, and for the BN-KL region with OH masers and one H₂O maser (we assume here—possibly erroneously [Sec. I.B.4a]—that the circular polarization measured in the H₂O maser is a result of Zeeman splitting). The field strength can also be derived from theoretical considerations as applied to observations. This has been done for the BN object (Sec. II.A.1 above) and for the time-variable H₂O “supermaser” (but possibly spuriously; see Sec. I.B.4b).

The known field strengths are summarized in Table II. Volume densities sampled by the different techniques range from $\gtrsim 400$ to $\sim 10^9$ cm⁻³, a range of about 6 orders of magnitude, and the total magnetic field strengths B range from ~ 0.05 to ~ 40 mG, a range of about 3 orders of magnitude. A reasonable fit to Table II, particularly if the lowest-density HI data are excluded, is $B = 1.0(n_{\text{H}}/10^6 \text{ cm}^{-3})^{1/2}$ mG. This corresponds to a density-independent Alfvén velocity $V_A = 1.8 \text{ km s}^{-1}$; it may be significant that molecular line widths tend to be comparable to this value.

a. *The large-scale environment.* The HI absorption line comprises two velocity components. In our opinion, this HI is not in the photodissociation region and does not directly abut the H II region. We support our opinion by two facts. One, the HI velocities of ~ 0 and 6 km s^{-1} are 3 and 9 km s^{-1} more *positive* than the H II velocity, while the absorption gas is in front of the H II region and, if it were gas from the photodissociation region, should be moving at *negative* velocity with respect to the H II region. Two, the HI is cold, but given the exciting stars for Orion, the HI in the photodissociation region should be warm (Tielens and Hollenbach 1985).

In the HI absorption lines, Troland et al. (1989) mapped the field strength with $25''$ resolution over most of the H II region, which occupies an area about $5'$ in diameter. They found B_{\parallel} to range from -43 to $-107 \mu\text{G}$. In both OH and HI absorption lines, Troland et al. (1986) measured Zeeman splitting for a single spot on the eastern edge of the H II region; they obtained -125 and $-49 \mu\text{G}$, respectively. We adopt $B = -100 \mu\text{G}$, and if this uniformly fills a $5'$ -diameter circle, the magnetic flux is -2.0 mG arcmin^2 .

b. *The masers.* The molecular “doughnut” (Plambeck et al. 1982) is a disk of dense (up to $\sim 10^7 \text{ cm}^{-3}$) gas with outer diameter $\sim 44''$ and a hole in the middle. It surrounds IRC2 and expands at $\sim 20 \text{ km s}^{-1}$. Its total mass is $\sim 15 M_{\odot}$, which seems to be too massive to have been ejected directly from IRC2. The expansion time scale (radius/velocity) ~ 3000 yr and the kinetic energy $\sim 5 \times 10^{46}$ erg, which amounts to $\sim 0.5\%$ of the luminosity of IRC2 for 3000 yr. Thus it is reasonable to consider the doughnut as being composed

TABLE II
Magnetic Field Strengths in the Orion Region

REGION	ΔRA^a	ΔDEC^a	V^b	B^c	n_{H}	ref
H ₂ O maser	-23	-9	-49.7	-38 ^g	$\sim 10^9$	FG, GD
H ₂ O supermaser	-5	-7	7.7	$\sim 30 $ ^g	$\sim 10^9$	GMH
OH maser	-9	4	6.0	-1.4	$\sim 10^7$	JMN ^d
OH maser	4	-13	7.7	-1.3	$\sim 10^7$	JMN ^d
OH maser	-3	-1	8.3	-2.0	$\sim 10^7$	JMN ^d
OH maser	1	1	14.8	-1.3	$\sim 10^7$	JMN ^d
OH maser	1	1	23.7	-0.8	$\sim 10^7$	JMN ^d

HI abs ^e	~ 0	~ 0	~ 6	~ -0.10	$\gtrsim 400$	THG
HI abs ^e	~ 0	~ 0	~ 0	~ -0.10	$\gtrsim 400$	THG

^a Position offsets in arcsec from IRc2.

^b Component velocity, km s⁻¹.

^c Measured B, mG. Values are from Zeeman splitting and the sign indicates the direction of the line-of-sight component unless surrounded by | |, in which case the sign is undetermined. For OH masers, total B; otherwise, B_{||}. The H₂O maser results may be spurious (see footnote g). The BN result is inferred from dust alignment and from theoretical arguments (Sec. II.A.1).

^d JMN neglected to quote the sign of B, and for the 1665 MHz line used an incorrect Landé g-factor (our factor b in Table I). For the the 1612 MHz line, we assumed $b = 1.31$, the intensity-weighted factor quoted in Table I.

^e THG mapped an area about 4' in diameter. B_{||} varied from -0.04 to -0.17 mG and may have been correlated with total column density. There was no apparent correlation between the two velocity components.

^f Data were taken with Nancay telescope, which has a narrow beam in the ew direction and a broad beam in the ns direction. The ns position is determined by the product of the OH opacity and the continuum intensity averaged over the telescope beam; the quoted ns offset is an estimate.

^g The H₂O maser result is from Zeeman splitting, and may be 'fake Zeeman splitting' (Sec. I.B.4a). The H₂O supermaser result is inferred from the existence of strong linear polarization using the older theories and may be spurious (Sec. I.B.4b).

of ambient material that has been swept up (i.e., shocked) by less massive, faster-moving or high-temperature ejecta from IRC2.

Such shocks bring us to the magnetic field/H₂O maser discussion of Sec. I.D.1. There are two classes of H₂O maser, the 18 km s⁻¹ (low-velocity) flow and the 30 to 100 km s⁻¹ (high-velocity) flow (Genzel et al. 1981). The low-velocity masers lie in the plane of the doughnut and trace its *outside* with diameter ~44"; they have $n_H \sim 10^9$ cm⁻³ and $B \sim 30$ mG, corresponding to an Alfvén velocity $V_A \simeq 1.8$ km s⁻¹. From the discussion of Elitzur et al. (1989) in Sec. I.D.1, this implies that the ambient magnetic field lies along the axis of the doughnut. The high-velocity masers lie on the axis of the doughnut and are probably the equivalent of Herbig-Haro objects.

The calculations of Elitzur et al. were for the case of fast, dissociative shocks, but 18 km s⁻¹ H₂O masers are not fast enough. However, the conditions in slower, nondissociative shocks can be similar, so it is likely that the low-velocity H₂O masers arise in shocks. Much of the emission in nondissociative shocks is predicted to occur near the velocity of the *unshocked* gas, where the heating due to ambipolar diffusion is greatest. However, in order to get saturated maser emission in masers of the observed size (which is comparable to the shock thickness), the density must be of order 10⁹ cm⁻³ (Elitzur et al. 1989); this suggests that the maser emission occurs at the density, and hence the velocity, of the *shocked* gas. The location of the H₂O masers at the outer perimeter of the doughnut is also consistent with the idea that they are in recently shocked gas.

Most of the OH masers lie within 8" of IRC2 and have velocities within 18 km s⁻¹ of IRC2 (Johnston et al. 1989). Thus it seems that the OH masers trace the *inside* of the doughnut, because both the velocities and gas densities match. The OH masers have $n_H \sim 10^7$ cm⁻³ and $B \sim 1.4$ mG, which gives $V_A \simeq 0.8$ km s⁻¹, about 2.2 times smaller than V_A for the H₂O masers. The OH maser is a ground-state transition, so exciting it does not require the temperature to be above several hundred degrees as does the water maser. (But the *production* of OH requires either high temperatures [Sec. I.A.2] or photodissociation of H₂O.) Thus the location of the OH masers at the inner edge of the doughnut is consistent with either radiative pumping or with weak shocks due to variations in the wind luminosity of IRC2.

Placing both the OH and the H₂O masers in the shocked gas leaves us with the apparently inexplicable puzzle as to why the pressure in the H₂O masers is so much greater than that in the OH masers, even though their radial velocities are the same. We cannot offer an explanation.

c. Equal magnetic fluxes? First, we estimate the magnetic flux through the doughnut. The OH masers see the magnetic field near the inside of the doughnut, about -1.4 mG, and the H₂O masers at the outside, about -30 mG. We do not know how the field strength varies within the doughnut, but if we brazenly assume the average field strength to be -5.4 mG then the doughnut, which we take as a circle 44" in diameter with a 16" diameter hole, contains the same magnetic flux as the ambient gas, about -2.0 mG arcmin². This is

equal to the flux obtained above for the diffuse ambient gas.

There is, in fact, absolutely no reason for these magnetic fluxes to be equal. Most importantly, the doughnut contains only a small fraction of the dense molecular gas, and presumably most of the magnetic field lines permeate the majority of the molecular gas. In addition, the ambient-medium flux was obtained from the HI absorption observations and thereby depends on the size of the H II region, which is determined by completely different considerations.

The approximate equality of the magnetic fluxes is probably just a coincidence, but we cannot be sure. This matter is discussed further in Sec. II.A.4 below.

3. *The Orion Region and BN-KL in Particular: \hat{B}_\perp from Linear Polarization.* In the vicinity of BN-KL, polarization of the thermal emission from aligned dust grains is observed. Far-infrared emission has been measured with 40'' angular resolution by Novak et al. (1989) and Gonatas et al. (1990), sub-mm-wave emission with $\sim 16''$ by Flett and Murray (1991), and mm-wave emission with $\sim 22''$ resolution by Barvainis et al. (1988) and Novak et al. (1990). Position angles derived by the various mm-wave measurements differ by about 24° , which is unimportant for the current discussion. Position angles for the far-infrared and mm wavelengths are similar, as expected (Sec. I.C.2). The position angle of the field as derived from the emitting grains, $\theta_{B,dust}$, is about 110° .

Higher angular resolution is required to establish whether small-scale variations of $\theta_{B,dust}$ exist. Unless one reverts to interferometric techniques, this requires going to shorter infrared wavelengths. Within $\sim 1'$ of IRC2, Burton et al. (1991) have achieved $\sim 2''$ resolution by mapping the linear polarization of the emission from the $v=1-0$ $S(1)$ line of H_2 at $2.1218 \mu m$. The emission is polarized by aligned *absorbing* grains that lie in front of the excited H_2 . The line emission provides an excellent background source because it is extended; this not only allows mapping, but also should reduce the effects of scattering. Outside $\sim 1'$ from the BN object, the polarization is very large and its direction is roughly perpendicular to the radial line to BN, which implies that it results from scattering.

But closer to BN, the polarization is smaller and systematically oriented with position angle $\theta_{pol} \sim 130^\circ$. Near ($\sim 10''$ from) BN, θ_{pol} "twists" by $\sim \pm 15^\circ$. A similar twist, but for the direction along the line of sight, is inferred from the existence of circular polarization of the absorbed BN radiation (Sec. II.A.1 above). Perhaps this second twist is *directly* indicated by the $\sim 20^\circ$ -difference between $\theta_{B,dust}$ and θ_{pol} (i.e., between the *emitting* dust seen at far-infrared and sub-mm wavelengths and the *absorbing* dust seen by Burton et al.).

Aitken et al. (1985) made $4''$ resolution spectropolarimetric observations of the mid-infrared ($8-13 \mu m$) *continuum* radiation from the six infrared sources within $\sim 12''$ of IRC2. In contrast to Burton et al. (1991), they found the position angle to vary considerably among the six positions. For all

positions except IRc2, they concluded that the polarization is produced by aligned grains, in contrast to the situation at $3.8\ \mu\text{m}$ (Werner et al. 1983). However, the discrepancy with the results of Burton et al. suggests that Aitken et al. may have underestimated the scattering.

$\theta_{B,dust} \sim 110^\circ$ is in very good agreement with the direction ($118^\circ \pm 4^\circ$) obtained for the point source BN by Aitken et al. (1985; Sec. II.A.1) and, of course, is close to the average angle $\theta_{pol} \approx 130^\circ$ obtained by Burton et al. It is also close to the position angle of $\sim 100^\circ$ for the huge surrounding area $\sim 1^\circ$ in extent obtained from optical polarization of background stars, which indicates the field direction in the ambient matter surrounding the dense molecular cloud. Thus we conclude that the field direction θ_B is about 110° in the vicinity of BN-KL where the dust is warm and it has small twists in the surrounding region outside a distance $\sim 10''$ ($\sim 5000\text{ AU} \sim 0.02\text{ pc}$) from BN-KL.

Position angles describe the orientations of various structural features in the interior of Orion, and we might expect them to be related to the local direction of the field. We exhibit them in Fig. 1 and discuss them in the following paragraphs:

(1) The low-velocity H_2O masers that are located within $\sim 10''$ of IRc2 tend to lie near a line having position angle $\theta_{line} \sim 30^\circ$ (Knowles and Batchelor 1978; Genzel et al. 1981). From our discussion in Sec. I.D.1., \hat{B}_\perp should be perpendicular to the line, at a position angle 120° , which is only 10° different from $\theta_{B,dust}$. We expect the masers to lie in an ellipse; the thickness of their positional distribution about the line implies that γ , the angle between the magnetic field and the line of sight, is $\sim 60^\circ$.

(2) The group of most intense OH masers, populations 1 and 2 of Norris (1984), lie on a line having position angle $\sim 60^\circ$. This differs by 30° from that of the H_2O masers. The OH masers lie toward the inside of the doughnut, while the H_2O masers lie on the outside; the field directions may differ in these regions. Alternatively, the prediction of the Elitzur et al. theory, that maser luminosity $\propto B_{\perp,shock}^4$, may not apply to OH masers.

(3) On the very smallest scale, the position angle of the bipolar flow from IRc2 is $\sim 130^\circ$; this is our estimate using the SO map of Erickson et al. (1982) and the SiO map of Wright et al. (1983). This is only about 20° from $\theta_{B,dust}$, and is equal to the position angle of the absorbing dust θ_{pol} seen by Burton et al. (1991); this implies that the flow is nearly aligned with the field directions in both the immediate vicinity and in the larger-scale ambient medium.

(4) Judging from the map of Vogel et al. (1984), the axis of the molecular doughnut has position angle 140° , which is nearly perfectly aligned with the bipolar flow from IRc2 and is only $\sim 30^\circ$ from $\theta_{B,dust}$.

(5) On the much larger scale of $\sim 0.5^\circ$ ($\sim 4\text{ pc}$), the molecular ridge in which the Orion complex is embedded has a position angle of $\sim 10^\circ$, and it contains filaments running along its length (Bally et al. 1987). This direction is within $\sim 10^\circ$ of the field direction implied by $\theta_{B,dust}$.

(6) The direction of linear polarization of H_2O masers is ambiguous. H_2O

masers in Orion tend to be linearly polarized and are time-variable on a scale as short as weeks. Unfortunately, however, there exist few published reports of the position angle of linear polarization, only for 5 maser components by Knowles and Batchelor (1978) and for the "supermaser" by Garay et al. (1989). Furthermore, the polarization direction can depend on maser parameters (Sec. I.B.4b). For these reasons we exclude maser polarization from the present discussion.

Figure 1. Directions of \hat{B}_\perp near Irc2 in Orion derived from the possible indicators discussed in the text. The direction for dust-grain alignment indicates the polarization of both the point source BN and the dense molecular cloud OMC-1. Aside from observational uncertainties, differences might be caused by changes in \hat{B}_\perp with position.

Figure 1 shows that all of the above angles lie within 20° of 130° . The above structural features represent anisotropies that could easily result from magnetic (or other anisotropic) forces. We conclude that position angles of various structural features may provide significant information on the magnetic field. However, we need much more than a statistical sample of one H II region. There is much to be done in the way of further observations, both on Orion itself and on other H II regions.

4. From the Smallest to the Largest Scales. We remarked above in Sec. II.A.2 that the line-of-sight components of magnetic fluxes in the ambient gas and in the doughnut are approximately equal, the possible implication being that most of the magnetic lines that thread the doughnut also thread the ambient gas. Furthermore, they have the same sign. This implies that the fields are not too highly inclined to the line of sight. On the other hand, we also discussed how both the BN dust alignment model and the distribution of H₂O masers on the sky imply that the field is not too closely aligned with the

line of sight. These somewhat contradictory requirements imply that γ , the angle between the magnetic field and the line of sight, is $\sim 45^\circ$.

With $\gamma \sim 45^\circ$, B_{\parallel} can be negative throughout the region while the field lines thread both the ambient gas and the dense molecular gas, satisfy the constraint $\nabla \cdot \mathbf{B} = 0$, and do not bend unduly sharply. This is because the H II region is roughly spherical (Balick et al. 1974), so that as the field lines diverge from the doughnut, which is located behind the H II region, to the ambient gas, which is located in front, they need not bend by more than $\sim 30^\circ$.

This all points to Orion/BN-KL as being an excellent example of the general (and surprising) trend found by Reid and Silverstein (1990) for the OH maser field directions to reflect the galactic field directions in their vicinity (Sec. I.B.4a). However, on slightly larger angular scales, the situation is not so clear-cut. Zeeman observations of OH in absorption against the H II region Orion B (NGC 2024), only 4° away from Orion A, show a *positive* field (Heiles and Stevens 1986). Thus, while Orion A is in accord with Reid and Silverstein (1990), Orion B is not.

This less than ideal state of affairs elicits two comments. First, Table II reveals the signs of B_{\parallel} for many measurements, but these can be considered to sample only two independent regions: the ambient gas overlying the H II region and the masers. The probability that the signs are the same in these two regions is equal to $1/2$, so the result of sign equality is hardly a surprise. Second, concerning the results of Reid and Silverstein, we suspect that the last word has not yet been written concerning the general trend for OH maser fields to reflect the ambient galactic field.

B. W3: Discrepant Aperture Synthesis Results

For W3 there are two independent studies of Zeeman splitting of the HI line in absorption against the H II region. They do not agree. Troland et al. (1989) used the VLA with $59''$ resolution and van der Werf and Goss (1990) used the WSRT (Westerbrook Synthesis Radio Telescope) with $16''$ and $30''$ resolution. Troland et al. detected significant polarization that should have been seen by van der Werf and Goss, but was not; the latter detected polarization that was too weak to have been seen by Troland et al. We cannot imagine a cause for the discrepancy except that one of the observational results is simply wrong. We conclude that discussions of physical interpretation are better left until reliable data are obtained. The sensitivity must be excellent. The angular resolution of Troland et al. is clearly inadequate, and future studies should use even better resolution than that of van der Werf and Goss.

III. OBSERVATIONAL EXAMPLES: DERIVING B

A. The Method: Statistical Treatment of Zeeman and Linear Polarization Measurements

Myers and Goodman (1991) have devised a method to specify almost completely the uniform component of \mathbf{B} ; here we present a brief summary and

the application to the dark cloud L204. The method involves relating measured fluctuations in B_{\parallel} to both measured fluctuations in the position angle of linear polarization and to fluctuations in B_{\perp} with a model. It requires (1) good statistical samples of B_{\parallel} from Zeeman splitting and of θ_B , the position angle of \hat{B}_{\perp} , from optical polarization; and (2) a model for the behavior of the fluctuations in \mathbf{B} . A related model by Jones (1989) uses only the optical polarization data, and is able to derive the direction of the mean field and the relative strengths of the random and uniform field components, but any model that does not include Zeeman measurements cannot derive the absolute field strength.

Consider the total magnetic field \mathbf{B} at any point in space to be the vector sum of a straight “uniform” field, \mathbf{B}_0 , and a spatially varying, nonuniform field, \mathbf{B}_r . If we average many Zeeman observations within a given region, the mean value is a good estimate of $B_{\parallel,0}$, and the dispersion about the mean approximates $\sigma_{B_{\parallel}}$, the dispersion in the line-of-sight field. Similarly, optical polarization maps provide the mean position angle of \hat{B}_{\perp} , $\langle\theta_{B_{\perp}}\rangle$, and its dispersion σ_{θ_B} ; clearly, σ_{θ_B} is related to $\sigma_{B_{\perp}}/B_{\perp,0}$.

Now introduce a model that relates $\sigma_{B_{\parallel}}/B_{\parallel,0}$ to $\sigma_{B_{\perp}}/B_{\perp,0}$ and also relates $\sigma_{B_{\parallel}}$ to $\sigma_{B_{\perp}}$. Then given the quantities derived from observations, namely $B_{\parallel,0}$, $\sigma_{B_{\parallel}}$, \hat{B}_{\perp} , and σ_{θ_B} , the magnitude of $B_{\perp,0}$ can be derived. This, together with $B_{\parallel,0}$, $\sigma_{B_{\parallel}}$, $\langle\theta_{B_{\perp}}\rangle$, and an estimate of the number of correlation lengths (N) of the field along the line-of-sight, provides \mathbf{B}_0 (with a two-fold directional ambiguity), and the average total field strength, $|\mathbf{B}|$.

Models include one for which \mathbf{B}_r is essentially two-dimensional, resulting from Alfvén waves (Zweibel 1990a; Myers and Goodman 1991), and a “turbulent” field model, in which \mathbf{B}_r is distributed isotropically in three dimensions (Myers and Goodman 1991). The isotropic model is more directly applicable in practice, but may be unrealistic because transverse fluctuations undergo weaker nonlinear damping than do aligned or longitudinal fluctuations. An ideal model would incorporate both density and magnetic field fluctuations using the concepts first enunciated by Chandrasekhar and Fermi (1953). In any model, there is the practical problem of separating fluctuations from systematic gradients.

There are some complications and uncertainties. First, measurement uncertainties increase $\sigma_{B_{\parallel}}$ above its true value, thus increasing the derived value of $B_{\perp,0}$. Second, both Zeeman and linear polarization measurements average along the line of sight. If there are N independent elements along the line of sight, then the fluctuations are reduced by $N^{1/2}$. It is impossible to determine N definitively, so one must make an educated guess and live with the resulting uncertainties. Finally, because polarization measurements do not give the sign of \hat{B}_{\perp} , one cannot derive the full vector $\mathbf{B}_{\perp,0}$ without a two-fold directional ambiguity, although in some cases, as in the L204 example given below (Sec. III.B), the ambiguity can be resolved by additional information.

We mention two important caveats. First, the Zeeman and polarization

observations highlight different portions of the cloud unless care is exercised in selecting the statistical samples. Zeeman observations emphasize the regions of high B_{\parallel} , which tend to be those of high n ; polarization observations are most easily obtained in regions of low extinction, which tend to have low n . Second, the result depends on the model used to describe the fluctuations in \mathbf{B} . Magnetic fluctuations are not inherently isotropic, so the relation between $\sigma_{B_{\parallel}}$ and $\sigma_{B_{\perp}}$ depends on γ , the angle between $\hat{\mathbf{B}}$ and the line of sight, which is itself derived from the model. Finally, in the best of worlds—but not necessarily in the real world—the model is consistent both with basic physical principles and with their application to the specific physical conditions in the region.

B. An Example: L204

In the dark cloud Lynds 204 (L204), Heiles (1988) has made HI Zeeman measurements on a grid of 27 positions covering approximately a 6 by 15 pc area. McCutcheon et al. (1986) have made well-sampled optical polarization measurements which cover a size scale equivalent to the Zeeman measurements and show a nonrandom plane-of-the-sky field. This is currently the only region where the method described in Sec. III.A could be applied.

The Zeeman spectra in L204 are best fit by a two-component model, comprised of a wide emission profile plus a narrower self-absorption feature. In this chapter, we consider only the self-absorption data, and we assume $N = 1$; Myers and Goodman (1991) also quote results for the main emission component and for various assumed values of N . The field values exhibit a tendency to correlate with velocity, so in calculating the mean and standard deviation for the measurements, Myers and Goodman (1991) must first subtract out this velocity dependence. For the $N = 1$ case, they find $B_{\parallel,0} = 6.4 \mu\text{G}$ and $\sigma_{B_{\parallel}} = 4.5 \mu\text{G}$. In analyzing the distribution of θ_B , they use the isotropic model and find $B_{\perp,0}/\sigma_{B_{\perp}} = 2.5$. Thus $B_{\perp,0} = 11 \mu\text{G}$. Adding $B_{\parallel,0}$ and $B_{\perp,0}$ in quadrature gives $B_0 = 13 \mu\text{G}$, so that $\gamma = \pm 60^\circ$. Based on two correlations, one between the cloud shape and line-of-sight velocity and one between B_{\parallel} and line-of-sight velocity, Heiles (1988) infers that $\gamma > 0$. The optical polarization data give $\langle \theta_{B_{\perp}} \rangle = 71^\circ$, so the absolute direction and magnitude of the uniform component, i.e., \mathbf{B}_0 , can be specified. Similarly, the magnitude of the total field, obtained by adding the uniform and fluctuating components in quadrature, is $|\mathbf{B}| = 15 \mu\text{G}$; for comparison, the $N = 10$ assumption yields $28 \mu\text{G}$. The actual value of N is thought to be between 1 and 10.

With a value of $N \sim 3$, the energy in the nonuniform magnetic field is about equal to the energy in the uniform field, and L204 is in approximate virial equilibrium. The correlations among cloud shape, line-of-sight velocity, and line-of-sight field found by Heiles (1988) also imply the presence of large-amplitude Alfvén waves, which may make the three-dimensional isotropic model inapplicable. Results for the (perhaps more relevant) case where \mathbf{B}_r is wave-like (i.e., isotropic in two-dimensions) are given in Myers and Goodman (1991).

IV. OBSERVATIONAL EXAMPLES: THE VIRIAL THEOREM AND CLOUDS

A. The Virial Theorem: Observational Considerations

Many observational treatments of molecular clouds rely on the virial theorem, written for a spherical cloud of uniform density and mass M (McK Eq. 9):

$$|W| + 3P_0V = 2T + \mathcal{M} \quad (5)$$

where W is the gravitational potential energy $-3GM^2/5R$ for a uniform cloud; $3P_0V$ is the external pressure term, equal to $2T_0$ in McK Eq. (3); T (McK Eq. 2) is the total kinetic energy $0.27M \Delta v^2$ ($2T$ is $3\bar{P}V_{cl}$ in McK Eq. 9); and \mathcal{M} is the total *net* magnetic energy $0.1B^2R^3$, where the factor 0.1 comes from setting $b = 0.3$ in McK Eq. (16), which is valid for self-gravitating clouds but not pressure-confined clouds. The external pressure P_0 includes both thermal and turbulent pressure, and for the case of a dark cloud surrounded by low-density gas should also include the interstellar radiation pressure. Here we use the observationally oriented Δv , which is the line width at half-peak intensity; McKee et al. use in their chapter the theoretically oriented one-dimensional velocity dispersion σ . For a Gaussian velocity distribution the two are related by

$$\sigma^2 = 0.18 \Delta v^2. \quad (6)$$

The McKee et al. chapter defines several additional virial-related parameters. Observers often neglect the surface terms and the magnetic field. Under this assumption, equilibrium is obtained when the parameter $\alpha \equiv 2T/|W|$ (McK Eq. 33) is equal to unity. If virial equilibrium prevails, then the question remains as to the stability of the equilibrium. The stability can be expressed in terms of various *critical masses*. In the absence of a magnetic field, the critical mass is M_J , the familiar Jeans mass: if $M/M_J > 1$, then the equilibrium is unstable to collapse. In the absence of gas pressure, the corresponding magnetic critical mass is M_Φ : if $M/M_\Phi > 1$, the cloud is “magnetically supercritical” and the equilibrium is unstable to collapse. The distinction between magnetically subcritical and supercritical clouds has been invoked to explain the possible bimodal character of star formation (“low-mass, low-efficiency” vs “high-mass, high-efficiency,” respectively [Shu et al. 1987a]). More generally, the critical mass is M_{cr} , which is approximately equal to $M_J + M_\Phi$.

The virial theorem allows the overall equilibrium to be described in terms of global cloud parameters, which can be derived directly from observational data. This is a minimalist approach, because it avoids dealing with the internal structure of clouds. The problem with this approach is the uncertainties in the virial terms. This problem is well exemplified by our discussion of the B1 cloud below in Sec. IV.B and, apart from matters such as surface terms and nonuniform cloud structure, involves three specific observational quantities: the assumed distance D , the conversion of B_\parallel to B , and the determination of the true H_2 content.

The distance uncertainty can be very serious and should never be ignored or minimized. Its seriousness depends on the method by which density and mass are determined. First, we have $\mathcal{M} \propto D^3$. If masses and volume densities are inferred from observations of *column* density, then $|W| \propto D^3$ while P_0V and $T \propto D^2$. Thus, virial equilibrium depends on the *first* power of the distance. However, if masses are determined from observations of *volume* density, then $|W| \propto D^5$ and P_0V and $T \propto D^3$; virial equilibrium depends on the *square* of the distance.

The second problem is a matter of projection angle. We usually measure B_{\parallel} instead of B . For a large sample $\langle B \rangle = 2\langle B_{\parallel} \rangle$ and $\langle B^2 \rangle = 3\langle B_{\parallel}^2 \rangle$. However, an individual case is generally different. The matter is important, because the magnetic term in the virial theorem $\mathcal{M} \propto B^2$ so the arbitrary use of the large-sample relations increases \mathcal{M} by a factor of 3 over its minimum value.

The third problem involves determination of the volume density n_{H_2} or, equivalently, the column density N_{H_2} or cloud mass M . Many clouds have been observed only in the (very) optically thick ^{12}CO line, and for these one usually assumes that M or $N_{\text{H}_2} \propto$ either the CO line luminosity or the line width (Solomon et al. 1987). The basis for this procedure involves assuming that the cloud is in virial equilibrium and has standard properties (e.g. $\langle n_{\text{H}} \rangle \sim 200 \text{ cm}^{-3}$, $T \sim 10 \text{ K}$; see the succinct review by Maloney [1990b]). Clearly, this procedure is undesirable in the present context, where ^{12}CO optical depths are high, and derived values of N_{H_2} are very uncertain. Density estimates using C^{18}O or ^{13}CO observations are more reliable, but only up to moderate density ($n \sim 10^4$) where optical depth again begins to become a problem.

In principle, N_{H_2} can be determined by observing dust associated with molecular clouds. Observations of extinction due to dust are limited by the dust optical depth at any given wavelength, and therefore cannot be used to measure column density when the cloud becomes opaque. Observations of far-infrared or sub-mm emission provide the temperature-weighted (relative to the cosmic background) dust column density if the dust opacity and dust-to-gas ratio are known (Draine 1990). But in opaque clouds, dust inside the cloud cannot be heated by starlight and will not be revealed in thermal emission unless there is an imbedded heating source such as a protostar. In practice, neither the dust opacity at long wavelengths (e.g., $600 \mu\text{m}$) nor the dust temperature distribution along the line of sight are well understood, so this technique cannot yet be reliably applied.

In summary, it is very difficult to obtain accurate measurements of *column* density. The *volume* density n_{H_2} can be determined directly from observations of molecular transitions, because these transitions are excited by collisions with H_2 molecules. However, in practice, there is rarely sufficient knowledge to obtain accurate results, because the derived densities also depend on the details of radiative transfer, which in turn depend on the velocity field. Models are usually employed, and the resulting volume densities are uncertain by

factors of order 2 or 3 (White 1977). Turner and Ziurys (1988) provide a contemporary summary of this problem.

In applying the virial theorem, even with distance uncertainties aside, it seems unlikely that the terms can be specified relative to each other more accurately than a factor of 2. Factors of 2 are good from the standpoint of astronomical accuracy but inadequate for a definitive discussion involving the virial theorem, as we shall see in our discussion of B1 below. If \mathcal{M} is comparable to other terms in the virial theorem which are, in turn, comparable to one another, then the uncertainties allow virial equilibrium to exist with or without \mathcal{M} .

B. Barnard 1 (B1): The Magnetic Field, Virial Equilibrium and Stability

B1 is, to our knowledge, the dark cloud about which most is known from the combined standpoints of structure and magnetic field, and represents the best example for application of the virial theorem. B1 is a well-defined cloud in the Perseus region. It was selected for Zeeman observations because it has the largest value of $\Delta v/R$, which implies a large magnetic field strength if it is in virial equilibrium with $\alpha \approx 1$ (Myers and Goodman 1988a); this may mean that it is not a representative cloud. B1 has been mapped in several molecular transitions, including ^{13}CO with 4.4 arcmin resolution by Bachiller and Cernicharo (1984); OH with 3 arcmin resolution by Goodman et al. (1989); and NH_3 with 40 arcsec angular resolution by Bachiller et al. (1990b). For these molecules— ^{13}CO , OH and NH_3 —the sizes decrease and the line widths decrease monotonically. This is a reasonable result, because the three molecules trace increasingly dense regimes of H_2 volume density, and according to the empirical “Larson’s laws” (Larson 1981; Solomon et al. 1987), size $\propto n_{\text{H}_2}^{-1}$ and line width $\propto n_{\text{H}_2}^{-1/2}$.

The appearance of B1 in these three molecules is depicted in Fig. 2. As the angular scale gets smaller B1 gets more complicated. We define the cloud *core* as the $\sim 3'$ -diameter portion of the cloud highlighted by the NH_3 lines. The core contains an IRAS source that exhibits an apparent outflow (E. Lada, personal communication), and thus is a protostar or newly formed star. The cloud core consists of two or three condensations, which we define as subcores, separated by about 1.2 arcmin, in which $n_{\text{H}_2} \sim 4 \times 10^4$ and $8 \times 10^4 \text{ cm}^{-3}$. If these subcores themselves have smaller substructure, it would not have been resolved by existing observations.

Zeeman splitting of the OH 1665 and 1667 MHz lines was measured by Goodman et al. and Goodman (1989). On the core, $B_{\parallel} \sim -27 \mu\text{G}$, while $4'$ to the southwest $B_{\parallel} \sim -12 \mu\text{G}$ (Fig. 2). On the core of B1, the brightness temperature of the OH 1667 MHz line peaks at $\sim 1.3 \text{ K}$, while those of the optically thick ^{13}CO and NH_3 lines peak at $\sim 6 \text{ K}$. This indicates that the OH line is optically thin. However, direct comparison of the 1667 and 1665 MHz lines indicates a 1667 MHz optical depth of 1.22. This is a potentially serious discrepancy. Its resolution probably lies in the 1667 and 1665 MHz lines having unequal excitation temperatures, as has been observed in other dark

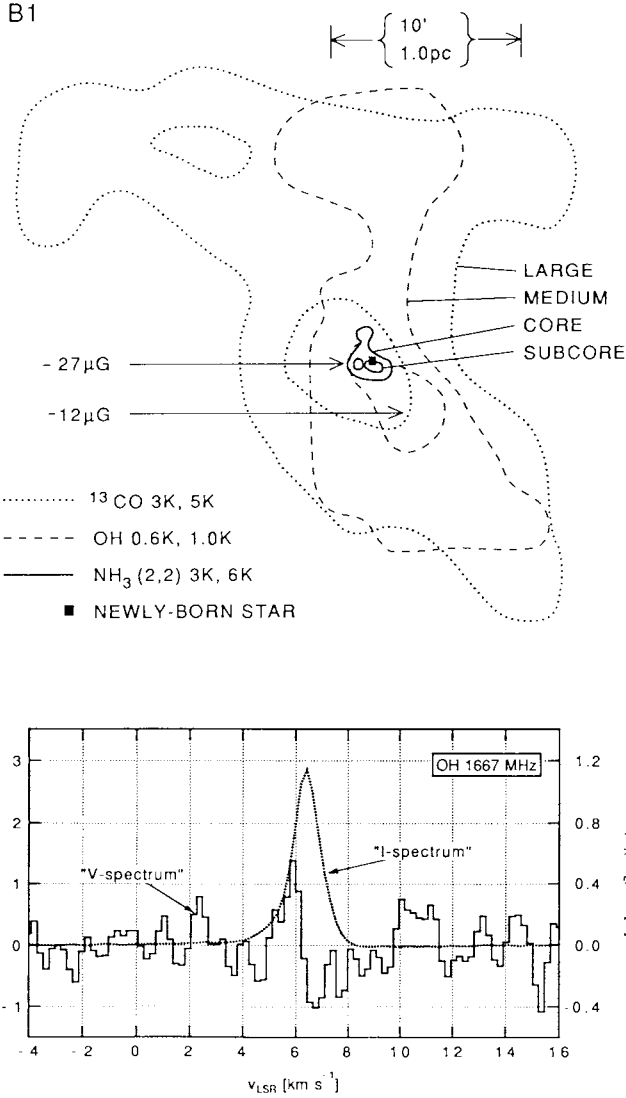

Figure 2. *Upper panel:* B1 as observed in ^{13}CO , OH and NH_3 . The three molecules highlight increasingly smaller size scales (see text). Only two contours are shown for each molecule, one near the peak and one about half the peak intensity. The four size ranges, ranging from large to subcore, are indicated, as are the two B_{\parallel} 's derived from OH Zeeman splitting. There are several young stars in the region; we show only the one located in the core. *Lower panel:* The Zeeman effect in the B1 core region, as observed at Arecibo (Goodman et al. 1989). Fits of the derivative of the Stokes I spectrum to the Stokes V spectrum (at 1665 and 1667 MHz) give $B_{\parallel} = -27 \pm 4 \mu\text{G}$.

clouds by Crutcher (1977). This is probably caused by excitation of the OH rotational ladders by far-infrared radiation. In the case of B1, a difference in excitation temperature of ~ 3 degrees would explain the discrepancy; this is only somewhat larger than Crutcher obtained for OH along the line of sight to 3C123, which is not far from B1 on the plane of the sky.

1. *The Field Strength in the Densest Portions of the Core.* Goodman's (1989) off-core result of only $-12 \mu\text{G}$ is less than half the field strength measured on the core, which implies that the field strength might increase in the core. Further, if we were able to sample exclusively the core gas, then the measured field strength might be even greater than the $-27 \mu\text{G}$ obtained from the OH, because OH may not sample the densest portions of the core. This is indicated by both an observational and a theoretical argument.

(1) Observationally, the OH line width is nearly twice as wide as the NH_3 line. According to Larson's empirical laws, line width tends to decrease with decreasing size and increasing volume density; this implies that the NH_3 samples a denser portion than the OH. However, we cannot unequivocally conclude that this is the case because the NH_3 maps show that considerable macroscopic velocity structure exists within the larger OH telescope beam, and there may be enough beam smearing to produce the observed OH line width. Furthermore, Crutcher et al. (in preparation) are in the process of determining whether the observed line width is wide because of the contribution of the "large" and "medium" sizes to the OH emission. At the time of this review, this observational question has not yet been resolved.

(2) At the high densities in the core, astrochemistry predicts that the OH volume density is roughly independent of the H_2 volume density, and therefore not a good tracer of H_2 (Sec. I.A.2).

The question of just how well OH traces high-density regions is a major one and deserves intense observational and theoretical attention.

2. *The Virial Theorem Applied to B1.* Figure 2 depicts four size ranges of B1: large, medium, core and subcore. We have reasonably complete information on physical conditions for each size range, which allows us to evaluate the virial terms in Eq. (5) and other quantities. Unfortunately, we do not have a complete sample of B_{\parallel} in the four size ranges, and there is always the annoying matter of converting B_{\parallel} to B . We assume $B = 2B_{\parallel}$ (and $B^2 = 4B_{\parallel}^2$) instead of the large-sample correction $B^2 = 3B_{\parallel}^2$). For the medium size and core, the observations provide $B_{\parallel} = -12$ and $-27 \mu\text{G}$, respectively. For the subcore, we assume that B_{\parallel} is the same $-27 \mu\text{G}$ that it is for the core. This may well be incorrect, because B_{\parallel} increases as we go from the medium size to the core, but it serves as a reasonably interesting example.

The external pressure term is not usually included in observational discussions, but it is important for the three smallest size ranges. Let P_0 be the external pressure at the boundary of each size range. At the boundary of the largest size range, P_0 should equal the ambient interstellar pressure, for which we adopt $P_0 = 1.6 \times 10^4 k_B \text{ dyne cm}^{-2}$ (Chapter by McKee et al.); we neglect the contribution from radiation pressure, which would add about

10% (Spitzer 1978). For the smaller size ranges, we set P_0 equal to the total pressure of the gas in the next larger size, calculated from the line width and density. That is, we take

$$P_0 = \rho \sigma^2 = 0.18 \times 10^{10} \rho \Delta v_3^2 \quad (7)$$

which amounts to assuming that the velocity field is “microturbulent.” There is some theoretical justification for this assumption, because in the subcore the damping length of MHD turbulence is about 0.005 pc (McK Eq. 38), which is 20 times smaller than the size of the subcore.

Table III gives numerical values for the virial terms. We emphasize that the accuracies are low. Virial equilibrium is easily achieved for any size by changing the mass by a factor of less than 2, which is within the observational uncertainties. For all size ranges, the virial theorem is satisfied as well by excluding \mathcal{M} as by including it, which is the inevitable consequence of the uncertainties and having all terms in the virial theorem comparable.

Table III also lists $\alpha (\equiv 2T/|W|, \text{McK Eq. (33)}; \alpha = 1$ implies gravitational virial equilibrium in the absence of magnetism and surface terms). α varies from 1.2 to 2.0, which is commensurate with approximate gravitational virial equilibrium. As mentioned in McKee et al.’s chapter, observers often estimate cloud masses by taking $\alpha = 1$ -2. This appears to be a valid procedure. However, α cannot be measured accurately enough to provide independent information on M/M_Φ or P_0/\bar{P} . If we had computed α from McK Eq. (34) and set $b' = b$, we would have obtained $\alpha \sim 1.2$ for all sizes but the medium size; the differences between this and the values in Table III presumably reflect the departure of the real world from the ideal theoretical model. Observational uncertainties render McK Eq. (34) less useful than McK Eq. (33) in practical applications.

We now forge ahead and discuss the stability of the virial equilibrium, temporarily assuming absolute accuracy. The magnetic field is crucial for the stability. Table III lists the cloud mass M in terms of the magnetic critical mass M_Φ (McK Eq. 17b), the Jeans mass M_J (McK Eq. 12), and the critical mass M_{cr} (McK Eq. 22). All sizes have $M/M_\Phi > 1$ and are magnetically supercritical, which means that without gas pressure, the cloud would collapse. The medium size and core have $M/M_J \sim 2.2$, which means that in the absence of the magnetic field, they would also be unstable to collapse. But the *combination* of magnetic and gas pressure prevents collapse: M_{cr} includes both, and these two sizes have $M/M_{cr} \sim 1$, which either removes the instability or makes it much less pronounced.

We emphasize again that the statements in the above paragraph are based on uncertain parameters. If we had used a more conventional definition of cloud radius, or different values for n_{H_2} , we would have reached different conclusions. Nevertheless, we are encouraged by the result $M/M_{cr} \sim 1$ for the core. The core has split into three subcores, and it also contains a protostar or new star. These are *observational* indications that the core of B1 is on the

TABLE III
B1 at Various Size Scales

^a $N(\text{H}_2)$ is defined as the total number of H_2 molecules in the cloud divided by the cloud area.

^b From Goodman et al. (1989), taking R in their Table 2 as the cloud diameter.

^c Twice the measured value, to account for orientation to line of sight.

^d Assumed. For the core, where B probably increases, this value is probably a lower limit.

^e From Eq. (7).

^f M_Φ is the magnetic critical mass from McK Eq. (17b) and McK Eq. (19).

^g M_J is the Jeans mass from McK Eq. (12) for the isothermal case with $c_J = 1.18$.

ⁱ α is the ratio of turbulent plus thermal energy to the gravitational energy (McK Eq. 33).

^j From Bachiller et al. (1990); these parameters apply to a single NH_3 subcore, and differ from the parameters given by those authors, which apply to the whole NH_3 core.

verge of instability. With $M/M_{cr} \sim 1$, we have a *theoretical* indication that it is close to instability. This argues that our numerical estimates in Table III are reasonably accurate.

As explained in McKee et al.'s Chapter, Sec. VI.A, low-mass stars form after magnetically subcritical clouds evolve via ambipolar diffusion until their cores become magnetically supercritical (Mouschovias 1977; Nakano 1979; Shu et al. 1987a). If this scenario were true for the B1 subcore (in which a protostar has recently formed), then the subcore should be magnetically supercritical ($M/M_\phi > 1$) and the surroundings magnetically subcritical ($M/M_\phi < 1$). However, ($M/M_\phi > 1$) for all four size scales in B1. This may be a result of either observational uncertainties or inapplicability of the theory.

C. Statistical Studies of Clouds for which Zeeman Measurements Exist

Myers and Goodman 1988a applied the virial theorem without surface terms systematically to all appropriate regions for which cloud maps *and* Zeeman splitting measurements of field strength existed. Their sample includes 2 atomic clouds, 6 molecular clouds (one of which, Orion, contains measurements in three different density regimes) and 6 H II regions associated with dense gas containing OH masers. They showed that all the regions roughly satisfy the virial theorem (Eq. 5) with approximate equality of $|W|$, $2T$ and \mathcal{M} . They used this conclusion to support the idea that $(B/\Delta v) \propto n_{H_2}^{1/2}$, i.e., that Δv is related to the Alfvén velocity.

Nevertheless, we must be a bit cautious. Virial terms for OH masers are really virial terms for clouds in which the masers are imbedded, having been calculated using measurements of cloud properties obtained from other molecules that highlight the clouds, such as NH_3 . In W3(OH), the OH masers trace the same gas as the NH_3 (Reid et al. 1987), and this conclusion may well apply elsewhere, but we cannot be absolutely certain of this. In addition, all the points in the sample are significantly biased towards having high magnetic fields because observers try to obtain measurements instead of upper limits.

The statistical reliability of the Myers and Goodman (1988a) conclusions is much increased by the large range of n_{H_2} and B over which approximate equilibrium is found. If, however, we consider the 6 dark clouds and 6 maser regions as separate groups, the ranges in n_{H_2} and B are much smaller, the intrinsic scatter in the data becomes more important, and the conclusions less certain. This is particularly the case for the conclusion that $(B/\Delta v) \propto n_{H_2}^{1/2}$: this is not a very good fit for the dark clouds alone, and the masers alone are better fit by a constant value for $(B/\Delta v)$.

Nevertheless, their primary conclusion, that the virial theorem is satisfied with rough equipartition between the kinetic and magnetic terms, is approximately valid for the non-maser clouds, and this statement can also be made for the masers if their conditions are the same as those in the larger clouds in which they are embedded.

D. Statistical Studies of Clouds for which Zeeman Measurements Do Not Exist

Myers and Goodman (1988*b*) have also applied the virial theorem to a large sample of 120 clouds for which observational data exist on size, velocity dispersion, and volume density, but not on magnetic field. They concluded that this sample is consistent with the smaller sample for which Zeeman measurements do exist if there is rough equipartition among $|W|$, $2T$, and \mathcal{M} in Eq. (5). Their conclusions are independent of cloud mass and volume density, because they depend only on the directly observed quantities Δv and cloud radius R . This is fortunate, because the references from which cloud parameters were obtained use methods for deriving cloud mass that, for an individual cloud, can differ by an order of magnitude; this illustrates the difficulty in deriving accurate masses.

Nevertheless, we consider that their conclusions are not much more than a consistency argument. The assumption of equipartition implies that $B \propto \Delta v^2/R$. Their basic result is that $\Delta v^2 \propto R$, which implies that clouds typically have $B \sim 30 \mu\text{G}$, \pm a factor of 3 or so. However, the result $\Delta v^2 \propto R$ is also a restatement of Larson's laws, and given our incomplete understanding of the interstellar medium, we have no special justification for assuming that magnetism is responsible for Larson's laws (except, of course, the results of Myers and Goodman (1988*a*; Sec. IV.C).

Equipartition between $2T$ and \mathcal{M} seems to neatly avoid the serious problem associated with highly supersonic line widths: it makes the line width comparable to the Alfvén velocity (Arons and Max 1975), eliminating the necessity for the observed macroscopic motions to produce strong shocks, which have a very high rate of energy dissipation. Zweibel and Josafatsson (1983) show that Alfvén waves are also subject to dissipation; this dissipation is not excessive and may contribute to the heating of the cloud (McKee et al. Chapter, Sec. V.B). Thus the dissipation problem is ameliorated.

In our opinion, discussions of the magnetic properties of clouds that are based on statistical analyses of the virial theorem alone, without actual data on magnetic field strength, should be interpreted with care.

V. ORIENTATION OF CLOUD FEATURE WITH RESPECT TO THE FIELD

Goodman (1991) has reviewed existing optical polarization maps of background starlight. Such maps cover portions of several molecular cloud complexes, including Taurus, Perseus, Ophiuchus, Orion and L204. The polarization maps typically exhibit a well-defined mean polarization position angle, with fluctuations about the mean which differ in magnitude from region to region. These regions also contain well-defined molecular clouds, many of which are elongated and some of which, such as Orion, are extremely so. Are these features aligned with the magnetic field? Section I.C.1 presented some basic cautions required to establish alignment reliably; here we illustrate

some of those with observational examples, and also summarize the recent literature concerning alignments.

We reiterate two important cautions that we listed in Sec. I.C.1. One, we must distinguish alignment *between cloud features* from that with the *magnetic field*. The evidence to date does not unequivocally show the magnetic field direction to be correlated with the orientations of cloud features. Two, one must take into account the statistics of the projection of three-dimensional angles between features into the two-dimensional plane of the sky. This point is almost always ignored in interpretive discussions of all types of alignment.

A. Basic Cautions: Observational Examples

Polarization maps of individual clouds, presented in isolation and removed from their environments, may be misleading. [Note: Also see Sec. I.C.1] For example, consider the elongated dark clouds B216/217 in Taurus (Fig. 3) and L1755 in Ophiuchus (Fig. 4). Analyzed individually, it would appear that \hat{B}_\perp in the B216/217 cloud is perpendicular to the cloud's long axis, while in L1755 \hat{B}_\perp is parallel to the cloud's long axis. Several discussions in past literature have emphasized such apparent alignments. If, however, we look at these clouds in the context of their respective complex-wide polarization maps (Figs. 3 and 4) we see, in both cases, that the polarization observed fits into a smooth, larger-scale field, and that the cloud orientation could be fortuitous. These figures also illustrate the tendency of optical polarization to probe only the edge, not the center, of a cloud.

In both infrared and optical polarization studies, there is a danger of examining maps at too small a scale. For example, Turnshek et al. (1980), in their study of NGC 1333, found a bimodal distribution in polarization position angle, which is also apparent at $2.2\ \mu\text{m}$ (Tamura et al. 1988). They further deduced that there is a significant spatial arrangement of the two different distributions within their map. However, Goodman et al. (1990) extended the map to include all of the Perseus complex and found that the bimodal distribution persists throughout the entire complex, so that the spatial correlation reported by Turnshek et al. may have been an artifact.

This narrow-view selection effect might also be at work in the analysis of Bok globule 2 discussed below.

B. Relation of Fields Within Clouds to the Ambient Field

The relatively small number of near-infrared polarization maps of dense clouds indicate that the magnetic field within the denser portions of a cloud does not deviate in direction very much from the "ambient" field indicated by optical polarization observations. In Orion (Sec. II.A), the directions are similar. In the densest part of the ρ -Ophiuchus molecular cloud, Wilking et al. (1979) found that the near-infrared polarization is similar in direction and dispersion to the surrounding optical polarization. The same situation exists in Taurus, where Tamura and Sato (1989) (with large-scale, but very sparse coverage) find no significant difference between optical and $2.2\ \mu\text{m}$ position angles.

Figure 3. Optical polarization map of the B216–B217 region (top) of the Taurus Molecular Cloud Complex (bottom). Polarization data is from Moneti et al. (1984), Heyer et al. (1987) and Goodman et al. (1990). Photograph from Palomar Sky Survey. Contours superposed on the lower panel indicate the extent of the dark clouds in the region (from Tamura and Sato 1989).

In three Bok globules, polarization vectors appear to be unaffected by the presence of the globule (Klebe and Jones 1990). In the dark cloud, Heiles Cloud 2, Tamura et al. (1987) possibly find weak evidence in their $2.2\ \mu\text{m}$ polarization maps for compression of field lines, although the mean orientation of the infrared polarization vectors is virtually identical to the well-determined mean optical polarization direction in the region.

In contrast, the interior of Bok globule 2 in the Southern Coalsack exhibits a definite change in the infrared polarization position angle (Jones et al. 1984). The total number of cases where comparisons can be made is small, but most do not show an easily discernable difference between the optical and infrared results.

C. Relation of Cloud Structure to the Ambient Magnetic Field

At the several-pc scale traced by extinction, ^{13}CO , and OH, many dark clouds are highly elongated. Theoretical models predict an orientation of the long axis either perpendicular or parallel to the field lines as indicated by optical polarization observations, depending on whether the cloud has collapsed or expanded along the field lines. However, in a comprehensive study of many clouds, Goodman et al. (1990) show that neither orientation is generally observed. Instead, it appears that the magnetic field in a complex is ordered on the several tens of pc scale, and that individual dark clouds within the complex are not oriented in a special way with respect to the magnetic field, although they are perhaps aligned with each other.

On a smaller ($\lesssim 1$ pc) scale, observations of bipolar outflows have been interpreted as being aligned with the local large-scale magnetic field. However, such alignments are not always observed and may even be rare. Cohen et al. (1984) reported that half of a sample of 10 outflows (located in several different clouds) are oriented within $\pm 20^\circ$ of the local field direction, which in turn is determined from previously existing polarization measurements of background stars relatively near the outflow in question. In B335 and L723, Vrba et al. (1986*b*) constructed optical polarization maps on an appropriate size scale and found good field/outflow alignment. Then, however, Langer et al. (1986) detected a new component to the CO outflow in B335, and Hodapp (1987) constructed new near-infrared polarization maps of B335, and the situation became much more complicated. It now appears that there is more than one preferred direction in the polarization map and more than one outflow, and it is not completely clear how these features are related. Several other sources do not show alignments. Wooten and Loren (1987) have written a paper summarily entitled "L1689N: Misalignment Between a Bipolar Outflow and a Magnetic Field." In a recent study of outflows by Hodapp (1990), in which polarization was explicitly mapped near outflows, one of the three cases shows an outflow roughly parallel to \hat{B}_\perp , one is roughly perpendicular, and the third is neither parallel nor perpendicular.

On the even smaller scale of optical jets, Heyer et al. (1987) searched for alignments between the jets and the local field at an appropriately small

Figure 4. Optical polarization map of the L1755 region (top) of the Ophiuchus Molecular Cloud Complex (bottom). Polarization data is from Vrba et al. (1976) and Goodman et al. (1990). Contours superposed on both panels indicate the extent of dark clouds in the region, as traced by ^{13}CO emission (Loren 1989b).

scale by constructing CCD polarization maps of background starlight. These give a high-resolution view of the local, rather than the global \hat{B}_\perp . In the three cases they studied (SVS 13/HH 7–11, HH 33/HH 40, and HH 12), two jets were well aligned ($\lesssim 15^\circ$) with the local magnetic field, but the third (HH 12) was oriented 60° from the field direction and is located only $2'$ to the north of HH 7–11. The authors conclude that the relation between a jet axis and the magnetic field direction may depend on the properties of the dense gas surrounding the source powering the jet, and they favor ionization as the important property. Numerous observations indicate the existence of large density gradients within clouds, and we believe that density gradients should also be included in the list of possibilities.

D. Relation of Cloud Structures with Each Other

There is no good evidence for the global alignment of CO outflows in a cloud complex. For example, in L1641 the five outflows for which a position angle can be defined to better than $\pm 40^\circ$ span a 135° range in orientation (Goodman and Myers 1991)—despite the seemingly contradictory fact that alignment is observed among the much smaller-scale (~ 0.05 pc) optical jets associated with young stars in the cloud.

These smaller jets are identified as fast-moving jets from optical observations of regions around young stars associated with HH objects. Strom et al. (1986) and Reipurth (1989*a, b*) have found more than ten such jets within L1641. Eleven of the 13 jets have position angles between 130° and 170° , with the other two being very far outside this range. This is good evidence for alignment of the 11 jets with each other at a position angle near 150° . However, \hat{B}_\perp as derived from optical polarization has position angle 110° (Vrba et al. 1988*a*), 40° away from the 150° which seems to characterize most of the flows. Thus the case for *magnetic* alignment has not been made. In contrast, density gradients present an attractive hypothesis for the alignment, because of the filamentary nature of this cloud (see Bally et al. 1987).

In Taurus, we used the results of Mundt et al. (1987) to find that the position angles of the 7 known optical jets have standard deviation 119° and are therefore uncorrelated on the complex-wide scale. These authors also emphasize that the jets are not linear, and conclude that asymmetries in optical jets are probably caused by asymmetric density distributions in the surrounding molecular cloud, and are quite possibly important for L1641.

E. Relation of Cloud Structure to Rotation

There appears to be no correlation between structure and rotation for cloud cores, which are elongated (Myers et al. 1991*a*) and often exhibit velocity gradients which can be interpreted as solid-body rotation (Fuller 1989; Goodman et al. 1991*b*). Rotation, as deduced from fits to observed velocity gradients, is not found to be energetically significant in the support of the cores (Goodman et al. 1991*b*). In a preliminary analysis of NH_3 data (Benson and Myers 1989) on cores in Taurus, no obvious structural correlations are found (Goodman

and Myers 1991). In a set of CS $J = 2 - 1$ observations of seven dense cores, Heyer et al. (1986) also find that the distribution of dense gas is often elongated, but that it shows no preferred orientation with respect to the field, to the rotational axis of the core, or to the outflow direction.

Molecular clouds seem to exhibit little rotation. This is in accord with theoretical prediction. For clouds that are dense relative to their surroundings, McK Eq. (45) applies; it predicts that the magnetic braking time is fairly short.

VI. PERSPECTIVE AND COMMENTARY

A. Techniques

The line-of-sight component of the magnetic field B_{\parallel} can be measured using Zeeman splitting (Sec. I.A). With molecules, there is often a danger that Zeeman splitting is a result of linear birefringence, and this possibility should be checked, particularly for H₂O masers. OH is the most widely used probe of molecular clouds because its Zeeman splitting is easiest to detect. However, the degree to which OH traces really *dense* regions is unclear (Sec. I.A.2). This is a major and fundamental question whose answer requires extensive observational and theoretical effort. Magnetic field strengths derived from OH masers in regions containing large velocity gradients are biased towards large values (Sec. I.B.4a). The few other suitable candidates for Zeeman observations are listed in Table I.

The direction of \hat{B}_{\perp} can be obtained from linear polarization of either attenuated background radiation or grain thermal emission, which is always either parallel or perpendicular to \hat{B}_{\perp} (Sec. I.C). We expect linear polarization of spectral lines to be weak in most cases, with ambiguous interpretation even if it is detected (Sec. I.B). The structure of \mathbf{B} within clouds, as revealed by the structure of \hat{B}_{\perp} , seems to be the best way to determine the importance of \mathbf{B} on cloud dynamics and evolution (see below). This cannot be obtained only from polarization of optical starlight, which can only probe the outer, less-dense portions of clouds. Infrared measurements, both of attenuated starlight and grain thermal emission, are required to probe the dense portions of clouds. Good angular sampling and resolution are required for reliable interpretation.

The goal of deriving $\langle \mathbf{B} \rangle$ (the uniform component) within an object, both in magnitude and direction, can be realized by obtaining a large sample of measurements of Zeeman splitting and linear polarization and, in addition, by applying a model of the field fluctuations (Sec. III). Statistical information on the fluctuations can also be obtained.

There are several possible indirect probes of the magnetic field (Sec. I.D). Shock-produced H₂O masers are predicted to be most luminous when the shock velocity is perpendicular to \hat{B} , and this should make the masers lie in an ellipse on the sky as is observed in Orion (Sec. II.A.3). Faraday rotation in small star-forming regions may be observable. And ambipolar diffusion, which affects ions differently from neutrals, may be directly observable.

In our opinion, the most rewarding observational paths will involve Zeeman splitting and linear polarization caused by aligned grains. For one desiring reliably useful results, such as a Ph. D. student, these are the recommended paths. For one who can afford to gamble on wasted effort, such as an independently wealthy middle-aged full professor, we suggest the indirect probes mentioned in the above paragraph.

B. Results and Interpretation

Combining all information on B_{\parallel} and \hat{B}_{\perp} can provide a reasonably complete picture of \mathbf{B} within a region. In this way, we described a crude picture of \mathbf{B} in Orion (Sec. II) and a surprisingly complete picture of L204 derived by Myers and Goodman (1991) (Sec. III). This shows the value of multi-pronged attacks: observers who employ different specialties should cooperate in selecting objects for study.

When results for all the regions where magnetic fields strengths have been measured are considered, over the sampled density range from 10 to 10^{10} cm^{-3} , B runs from just a few μG up to several tens of mG. The existing data are well fit by the relation $B = An^{\kappa}$, where $\kappa = 0.5$ and $A \sim 1.5$, with a fair amount of scatter about this trend. (See Troland and Heiles [1986], Fiebig and Güsten [1989], and Myers and Goodman [1988a] for summary plots of B vs n_{H} .) (Here B is expressed in μG , n in cm^{-3} , and velocity in km s^{-1} .) With $\kappa = 0.5$, A can be thought of as giving a “typical” Alfvén speed; the “fit” to the existing data gives 2.1 km s^{-1} , with a scatter corresponding to about a factor of 3.

Studies using the virial theorem are interesting, but the usefulness is limited because of the inherent inaccuracies. Furthermore, it must be applied correctly. If cloud B1 is representative (Sec. IV.B), the magnetic term \mathcal{M} is important, but less so than the external pressure term $3P_0V$ (Eq. 5). However, the external pressure term is rarely included in observational analyses. The inherent inaccuracies in the virial terms suggest that the direct measurement of magnetic topology using the direction of \hat{B}_{\perp} , together with theoretical models, may provide a more useful indication of the influence of magnetic forces on cloud structure and dynamics.

Past published papers aside, the jury is still out concerning the alignments of clouds and their internal structures with either \hat{B} or with each other (Sec. V). Conclusions based on qualitative appearance are not sufficient. In many individual cases, including Orion (Sec. I.B), alignments are observed. However, a definitive statistical study is required to establish the generality and validity of the alignments. Reliable conclusions require an enormous amount of work (Sec. I.C.1) in obtaining sufficient statistical data, and this has been done only recently for a small number of regions.

Acknowledgment. We acknowledge, with extreme pleasure, the dedicated efforts of the many observers and theorists who have worked so hard to bring the state of knowledge to its present level. If we had written this Chapter

ten years ago, it would have been so short as to *easily* fit into the page limits prescribed for this book. As it is, we have unavoidably exceeded those limits by approximately a factor of two. CH acknowledges with pleasure the hospitality of the Joint Institute for Laboratory Astrophysics, which provided the ideal environment for writing his portion of this Chapter. We are grateful to R. Bachiller, V. Burdyuzha, R. Crutcher, R. Güsten, R. Hildebrand, T. Jones, K. Menten, M. Reid and T. Troland for providing unpublished material; and to J. Bally, G. Fuller, M. Goss, R. Hildebrand, T. Jones, N. Ladd, N. Kylafis, P. Myers, B. Turner and P. van der Werf for instructive discussions and comments. We especially thank B. Draine, S. Spangler and W. Watson for careful reading of an early version of the manuscript and for a number of detailed and constructively critical comments. CH was supported in part by an NSF grant. AG is supported in part by a President's Fellowship at the University of California, Berkeley. CFM's research is supported by an NSF grant; his research on star formation is supported in part by a NASA grant to the Center for Star Formation Studies. EAZ was supported in part by an NSF grant, and by a grant of the Institute for Theoretical Physics.

MAGNETIC FIELDS IN STAR-FORMING REGIONS: THEORY

CHRISTOPHER F. McKEE

University of California, Berkeley

ELLEN G. ZWEIBEL

University of Colorado

and

ALYSSA A. GOODMAN, CARL HEILES

University of California, Berkeley

Magnetic fields are essential in supporting molecular clouds and the clumps within them from gravitational collapse. The virial theorem, including the effects of fluctuating magnetic fields and a turbulent ambient medium, can be used to show that observations imply that the magnetic flux threading a cloud and the internal motions within it are of comparable importance in cloud support. For clouds and clumps within clouds in which the magnetic energy exceeds the gravitational energy, star formation occurs on the time scale for the field to leak out of the cloud by ambipolar diffusion; the field is effective in removing the angular momentum from the cloud in this case. Reduction of the magnetic flux to the small values found in stars occurs only after the collapsing cloud reaches very high densities. Massive stars may well form in regions in which the magnetic energy is less than the gravitational energy, and this process is less well understood. It appears that molecular clouds form as a result of gravitational instabilities in the interstellar medium, but a full understanding of the role of the magnetic field in the formation and subsequent evolution of molecular clouds remains a challenge for the future.

I. INTRODUCTION

The theory of magnetic fields in star formation has a long and distinguished history, with major contributions by Mestel, Spitzer, Mouschovias, Elmegreen, Nakano and many others. Attention was drawn to magnetic fields early on by a fundamental question: how do stars form with so little magnetic flux? The observation of magnetic fields in star-forming regions, on the other hand, has a short, but also distinguished history which is reviewed in a companion Chapter by Heiles et al. Indeed, the major development in our understanding of magnetic fields in star-forming regions since *Protostars and Planets II* (Black and Matthews 1985) was published has come from

observations which show that these fields are about as strong as theoretically expected.

This review is an attempt to provide a comprehensive view of our understanding (and our ignorance) of the role of magnetic fields in the structure and evolution of the molecular clouds and cloud cores out of which stars are born. We do not address the effects of magnetic fields in the formation and evolution of protostars and protostellar disks; this topic is covered in the Chapter by Königl and Ruden. We have drawn on several excellent previous reviews by Nakano (1984), Mestel (1985), Mouschovias (1987*a, b*), and Shu et al. (1987*b*). Literature up to mid 1990 is thoroughly reviewed, whereas subsequent literature is unevenly reviewed. We begin with a discussion of the virial theorem, which provides a framework in which to treat the competing effects of magnetic fields and gravity on the structure of molecular clouds (Sec. II). The utility of the virial theorem in estimating the masses of molecular clouds is assessed. Models of molecular clouds, both static and dynamic (i.e., explicitly allowing for turbulence) are reviewed in Sec. III. The rotation of molecular clouds and the effectiveness in magnetic fields in braking the rotation are discussed in Sec. IV. To this point, the discussion has assumed that the flux is frozen to the matter. In Sec. V, we consider violation of this assumption by ambipolar diffusion, a process of fundamental importance in star formation, and by magnetic reconnection, which is less well understood. The effects of ambipolar diffusion and flux loss on star formation (subcritical vs supercritical star formation, contraction of magnetized clouds, and the rate of star formation) are described in Sec. VI. A somewhat speculative discussion of the magnetic evolution of molecular clouds is given in Sec. VII. Our conclusions are briefly summarized in Sec. VIII.

II. MAGNETIC FIELDS VERSUS GRAVITY

A. The Virial Theorem

The effect of magnetic fields on the structure and evolution of molecular clouds can be estimated by the virial theorem (Chandrasekhar and Fermi 1953; Mestel and Spitzer 1956; Strittmatter 1966), which can be written as

$$\frac{1}{2}\ddot{I} = 2(\mathcal{T} - \mathcal{T}_0) + \mathcal{M} + \mathcal{W}. \quad (1)$$

The left-hand side of this equation expresses the effects of changes in the shape or volume of the cloud through variations in $I = \int \rho r^2 dV$, which is like the moment of inertia. The kinetic energy of the cloud is

$$\mathcal{T} = \int_{V_{cl}} \left(\frac{3}{2} P_{th} + \frac{1}{2} \rho v^2 \right) dV = \frac{3}{2} \bar{P} V_{cl} \quad (2)$$

where v is the fluid velocity relative to the center of mass of the cloud, \bar{P} is the mean total pressure in the cloud, thermal plus turbulent, and V_{cl} is

the volume of the cloud. We are defining the turbulent pressure broadly to include all turbulent motions, such as large amplitude Alfvén waves, as well as the motions associated with large-scale flows, such as rotation, expansion, contraction, or changes in shape. We shall focus on nonrotating clouds in this section for simplicity; in any case, rotation is observed to be not very important in molecular clouds (Goldsmith and Arquilla 1985; see Sec. IV.A). The term in the virial theorem that represents the surface pressure may be expressed as

$$\mathcal{T}_0 = \int_{S_{cl}} P_{th} \mathbf{r} \cdot d\mathbf{S} \simeq \frac{3}{2} P_0 V_{cl} \quad (3)$$

where P_0 is the total pressure in the ambient medium. The demonstration that the integral of the thermal pressure over the cloud surface is proportional to the total pressure in the ambient medium P_0 , including the turbulent pressure, is given by McKee and Zweibel (1992). They show that for purely hydrodynamic turbulence ($B = 0$), the surface term \mathcal{T}_0 is actually somewhat less than $(3/2)P_0 V_{cl}$ because the turbulence in the intercloud medium is anisotropic near the cloud; we shall ignore this complication here. The premise of the demonstration is that the intercloud medium has a much lower density than the cloud, which should be valid for star-forming molecular clouds in the interstellar medium.

The magnetic term \mathcal{M} is the net magnetic energy:

$$\mathcal{M} = \frac{1}{8\pi} \int_{V_a} B^2 dV + \frac{1}{4\pi} \int_{S_a} (\mathbf{r} \cdot \mathbf{B}) \mathbf{B} \cdot d\mathbf{S} - \frac{1}{8\pi} \int_{S_a} B^2 \mathbf{r} \cdot d\mathbf{S} \quad (4)$$

where V_a is the volume of integration, and S_a is the bounding surface. This has a simple form if the intercloud medium is of low density and in a steady state: V_a then can be taken to be large enough that the field has dropped to its asymptotic value in the ambient medium B_0 (which we shall term the ambient field), and \mathcal{M} becomes (McKee and Zweibel 1992)

$$\mathcal{M} = \frac{1}{8\pi} \int_{V_a} (B^2 - B_0^2) dV. \quad (5)$$

Fluctuations $\delta\mathbf{B}$ of the magnetic field will in general accompany a turbulent velocity field. The contribution of these fluctuations to \mathcal{M} can be shown to be of the same form as Eq. (4), with B^2 and B_0^2 replaced by time averages of δB^2 and δB_0^2 . Hence, the magnetic term is just the total magnetic energy associated with the cloud, including the fluctuating field; because the presence of a field inside the cloud distorts the field outside, the energy is not confined to the volume of the cloud.

Finally, if the gravitational field is dominated by the self-gravity of the cloud, then the gravitational term \mathcal{W} is simply the binding energy of the cloud,

$$\mathcal{W} = -\frac{3}{5} a \left(\frac{GM^2}{R} \right) \quad (6)$$

where the coefficient a allows for deviations from the simplest case of a uniform, spherical cloud. For example, a spherical cloud with a density distribution $\rho(r) \propto r^{-k_\rho}$ has $a = (1 - k_\rho/3)/(1 - 2k_\rho/5)$; a thin, uniform disk has $a = \pi/2$. The case of arbitrary oblate and prolate clouds has been considered by Bertoldi and McKee (1992).

We shall assume that the cloud is approximately in virial equilibrium, so that the left-hand side of Eq. (1) is negligible. To see when this is valid, consider a uniform sphere of mass M and radius R , which has $I = \frac{2}{5}MR^2$. Define the characteristic time scale for I to vary, t_I , by the relation $|d^2I/dt^2| \equiv I/t_I^2$. We shall compare t_I to the gravitational free-fall time for a sphere of mean density $\bar{\rho}$,

$$t_{ff} = \left(\frac{3\pi}{32G\bar{\rho}} \right)^{1/2} = \frac{4.35 \times 10^7}{\bar{n}_H^{1/2}} \text{yr} \quad (7)$$

where \bar{n}_H is the mean density of hydrogen nuclei in the cloud; if the gas is entirely molecular, then $n_H = 2n(\text{H}_2)$. The ratio of the of the left-hand side of Eq. (1) to the gravitational energy is then

$$\frac{|\frac{1}{2}\ddot{I}|}{|\mathcal{W}|} \simeq 0.5 \left(\frac{t_{ff}}{t_I} \right)^2. \quad (8)$$

If the volume or shape of a self-gravitating cloud is changing on a time scale t_I exceeding about two free-fall times, the cloud may be considered to be in approximate gravitational virial equilibrium. Clouds that are confined by the pressure of the surrounding medium rather than by their own self-gravity can also be in virial equilibrium; in this case, it is necessary for t_I to exceed the sound crossing time of the cloud. Even if the cloud is not in equilibrium, so that the variation in the moment of inertia is important, the average value of \ddot{I} for an ensemble of clouds will tend to vanish: the equilibrium virial theorem will be more accurate for a sample of observed clouds than for an individual one.

The virial theorem then simplifies to

$$3(\bar{P} - P_0)V_{cl} - \frac{3}{5}a \frac{GM^2}{R} \left(1 - \frac{\mathcal{M}}{|\mathcal{W}|} \right) = 0 \quad (9)$$

for equilibrium clouds. The rationale for taking the ratio of the magnetic and gravitational terms will become apparent in Sec. II.C below.

B. Pressure-Supported Clouds ($B = 0$)

In order to understand the effects of magnetic fields on molecular clouds, it is first necessary to consider the field-free case. In this case, the cloud is spherical, and the virial equilibrium Eq. (9) with $\mathcal{M} = 0$ implies

$$\bar{P} - P_0 = \left(\frac{3\pi a}{20} \right) G \Sigma^2 \quad (10)$$

where $\Sigma \equiv M/\pi R^2$ is the mean surface density of the cloud. This result is relatively independent of the shape of the cloud, so it provides a useful estimate of the gas pressure even when a field is present. For example, for a planar cloud, integration of the equation of hydrostatic equilibrium shows that the pressure in the midplane is $(\pi/2)G\Sigma^2$, so that, independent of the shape of the cloud, the pressure due to self-gravity is of order $G\Sigma^2$. Numerically, this can be expressed in terms of the mean column of hydrogen, $N_H \equiv 10^{21} N_{21} \text{ cm}^{-2}$, or the mean extinction, $\bar{A}_V = 0.5 N_{21} \text{ mag}$. For example, for a spherical cloud with a r^{-1} density profile, we have

$$\frac{\bar{P} - P_0}{k_B} = 1340 N_{21}^2 \text{ cm}^{-3} \text{ K} = 5540 \bar{A}_V^2 \text{ cm}^{-3} \text{ K} \quad (11)$$

where k_B is Boltzmann's constant. Because the interstellar kinetic pressure is about $(1 \text{ to } 2) \times 10^4 \text{ cm}^{-3} \text{ K}$ (see, e.g., Cox 1988), this means that any cloud with a mean extinction exceeding 2 mag is strongly self-gravitating ($\bar{P} \gtrsim 2P_0$). Equation (11) is satisfied by the cloud B1 discussed in the Chapter by Heiles et al. to within a factor 2 for the four different size scales considered there, consistent with the observation that the magnetic field is not dominant in that cloud.

Calculations of the structure of nonmagnetic, isothermal clouds were carried out a number of years ago by Bonnor (1956) and Ebert (1955). For a given external pressure, equilibrium is possible only up to a maximum mass, sometimes termed the critical mass, M_{cr} . The critical mass also represents the threshold for gravitational instability. Below the critical mass, there are additional equilibria with higher central densities; indeed, if the mass equals that of a critical isothermal sphere with $\rho \propto r^{-2}$, there are an infinite number of equilibria. Only the one with the lowest central concentration is stable (see, e.g., Stahler 1983). Bonnor and Ebert showed that the maximum stable mass for a given external pressure is

$$M_J = 1.18 \frac{\sigma^4}{(G^3 P_0)^{1/2}} \quad (12)$$

where $\sigma^2 = \bar{P}/\bar{\rho}$ is the one-dimensional velocity dispersion; for purely thermal motions, $\sigma^2 = k_B T/\mu$, where μ is the mean mass per particle. This mass is often called the Bonnor-Ebert mass. However, we prefer to term it the Jeans mass, because it corresponds to the widespread intuitive concept of the Jeans mass as the maximum mass that is stable against gravitational collapse. The surface density corresponding to the Jeans mass depends only on the pressure,

$$\Sigma_J = \frac{M_J}{\pi R^2} = 1.60 \left(\frac{P_0}{G} \right)^{1/2}. \quad (13)$$

Physically, the Jeans mass corresponds to the mass such that the gravitational binding energy is comparable to the internal energy, and as a result

it can be inferred from the virial theorem with reasonable accuracy (McCrea 1957; Spitzer 1968a). Solving the virial equation for the ambient pressure yields

$$P_0 = \frac{3M\sigma^2}{4\pi R^3} - \frac{3aGM^2}{20\pi R^4}. \quad (14)$$

As R is varied, P_0 reaches a maximum value for a given mass. Correspondingly, this maximum value of P_0 determines the maximum mass which can be supported by gas pressure, M_J . This treatment is approximate because the parameter a , which is a weak function of R , is held fixed during the variation; the effective value of a in Eq. (14) corresponding to the Jeans mass is 1.31. Molecular clouds typically have $M \sim (1-2)M_J$ (see Sec. II.E below), where the velocity dispersion σ is due primarily to turbulence. Low-mass clumps within a cloud often have smaller line widths, so that thermal broadening is more important (Myers 1985). In the limit in which the clump is entirely supported by thermal pressure, we have $\sigma = 0.188(T/10 \text{ K})^{1/2} \text{ km s}^{-1}$, and the Jeans mass is

$$M_J = 11.5 \frac{(T/10 \text{ K})^2}{(P_{0,\text{clump}}/10^3 \text{ cm}^{-3} \text{ K})^{1/2}} M_\odot = 5.7 \frac{(T/10 \text{ K})^2}{\bar{A}_V} M_\odot. \quad (15)$$

Here $P_{0,\text{clump}}$ is the total gas pressure at the surface of the clump; the clump itself has been assumed to be supported entirely by thermal pressure. We have assumed that $P_{0,\text{clump}}$ is of order the mean pressure in the cloud as a whole so that it can be estimated in terms of \bar{A}_V , the mean extinction of the entire cloud, from Eq. (11); we have also assumed that it is large compared to P_0 , the pressure at the surface of the entire cloud. Equation (15) shows that the scale of a solar mass is naturally selected in observed molecular clouds, which have $\bar{A}_V \sim 3-8$. Low-mass stars ($M \lesssim \frac{1}{2}M_\odot$) that form in self-gravitating molecular clouds must do so either in regions of very high extinction ($\bar{A}_V \gtrsim 10$) or as fragments of larger clumps.

C. Effects of a Steady, Poloidal Magnetic Field

It was recognized early on that the magnetic and gravitational terms in the virial theorem scale in the same way with R : for a poloidal field (one with no azimuthal component) that is time independent, the magnetic energy scales as $\mathcal{M} \propto B^2 R^3 \propto \Phi^2/R$, where Φ is the magnetic flux threading the cloud, whereas the gravitational energy scales as $W \propto M^2/R$. This argument is quite crude because, as we have seen above, the magnetic energy actually scales as $(B^2 - B_0^2)R^3$, and the difference $B - B_0$ also depends on the size of the cloud. Nonetheless, this argument reveals a basic result that is borne out by more complete calculation; if the mass-to-flux ratio exceeds a certain value (magnetically supercritical clouds), the magnetic field cannot prevent gravitational collapse; if it is less than this value (magnetically subcritical clouds), the magnetic energy is large enough that collapse is impossible, so long as flux freezing holds.

First consider the case in which the gas pressure vanishes ($M_J = 0$); the gas then settles into a thin disk normal to the field (Parker 1974; Mestel and Ray 1985; Barker and Mestel 1990). Assume that the distribution of the mass per flux is specified—e.g., that corresponding to a uniform field threading a spheroidal cloud. If the ambient field B_0 also vanishes, then there is a unique equilibrium mass for a given flux. On the other hand, if the field in the cloud is connected to an ambient field, then there is a sequence of equilibria of increasing mass for a given flux (magnetically subcritical clouds) up to the magnetic critical mass M_Φ , where the magnetic and gravitational energies are equal. To determine M_Φ , we define $\bar{B} \equiv \Phi/(\pi R^2)$ to be the mean field threading the cloud, and we define the parameter b , which is of order unity, to be proportional to the net magnetic energy of the critical cloud (cf. Nakano 1984):

$$\mathcal{M}_{\text{cr}} \equiv \frac{b}{3} \bar{B}^2 R^3 = \left(\frac{b}{3\pi^2} \right) \frac{\Phi^2}{R}. \quad (16)$$

Note that the dependence on the ambient field has been absorbed into b . In general, the cloud will be flattened along the field, and in this case R is the semimajor axis. For $B_0 = 0$ (completely closed field topology), Strittmatter (1966) found that $b = 3/4$ for a sphere and $b = \pi^{-1}$ for a thin disk; for a completely open field topology, the numerical calculations cited below give $b \simeq 0.3$ for clouds on the verge of gravitational collapse. Then the magnetic critical mass M_Φ is determined by the condition $|\mathcal{W}_{\text{cr}}| = \mathcal{M}_{\text{cr}}$:

$$\frac{3}{5} a \frac{GM_\Phi^2}{R} \equiv \frac{b}{3\pi^2} \left(\frac{\Phi^2}{R} \right) \quad (17a)$$

so that

$$M_\Phi^2 = \left(\frac{5b}{9\pi^2 a} \right) \frac{\Phi^2}{G} \equiv c_\Phi^2 \frac{\Phi^2}{G}. \quad (17b)$$

For axisymmetric modes, M_Φ is also the maximum stable mass (Tomisaka et al. 1988b). It remains to be demonstrated that this is also true for non-axisymmetric modes.

Equation (16) for the magnetic energy can be extended to subcritical masses ($M < M_\Phi$) by noting that \mathcal{M} remains equal to $|\mathcal{W}|$ in this case because there is no thermal or turbulent energy ($M_J = 0$). The condition $\mathcal{M} = |\mathcal{W}|$ implies

$$\mathcal{M} = \frac{b}{3} \bar{B}^2 R^3 \left(\frac{M}{M_\Phi} \right)^2 \quad (M_J = 0). \quad (18)$$

The magnetic energy in the subcritical case is less than that in the critical case by a factor $(M/M_\Phi)^2$ because the field is less distorted.

Next consider the more general case in which thermal gas pressure (turbulent pressure involves time-dependent fields and is discussed in Sec. II.D

below) also contributes to the support of the cloud ($M_J > 0$). The critical mass M_{cr} , which is the maximum equilibrium mass, now exceeds M_Φ because the gas pressure adds to the support against gravitational collapse. For clouds which are strongly self-gravitating (i.e., close to the critical mass), the magnetic energy is proportional to M_Φ^2 [Eqs. (16) and (17b)] and the gravitational energy is proportional to $M^2 \simeq M_{\text{cr}}^2$; as a result, the ratio of magnetic to gravitational energies is

$$\frac{\mathcal{M}}{|\mathcal{W}|} \simeq \left(\frac{M_\Phi}{M_{\text{cr}}} \right)^2. \quad (19)$$

This same relation should continue to hold for subcritical clouds. Consider a cold cloud with mass $M = 0.1M_{\text{cr}}$, for example; because it is cold, $M_\Phi = M_{\text{cr}}$. The energy ratio is unity in this case. Now heat the cloud, while at the same time increasing its mass so that it remains at $0.1M_{\text{cr}}$. Under these conditions, the radius of the cloud will not change significantly, and its magnetic energy will remain about constant [$\sim G(0.1M_\Phi)^2/R$]. On the other hand, the gravitational energy will increase as $G(0.1M)^2/R = G(0.1M_{\text{cr}})^2/R$, and Eq. (19) remains valid. As a consequence, the magnetic energy may be expressed in general as

$$\mathcal{M} \simeq \frac{b}{3} \bar{B}^2 R^3 \left(\frac{M}{M_{\text{cr}}} \right)^2. \quad (20)$$

The ratio of the *net* magnetic energy \mathcal{M} to the magnetic energy in the cloud is then

$$\frac{\mathcal{M}}{(B^2/8\pi)V_{\text{cl}}} \simeq 2b \left(\frac{M}{M_{\text{cr}}} \right)^2. \quad (21)$$

This ratio becomes small for very subcritical clouds because the field becomes almost uniform, making the net magnetic energy small. The accuracy of Eqs. (19)–(21) remains to be checked for such clouds.

With the aid of the virial theorem, it is straightforward to estimate the maximum mass M_{cr} for a magnetized cloud using a procedure similar to that used for the nonmagnetic cloud above (Mouschovias and Spitzer 1976; cf. Nakano 1984):

$$M_{\text{cr}} = c_J M_J \left[1 - \left(\frac{M_\Phi}{M_{\text{cr}}} \right)^2 \right]^{-3/2} \quad (22)$$

where $c_J = (3.15/1.40a^3)^{1/2}$ is a constant to be determined; it allows for the value of a to differ from that appropriate for the case of no magnetic field. The results of Mouschovias and Spitzer (1976) correspond to $c_J = 1.16$ and $c_\Phi = 0.126$. The more extensive numerical calculations of Tomisaka et al. (1988b) give similar results, $c_J = 1.18$ and

$$c_\Phi \equiv \frac{M_\Phi}{\Phi/G^{1/2}} = 0.12. \quad (23)$$

We shall adopt the latter values for numerical evaluation; they correspond to $a = 1.17$ and $b = 0.30$. Tomisaka et al. (1988*b*) show that there is one stable equilibrium for $M < M_\Phi$; two equilibria, of which only the less dense one is stable, for $M_\Phi < M < M_{\text{cr}}$; and no equilibria for $M_{\text{cr}} < M$.

This numerical value for M_Φ , the maximum equilibrium mass in the absence of gas pressure, is based on a particular distribution of flux within the cloud. It is convenient to define the mass to flux distribution in terms of a "parent cloud" in which the field and density are both uniform, as they would be in the absence of gravity. The value of c_Φ given above corresponds to a spheroidal cloud; the ratio of the major and minor axes is arbitrary. Tomisaka et al. (1988*b*) have shown that the stability of clouds with axisymmetric flux distributions is governed primarily by the flux to mass ratio on the axis of the cloud, $d\Phi/dM$ evaluated at $r = 0$. Eq. (22) can be generalized to other flux distributions by the replacement

$$\frac{M_\Phi}{M_{\text{cr}}} \rightarrow \frac{0.17}{G^{1/2}} \left(\frac{d\Phi}{dM} \right)_{r=0}. \quad (24)$$

For the particular case of a spheroidal parent cloud, a more accurate expression is obtained by replacing 0.17 by $0.18 = (3/2)c_\Phi$, as the column density along the axis of a spheroid exceeds the mean value of the column density by a factor $3/2$. The value of the central column density of a critical cloud is $0.17\bar{B}/G^{1/2}$, which is quite close to the maximum stable column density of a slab of gas with a uniform field perpendicular to the slab, $B/(2\pi G^{1/2}) \simeq 0.16B/G^{1/2}$ (Nakano 1984).

The numerical value of the field in the cloud can be related to its column density by noting that $M/M_\Phi \propto \Sigma/\bar{B} \propto N_H/\bar{B}$, so that

$$\bar{B} = 5.05 \left(\frac{N_{21}}{M/M_\Phi} \right) \mu\text{G} = 10.1 \left(\frac{\bar{A}_V}{M/M_\Phi} \right) \mu\text{G}. \quad (25)$$

For example, a cloud with $\bar{A}_V \simeq 6$ and $M \simeq 2M_\Phi$, which we shall see is typical (Sec. II.E), has a mean field of $30 \mu\text{G}$. To evaluate M_Φ numerically, it is convenient to define the characteristic mass M_B , which is independent of the size of the cloud, by the relation (Mouschovias and Spitzer 1976):

$$\frac{M_B}{M} \equiv \left(\frac{M_\Phi}{M} \right)^3. \quad (26)$$

The ratio M_B/M determines whether a cloud is magnetically supercritical, just as does M_Φ/M . For a spheroidal cloud of volume $4\pi R^2 Z/3$, we have

$$M_B = 512 \left(\frac{R}{Z} \right)^2 \frac{\bar{B}_{1.5}^3}{(\bar{n}_3)^2} M_\odot \quad (27)$$

which is independent of the cloud size, as stated above; here $B_{1.5}$ is the field in units of $10^{1.5} \mu\text{G}$ and $\bar{n}_3 \equiv (\bar{n}_H/10^3 \text{ cm}^{-3})$ is the density of hydrogen

nuclei in units of 10^3 hydrogen nuclei cm^{-3} . Thus, for example, stellar mass clumps of density 10^3 cm^{-3} in a giant molecular cloud (GMC) with a mean field of $30 \mu\text{G}$ are very magnetically subcritical. Note that M_B , like M_Φ , remains constant if the mass and flux of the cloud are constant. Spherical atomic clouds in the diffuse interstellar medium (ISM) have $B \sim 3 \mu\text{G}$ and $\bar{n}_H \sim 30 \text{ cm}^{-3}$, so that $M_B \sim 500 M_\odot$, independent of size; if such clouds were subsequently incorporated as clumps into a molecular cloud, they would all retain the same value of M_B . The observed values of M_B for clumps in GMCs are uncertain, but appear to be somewhat smaller than this (Bertoldi and McKee 1992).

An approximate solution of Eq. (22) which is accurate to within 5% for $M_{\text{cr}} < 8M_\Phi$ is (McKee 1989)

$$M_{\text{cr}} \simeq M_J + M_\Phi. \quad (28)$$

For larger values of M_{cr}/M_Φ the critical mass approaches the Jeans mass and Eq. (28) becomes more accurate than Eq. (22). Equation (28) clearly demonstrates that the effects of gas pressure and magnetic pressure in supporting the cloud against gravitational collapse are approximately additive.

D. Time-Dependent Magnetic Fields

The primary case considered to date in the literature is that of a steady axisymmetric field. Observed fields are more complex; because the observed turbulent velocity fields will induce turbulent magnetic fields, the latter must be time dependent, thereby increasing the strength of the field while leaving the true flux constant. The role of time-dependent motions (primarily Alfvén waves) in the structure of molecular clouds is discussed in Sec. III.B below. Here we give a brief discussion of how wave motions may be included in the virial theorem, following the treatment of McKee and Zweibel (1992).

If we divide the energies into steady and wave components, $\mathcal{T} = \mathcal{T}_s + \mathcal{T}_w$, etc., we can express the virial theorem for a cloud in a steady state as

$$2(\mathcal{T}_s - \mathcal{T}_{0s}) + \mathcal{M}_s + \mathcal{W}_s + 2(\mathcal{T}_w - \mathcal{T}_{0w}) + \mathcal{M}_w + \mathcal{W}_w = 0. \quad (29)$$

This division is precise only if the cloud is very nearly in a steady state, so that there is a clear distinction between the internal wave motions and the dynamical evolution of the cloud as a whole. The steady kinetic energy \mathcal{T}_s includes thermal energy and the energy associated with steady rotation; all the turbulent motions are contained in \mathcal{T}_w for the cloud and \mathcal{T}_{0w} for the intercloud medium. Now, the level of magnetic fluctuations is related to the associated fluctuations in the kinetic energy by the principle of equipartition (Whitham 1974; Zweibel and McKee, in preparation). This states that the kinetic energy of the wave equals the total potential energy associated with the wave, including the magnetic, gravitational and thermal energies. The thermal

term is negligible for Alfvén waves, so we ignore it here. The equipartition principle then becomes

$$\mathcal{M}_w + \mathcal{W}_w = \mathcal{T}_w - \mathcal{T}_{0w}. \quad (30)$$

Defining the coefficient

$$c_w \equiv 1 + \frac{\mathcal{T}_w - \mathcal{T}_{0w}}{2(\mathcal{T} - \mathcal{T}_0)} \quad (31)$$

we can express the virial theorem as

$$2c_w(\mathcal{T} - \mathcal{T}_0) + \mathcal{M}_s + \mathcal{W}_s = 0. \quad (32)$$

This is of the same form as Eq. (9), except that the kinetic energy term is multiplied by a factor c_w and the magnetic and gravitational terms are based on the time-averaged field and density, respectively.

Molecular clouds and the CO clumps within the clouds are generally highly turbulent, with $\mathcal{T} \simeq \mathcal{T}_w$; in this case, $c_w = 3/2$. On the other hand, thermal motions are often dominant in cloud cores (Myers 1985), and in such cores, c_w is closer to unity. In general then, we expect $1 \leq c_w \leq 3/2$.

The effect of the wave energy on the critical masses described in Sec. II.B and C above is straightforward: the Jeans mass is increased by a factor $c_w^{3/2} < 1.84$, whereas the magnetic critical masses M_Φ and M_B are unchanged so long as time-averaged field B_s is used. As the flux is determined by B_s , not by the rms field $B_{\text{rms}} = (B_s^2 + B_w^2)^{1/2}$, the critical mass M_Φ is completely unaffected by the inclusion of time-dependent fields. As discussed in the Chapter by Heiles et al., the strength of the observed field is determined from Zeeman observations that average along the line of sight. This spatially averaged field should be closer to B_s than to the rms field, making this form of the virial theorem particularly suitable for analyzing observations.

E. Implications

The mass of a molecular cloud is often estimated from the virial theorem, as direct measurements of the the mass from ^{13}CO or extinction observations show that this is generally valid, though the scatter is considerable (Larson 1981). An approximate form of the virial theorem Eq. (9), ignoring the complications associated with internal density variations (a), surface pressure (P_0), and magnetic fields (\mathcal{M}), gives a mass $M = 5\sigma^2 R/G$. We introduce the *virial parameter* α , which measures the ratio of the thermal plus turbulent energy to the gravitational energy, to make this relation exact:

$$M \equiv \frac{1}{\alpha} \left(\frac{5\sigma^2 R}{G} \right). \quad (33)$$

For a cloud in approximate virial equilibrium ($t_l \gtrsim 2t_{ff}$ —see above), the value of α can be evaluated from Eq. (9),

$$\alpha = \frac{a}{(1 - P_0/\bar{P})} \left(1 - \frac{\mathcal{M}}{|\mathcal{W}|} \right) \simeq \frac{1 - (M_\Phi/M_{cr})^2}{1 - (P_0/\bar{P})}. \quad (34)$$

The second step follows from Eq. (19) and from the fact that the parameter a is of order unity.

In applications of Eq. (33) to estimate cloud masses, the surface pressure and magnetic energy are generally ignored, and α is taken to be of order unity: for example, Larson took $\alpha = 2.0$, Solomon et al. (1987) adopted $\alpha = 1.11$, and Myers and Goodman (1988*a, b*) set $\alpha = 1.0$. Barring a fortuitous cancellation, it is clear from Eq. (34) that this procedure is valid only if two conditions are satisfied. First, the mean pressure in the cloud must significantly exceed the surface pressure ($\bar{P} \gg P_0$); otherwise the observed line width reflects the confinement by external pressure and the mass would be overestimated. Second, the cloud must not be too highly magnetized (e.g., a cloud at the critical mass should have $M = M_{cr} \gtrsim 2M_\Phi$); otherwise the observed line width reflects the small role played by the gas pressure in supporting the cloud and the mass would be underestimated. In the absence of a magnetic field, an isothermal cloud at the Jeans mass has $\alpha = 2.04$. Magnetized clouds have smaller values of α : estimating the cloud radius for a flattened cloud as $(R^2 Z_{\max})^{1/3}$, where Z_{\max} is the maximum height of the cloud above the plane of symmetry, we find that Mouschovias's (1976) models have $M \simeq 2M_\Phi$ and $1.1 \lesssim \alpha \lesssim 1.33$, consistent with the Tomiska et al. (1988*b*) result $\alpha = 1.19$ for their model with $M \simeq 2M_\Phi$; on the other hand, their most strongly magnetized model (their $\beta_0 = 0.02$) has $M \simeq M_\Phi$ and $\alpha \simeq 1/3$. Elmegreen (1989*a*) has estimated the effect of the magnetic field on virial mass estimates using the Nakano (1984) model for the field, and finds that α is typically close to unity. It is clear that in the absence of some knowledge of the magnetization of the cloud, the virial estimate of the cloud mass is subject to large uncertainties. For the case in which turbulent motions and the magnetic field are of comparable importance in supporting the cloud and in which the cloud is close to the critical mass ($M_J \sim M_\Phi \sim 0.5M_{cr}$), the virial estimate with $\alpha \simeq 1$ can in principle provide a reasonably accurate estimate of the mass.

These conditions are just those found by Myers and Goodman (1988*a, b*). Figure 3 in their 1988*b* paper plots the quantity $15\sigma^2/(4\pi\bar{\rho}GR^2)$, which (assuming a spherical cloud) is just α . Their data show that $\alpha \simeq 1$, albeit with considerable scatter; the mean value is 1.2. In their 1988*a* paper, they compare a theoretical field strength B_{eq} with measured values. Equations (17) and (33) give the relation between B_{eq} and the actual mean field \bar{B} as

$$B_{eq} \equiv \frac{3\sigma^2}{R} \left(\frac{5}{G} \right)^{1/2} = \frac{3\pi c_\Phi \alpha}{\sqrt{5}} \left(\frac{M}{M_\Phi} \right) \bar{B} = \frac{\alpha}{1.98} \left(\frac{M}{M_\Phi} \right) \bar{B}. \quad (35)$$

They find good agreement between B_{eq} and observation, on average; hence, as $\alpha \simeq 1$, it follows that typically $M \simeq 2M_\phi$. In particular, this result holds, within the observational uncertainties, for the dark cloud B1, which is discussed at some length in the Chapter by Heiles et al. (see their Table III). Myers and Goodman assume that the observed line width (excluding any thermal contribution) satisfies $\sigma^2 = v_A^2/3$, where v_A is the Alfvén velocity. Direct evaluation shows that

$$\frac{\sigma}{v_A/\sqrt{3}} = \frac{\sqrt{\alpha}}{1.98} \left(\frac{M}{M_\phi} \right) \quad (36)$$

for a spherical cloud, so that this assumption is satisfied for the typical observed values of α and M/M_ϕ . Thus, Myers and Goodman's approximate analysis, which ignored surface terms in the virial theorem and did not treat the magnetic field self-consistently, remains reasonably accurate when these effects are included properly, as we have done here.

Molecular clouds are observed to be at substantially higher pressures than the ambient medium: for example, a cloud with an extinction of 6 magnitudes has a mean pressure of $\sim 2 \times 10^5 \text{ cm}^{-3} \text{ K}$ according to Eq. (11), far greater than the typical interstellar pressure of 1 to $2 \times 10^4 \text{ cm}^{-3} \text{ K}$. This is possible only for clouds which are close to the critical mass. For isothermal clouds, \bar{P}/P_0 drops from its maximum value of ~ 2.5 at $M/M_J = 1$ to only ~ 1.36 at $M/M_J = 0.5$. Mestel (1985) has emphasized that the same result holds for magnetized clouds: having \bar{P} significantly greater than P_0 requires that M be close to M_{cr} . Reference to the numerical calculations of Tomisaka et al. (1988*b*) shows that, for the case in which the magnetic and gas pressures are comparable in the ambient medium, the central pressure drops from ~ 30 times the ambient value at $M = M_{\text{cr}}$ to only about twice the ambient value at $M = 1/2 M_{\text{cr}}$. Hence, molecular clouds are almost critical, $M \simeq M_{\text{cr}}$. As GMCs are generally not highly flattened, random motions in the gas must also be important in supporting the cloud against gravity. It follows that $M_J \gtrsim M_\phi$, and hence that $M \simeq M_{\text{cr}} \simeq M_J + M_\phi \gtrsim 2M_\phi$: GMCs are magnetically supercritical (McKee 1989). We do not expect M to be too much greater than M_ϕ , both because the turbulence would then be highly super-Alfvénic (Eq. 36) and subject to rapid dissipation, and because the large amplitude motions would tend to amplify the field. This is consistent with the observational result that $M \simeq 2M_\phi$ discussed above. Then, as $M \simeq M_{\text{cr}}$, we conclude that $M_\phi \simeq M_J$: molecular clouds appear to be supported about equally by magnetic flux threading the cloud and by MHD turbulence, a result which appears to have been first suggested by Elmegreen (1978*a*). The existing data, which is discussed in the Chapter by Heiles et al., is consistent with these conclusions, but at present observational uncertainties make it impossible to determine the mass of a given cloud, or its critical mass, to better than a factor 2.

These conclusions need not apply to clumps within GMCs, however; because the clumps are not necessarily highly pressured with respect to their

surroundings, they are not necessarily close to critical. Observational data which suggest that clumps obey the same scaling laws as entire molecular clouds (Larson 1981; Myers and Goodman 1988*b*) are subject to observational selection for small clumps. More complete surveys of low-mass clumps in ^{13}CO show that such clumps in molecular clouds are typically subcritical (Carr 1987; Loren 1989). These subcritical clumps are confined by the pressure in the molecular cloud, not by their self-gravity; they apparently continue to obey the equipartition relation $\sigma \simeq v_A/\sqrt{3}$, however (Bertoldi and McKee 1992). On the other hand, the most massive clumps in GMCs ($M \gtrsim 10^2$ to $10^3 M_\odot$, depending on the GMC), which contain a significant fraction of the mass, are magnetically supercritical and in gravitational virial equilibrium, like GMCs as a whole (Bertoldi and McKee 1992).

III. MAGNETIC STRUCTURE OF MOLECULAR CLOUDS

A. Static Cloud Models

The usual idealized theoretical picture of a nonrotating, magnetically supported cloud is an oblate spheroid with its minor axis parallel to the magnetic field. The field-line configuration resembles an hourglass, compressed by the cloud and becoming uniform at large distances. Such a model can be imagined as the outcome of an evolutionary process, in which some volume of gas in an initially uniform medium with infinite electrical conductivity is designated the “parent cloud,” and then cooled or otherwise driven out of equilibrium so that it contracts under the influence of gravity to another equilibrium state. As indicated in Sec. II, this picture is relevant primarily to clouds or clumps within clouds that are smaller than a few tens to a few hundred solar masses; larger clouds are magnetically supercritical, and turbulence is essential for their support.

If we measure density and magnetic field in units of their initial values, then three parameters and one function characterize this problem. The three parameters are the cloud mass normalized to the Jeans mass (M/M_J), the ratio of gas to magnetic pressure at infinity ($\beta_0 = 8\pi P_0/B_0^2$), and the initial ratio of external to cloud gas pressure. Alternatively, the parent cloud may be considered to be in pressure equilibrium with its surroundings; the cloud would then be spheroidal in shape, and the third parameter is the aspect ratio of the spheroid. The effects of the second and third parameters are contained primarily in the ratio M/M_Φ (see Sec. II). The equilibrium also depends on the function describing the distribution of the mass to flux in the cloud; this is often taken to be that of a uniform field threading a sphere. Although it is simple to sketch this picture, it is rather difficult to quantify it. Some relationships between the magnetic geometry and the degree of flattening can be derived analytically from the tensor virial theorem (Zweibel 1990*b*). Parker (1973) was the first to construct self-gravitating, magnetized equilibrium models. His method, although self-consistent, did not control the magnetic topology, and the magnetic fields in some of his models were only partially connected

to the ambient field. Such clouds could not condense from a medium with a uniform magnetic field if the flux were frozen.

The calculations by Mouschovias (1976*a, b*) do specify the magnetic topology, and are the realization of the initial value problem described above. Mouschovias found the critical states already described in Sec. II—clouds which are at the maximum possible equilibrium mass given their temperature, magnetic flux, and ambient pressure. His published results include clouds with central to surface density ratio ρ_c/ρ_s up to ~ 23 , and he found the important result that the value of B at cloud center B_c scales as $\rho_c^{1/2}$. Isotropic contraction would have given an exponent of $2/3$.

Tomisaka et al. (1988*a, b*) studied a problem similar to Mouschovias', but they departed somewhat from the initial value formulation by specifying ρ_c/ρ_s instead of the initial pressure contrast as a third parameter. For $M > M_\Phi$, they found second, more centrally condensed models as well as those found by Mouschovias (as we mentioned in Sec. II, the unmagnetized problem has an infinite number of solutions); they showed that the more centrally condensed solutions are almost certainly unstable to collapse. Their published models include both stable and unstable clouds, and have ρ_c/ρ_s as high as 10^4 ; stable clouds are restricted to $\rho_c/\rho_s < 30$ for $\beta_0 = 1$ and $\rho_c/\rho_s < 10^3$ for $\beta_0 = 0.02$. For large values of ρ_c/ρ_s the density distribution in the cloud approaches $1/r^2$, just as in the case of unmagnetized clouds (Bodenheimer and Sweigert 1968). These calculations have been extended to include toroidal fields by Tomisaka (1991).

Tomisaka et al. (1988*b*) proposed a modification to Mouschovias' $B_c \propto \rho_c^{1/2}$ scaling law:

$$\frac{B_c}{B_0} \sim \left[1 + \frac{4\pi\rho_c\sigma^2}{B_0^2} \left(1 - \frac{\rho_s}{\rho_c} \right) \right]^{1/2}. \quad (37)$$

If the ambient field B_0 is large enough, the cloud collapse can be highly aligned with the magnetic field, which is then hardly compressed at all. On the other hand, if the magnetic pressure at infinity is much less than the central gas pressure, B_c scales as $\rho_c^{1/2}$, with the constant of proportionality such that the Alfvén and acoustic speeds at the center of the cloud are equal. It should be noted that this scaling applies only to clouds that are approximately magnetically critical ($M \sim M_\Phi$), because it was obtained for magnetized clouds ($M_\Phi \gtrsim M_J$) that must be close to the critical mass ($M \sim M_{cr} \sim M_\Phi$) in order that there be a large pressure drop from the center to the edge of the cloud. The approximate equality of the velocity dispersion σ and the Alfvén velocity v_A then follows from the fact that a cloud with $M \sim M_\Phi$ is supported in the radial direction by the magnetic pressure and in the vertical direction by the thermal pressure; near the center, these pressures must be approximately equal (cf. Umebayashi and Nakano 1990). As a consequence, the central regions of highly condensed clouds are not magnetically dominated, even though the field may be quite strong there. In fact, the models of Tomisaka et

al. (1988*b*) show that for $\beta_0 \lesssim 1$, the field compression is not large: $B_c/B_0 \lesssim 5$ and $\bar{B}/B_0 \lesssim 1.1$.

Cloud models based on the tensor virial theorem, which do not constrain the magnetic topology, show that when \bar{B}/B_0 is large, the field lines are not all connected with the asymptotic field (Strittmatter 1966; Zweibel 1990*b*). This may be understood intuitively by noting that when \bar{B}/B_0 is very large, the field lines passing through the cloud must spread out by a large amount in order to connect properly with the field at infinity. The requirement $\nabla \cdot B = 0$ places a geometrical constraint on the degree of spreading, and most of the field lines must then return to the cloud. A distinctive feature of a closed topology is that the mean field would reverse direction, which could be detected through observations of Zeeman splitting.

Observed clouds appear to have values of $\bar{B}/B_0 \sim 10$, which greatly exceed those in any of the numerical models to date. Including the HI envelopes surrounding the molecular clouds cannot significantly reduce the discrepancy because the envelopes do not have a large fraction of the mass for typical star-forming clouds with $\bar{A}_V \gtrsim 6$ (Elmegreen 1985*a*). For example, the atomic envelope around the Orion molecular cloud has $\sim 30\%$ of the mass of the entire cloud (Chromey et al. 1989). There are several possible explanations for the large observed values of \bar{B}/B_0 . One possibility is that molecular clouds occur in regions of high interstellar pressure and high magnetic field; 21 cm Zeeman observations could determine if this is the case. Another possibility is that the clouds are not isothermal, but rather have an effective polytropic index corresponding to a specific heat ratio exceeding unity so that the clouds are cooler at the surface, like stars (McKee and Lin 1988); Elmegreen (1989*a*) has shown that this may indeed give greater compressions. It should be noted that the “specific heat” here refers to the turbulence in the cloud, not to the thermal properties, and as yet there is no theory for its value. Finally, there is the possibility that the field topology is partially closed, because, as just discussed, this can lead to higher internal fields. One way this can occur is by reconnection, which is discussed in Sec. V.C below.

B. Dynamical Effects on Cloud Structure

One of the fundamental questions concerning molecular clouds is the nature of the line widths, which greatly exceed the sound velocity in the gas. Arons and Max (1975) first suggested that these motions are large amplitude Alfvén waves, and this idea has been the basis of much of the subsequent theoretical work (see, e.g., Zweibel and Josafatsson 1983; Falgarone and Puget 1986; Carlberg and Pudritz 1991; Elmegreen 1990*b*). As described in the Chapter by Heiles et al., observed fields in molecular clouds are strong enough that the Alfvén velocity is comparable to the observed velocity dispersion, thereby confirming Arons and Max’s hypothesis. As described in Sec. II, it is possible to include the effects of fluctuating fields on the structure of the cloud in terms of a turbulent pressure (see, e.g., Lizano and Shu 1989). Here we consider hydromagnetic fluctuations explicitly, on both the large scale of individual

GMC's and the small scale corresponding to individual clumps.

On the large scales, one of the most basic questions is the role of the magnetic field in the dissipation of internal cloud motions. The mechanism by which internal random velocities are apparently maintained over several free-fall times remains problematic, and we can ask whether a large-scale magnetic field enhances or reduces the dissipation. Many of the relevant processes have been discussed by Elmegreen (1985*b*). He considered radiation of the energy of internal cloud motions as Alfvén waves which propagate along the field lines away from the GMC, as well as remote cloud collisions, in which clouds interact via forces transmitted by the magnetic fields which thread them without direct physical contact. Both of these mechanisms increase the dissipation. Two other factors mitigate the dissipation, however. These are the increased elasticity of direct collisions between magnetized clouds and the inhibition of collisions by magnetic tension forces (the latter effect was estimated by Zweibel 1990*a*). At the present time, the conditions under which magnetic fields either increase or decrease the rate of bulk kinetic energy dissipation are not fully clear and more work is needed on the problem.

The small-scale fluctuation spectrum is coupled to the large-scale spectrum, as was recognized by Falgarone and Puget (1986). These authors computed the internal Alfvénic disturbance induced by grazing clump-clump collisions transverse to the ambient magnetic field. Relatively long wavelength modes (with wavelength comparable to the size of the clump) are generated by this process. These waves either decay directly or steepen into short-wavelength fluctuations. It is not firmly established that the rate of clump-clump collisions is sufficient to explain the nonthermal velocities seen in clumps, and internal sources or transmittal of other disturbances from the interclump medium may also be required. As pointed out by Shu et al. (1987*b*), the existence of waves in a clump is not sufficient to support it against gravitational collapse: in addition, the energy density of the waves must decrease outward, which could indicate an internal energy source.

Clumps of sufficiently small size cannot sustain a hydromagnetic wave population, and thus cannot be turbulently supported (Mouschovias 1987*a*; Carlberg and Pudritz 1991). The critical size results from the cutoff wavenumber (or frequency) given by Eq. (52) below, which gives a cutoff clump radius,

$$R_{\text{cut}} = \frac{\pi}{k_{\text{cut}}} = \frac{\pi V_A}{2\nu_{ni}} \simeq 0.20 \left(\frac{B_{1.5}}{K_{i-5} n_3} \right) \text{pc} \quad (38)$$

corresponding to a mass

$$M_{\text{cut}} \simeq 1.1 \left(\frac{B_{1.5}^3}{K_{i-5}^3 n_3^2} \right) M_{\odot} = \left(\frac{2.2 \times 10^{-3}}{K_{i-5}^3} \right) M_B \quad (39)$$

where the magnetic mass M_B is given by Eq. (27), the neutral-ion collision frequency ν_{ni} is given in Eq. (49), and the ionization parameter K_i is defined

in Eq. (48). Clumps of lower mass must have essentially negligible pressure associated with turbulent magnetic fields; however, they are well supported by the static magnetic field since $M \ll M_B$. Cloud cores are observed to have $M \gtrsim M_B$ (e.g., Table III in the Chapter by Heiles et al.) and so are large compared to M_{cut} ; nonetheless, since the wavelength $\propto M^{1/3}$, the range of wavelengths which can propagate in such cores is severely restricted (Carlberg and Pudritz 1991).

On length scales less than R_{cut} and less than a gravitational scale height, the thermal pressure along field lines is constant. If the boundaries of the clumps within clouds are sharper than this, then the clump and the interclump medium would have the same thermal pressure. The interclump medium could have a substantial atomic component (Blitz et al., in preparation). If this component of the interclump medium had a temperature similar to that of the intercloud medium of the diffuse interstellar medium ($T \sim 10^4$ K), then its thermal velocity would be larger than the turbulent velocity in the cloud, enabling the thermal pressure of the interclump medium to be constant throughout the molecular cloud and about the same as that in the ambient medium (McKee 1989); the surface layers of the clumps in the cloud would be at the same thermal pressure. The thermal pressure in a typical clump ($n \sim 10^3 \text{ cm}^{-3}$, $T \sim 10$ K) is indeed comparable to that in the diffuse interstellar medium; cloud cores, being self-gravitating, have higher pressures.

If turbulence is the primary source of support against gravitational collapse, the Jeans criterion can be modified substantially. It was first pointed out by Chandrasekhar (1951*b*) that the stability of a region of some given size L will be determined by the turbulent energy on scales less than L . This raises the intriguing possibility that shorter scales can be less stable than longer scales. Bonazzola et al. (1987) and Pudritz (1990) have elaborated upon this basic idea. (However, note that these treatments of the gravitational stability of turbulent media have not allowed for the clumpiness of molecular clouds, which renders the mean density, and hence the effect of gravity, substantially less on large scales than on the scale of individual clumps.) The gravitational stability properties of the medium, in this picture, depend upon the turbulence spectrum, i.e., the relative distribution of power at different scales. At present, there is no *ab initio* calculation of this spectrum, but the cutoff at short wavelength clearly depends upon the damping, just as for the equilibria discussed above. In the first numerical calculation of the effects of a given spectrum of hydromagnetic waves on an initially isothermal cloud, Carlberg and Pudritz (1991) have found that the cloud undergoes a global, isotropic collapse at about 1/4 the free-fall rate.

IV. ROTATION AND MAGNETIC BRAKING

A. Rotation of Molecular Clouds

Magnetic fields couple molecular clouds to the rest of the interstellar medium and thereby regulate the rotation of the clouds. How important is rotation to

the structure of the clouds? Stahler (1983*b*) studied the equilibria of rotating, isothermal clouds with an angular momentum distribution corresponding to that of a uniform sphere. Kiguchi et al. (1987) studied a wider range of conditions than Stahler, but, as they pointed out, nonaxisymmetric instabilities are likely to disrupt the clouds rotating more rapidly than those considered by Stahler. Tomisaka et al. (1989) have provided a simple interpretation of the results of Kiguchi et al.: just as M_J represents the maximum mass that can be supported by gas pressure and M_ϕ represents the maximum mass that can be supported by magnetic fields, so

$$M_{\text{rot}} = 5.1 \left(\frac{\sigma J}{GM} \right) \quad (40)$$

where J is the angular momentum of the cloud, represents the maximum mass that can be supported by rotation. In contrast to M_ϕ , which can take on arbitrary values relative to M_J , there is a limit $M_{\text{rot}}/M_J \lesssim 3.6$ in Stahler's models; in other words, some thermal support is essential for nonmagnetized rotating clouds in order to avoid instability. Tomisaka et al. have shown how to include the effect of magnetic fields on the critical mass: with the approximation (Eq. 28), their result for the critical mass for magnetized, rotating clouds becomes

$$M_{\text{cr}} \simeq [(M_J + M_\phi)^2 + M_{\text{rot}}^2]^{1/2}. \quad (41)$$

This simple approximation agrees with the numerical calculations of Tomisaka et al. (1989, Table 4) to within $\sim 5\%$.

We can characterize the rotation of a cloud by the parameter

$$\alpha_\Omega \equiv \frac{\Omega^2 R^3}{GM} = 231 \frac{\Omega_{\text{ksp}}^2 R_{\text{pc}}^3}{M/M_\odot} = 1.61 \frac{\Omega_{\text{ksp}}^2}{\bar{n}_3} \quad (42)$$

where $\Omega = J/I$ is the mean angular velocity of the cloud and Ω_{ksp} is in units of $\text{km s}^{-1} \text{pc}^{-1}$. This parameter measures the ratio of the centrifugal force to the gravitational force, and is similar to the rotation parameter α used by Mestel and Paris (1984); for an oblate spheroid with an eccentricity < 0.7 , the two quantities differ by $< 20\%$. The rotational mass can be expressed in terms of α_Ω by $M_{\text{rot}} \simeq 0.64(\alpha_\Omega \alpha)^{1/2} M$, where we have used Stahler's (1983*b*) results to evaluate the moment of inertia at the maximum stable mass. Based on Stahler's models, we find that a sufficient condition for clouds to be primarily supported by gas pressure rather than rotation (i.e., $M_{\text{rot}} < M_J$) is $\alpha_\Omega < 0.5$. The rotational kinetic energy \mathcal{T}_{rot} is directly related to α_Ω : Stahler's (1983*b*) results show that $\alpha_\Omega \simeq (3 \sim 6) \mathcal{T}_{\text{rot}}/|\mathcal{W}|$, where the factor 3 is appropriate for a rigidly rotating sphere. The parameter α_Ω is also useful for characterizing the disk formed by a cloud which collapses while conserving its angular momentum: if the cloud begins at a radius R_0 with a

rotation parameter $\alpha_{\Omega 0} < 1$, then, as $\alpha_{\Omega} \propto J^2/R$, it will form a disk with a radius $R_c \simeq \alpha_{\Omega 0} R_0$ (cf. Terebey et al. 1984).

Remarkably enough, the importance of rotation in observed molecular clouds remains somewhat unclear. Based on CO observations, Goldsmith and Arquilla (1985) have reported that the line widths of rotating clouds do not differ significantly from those of non-rotating clouds; we interpret this as implying $\Omega D < \Delta v$, where $\Delta v = (8 \ln 2)^{1/2} \sigma$ is the FWHM of the line and $D = 2R$ is the cloud diameter. As

$$\frac{\alpha_{\Omega}}{\alpha} = \frac{\Omega^2 R^2}{5\sigma^2} = 0.28 \left(\frac{\Omega D}{\Delta v} \right)^2 \quad (43)$$

and as $\alpha \sim 1$ (Sec. II), we infer that $\alpha_{\Omega} \lesssim 1/4$, so that rotation is not that important in supporting the clouds in their sample. This conclusion is consistent with that of Goldsmith and Arquilla. In fact, they point out that their sample is biased towards clouds which show rotation, so the mean rotation of all clouds could be smaller yet. On the other hand, evaluation of α_{Ω} from their mean value, $\Omega_{\text{ksp}} = 0.64 \bar{n}_3^{0.4}$, gives $\alpha_{\Omega} \simeq 0.65 \bar{n}_3^{-0.2} \sim 1$, which would suggest that rotation is essential. Arquilla and Goldsmith (1986) made a detailed study of eight clouds, six with reported rotation. Five of the eight clouds in this biased sample showed $T_{\text{rot}}/|\mathcal{W}| \gtrsim 0.3$, corresponding to $\alpha_{\Omega} \gtrsim 1$, so that rotation is important in the structure of these clouds. Although the numerical evaluation of α_{Ω} is uncertain, it appears that rotation is significant in at least some clouds. Rotation is observed to be unimportant in the cloud B1, which is extensively discussed in the Chapter by Heiles et al. Furthermore, recent observations of cloud cores in NH_3 by Goodman et al. (1991a) confirm that rotation is not important ($\alpha_{\Omega} < 1$) for these objects, at least. Observations are needed to determine the fraction of clouds that are rotationally supported, and the conditions under which this occurs.

B. Magnetic Braking

The role of magnetic fields in regulating the rotation of clouds seems to have first been studied by Ebert et al. (1960), and subsequently by Mestel (1965b); it has been reviewed recently by Mestel and Paris (1984), Mestel (1985), and Mouschovias (1987a, b). The basic process is quite simple: if the rotation of the cloud differs from that of the ambient medium, torsional Alfvén waves are launched into the ambient medium (and into the interior of the cloud) which transport angular momentum and tend to bring the cloud into corotation with the ambient medium. The characteristic time scale for this magnetic braking, t_b , is basically the time for the outwardly propagating Alfvén waves to engulf an amount of ambient material with a moment of inertia equal to that of the cloud. The braking time thus depends on the geometry of the field, because the rate at which the field spreads out determines the rate of increase of the moment of inertia inside the wavefront. The simplest case is that of a cloud embedded in a uniform magnetic field \mathbf{B}_0 with its angular momentum parallel

to \mathbf{B}_0 (Ebert et al. 1960; Mouschovias and Paleologou 1980; Mestel and Paris 1984). For a spherical cloud, the braking time is

$$t_b = \frac{8}{15} \left(\frac{\bar{\rho}}{\rho_0} \right) \frac{R}{v_{A0}} \simeq 0.3 \frac{M}{M_\Phi} \left(\frac{\bar{\rho}}{\rho_0} \right)^{1/2} t_{ff} \quad (44)$$

where v_{A0} is the Alfvén velocity of the ambient medium, etc. If the cloud is cylindrical rather than spherical, the result is the same, except that the factor $(8/15)R$ is replaced by Z , the half-height of the cylinder (Mouschovias and Paleologou 1980). This result shows that magnetically subcritical clouds ($M/M_\Phi < 1$) which are not very dense are braked on an extremely short time scale. Magnetically supercritical clouds that are substantially denser than their surroundings ($\bar{\rho} \gtrsim 10\rho_0$) would be braked slowly enough that rotation could inhibit collapse, but the assumption of a uniform field is less likely to be valid in this case.

Clouds are observed to have fields substantially larger than the ambient one, suggesting that (if the cloud field is connected to the ambient field) a radial field in the ambient medium is a better approximation than a uniform one. Gillis et al. (1974, 1979) and Mestel and Paris (1979, 1984) have shown that in this case the cloud is coupled to a larger volume of ambient gas and the braking time is somewhat shorter; in our notation, their result is

$$t_b \simeq 0.2 \frac{M}{M_\Phi} \left(\frac{\bar{\rho}}{\rho_0} \right)^{1/10} t_{ff}. \quad (45)$$

Thus, if the field in the cloud substantially exceeds the ambient one, the braking time is almost entirely dependent on the ratio of the mass to the magnetic critical mass, M/M_Φ , and almost independent of the density contrast. The numerical coefficient in Eq. (45) is several times smaller than that found by Mestel and Paris (1984) because we have used a more accurate value for M_Φ . This result implies that prior to the onset of collapse, rotation should be unimportant in clouds. If the cloud undergoes gravitational contraction at a velocity of order of or faster than the Alfvén velocity, this expression breaks down because the Alfvén waves responsible for braking the cloud become trapped (Mouschovias 1989). The cloud will then evolve to a state in which centrifugal support is important and the evolution is governed by magnetic braking (see, e.g., Mestel and Paris 1984).

The results in Eqs. (44) and (45) are both based on the assumption that the angular momentum is parallel to the field; in the opposite case in which the two vectors are orthogonal, the braking time is shorter (Mouschovias and Paleologou 1979), although the difference from the parallel case is small in the case of a spherical cloud with a compressed field (Mestel and Paris 1984). All the calculations are based on flux freezing (i.e., $t_b < t_{AD}$), an assumption verified by Mouschovias and Paleologou (1986).

The numerical calculations carried out to date are consistent with the analytic results just described. Dorfi (1982) followed the evolution of a

magnetized, rotating cloud with $M \simeq M_\phi$ in three dimensions, and he found that the braking time for the case with \mathbf{J} parallel to \mathbf{B}_0 is $t_b \simeq 0.5t_{ff}$, consistent with Eq. (44). For the case in which \mathbf{J} is perpendicular to \mathbf{B}_0 , he found that the braking time is a good deal shorter, $t_b \lesssim 0.1t_{ff}$, consistent with the estimate of Mouschovias and Paleologou (1979). He assumed flux freezing, but found substantial numerical diffusion of the field in his calculations. Tomisaka et al. (1990) have carried out calculations which include ambipolar diffusion, but are restricted to quasi-static flows with axisymmetry; because of these restrictions, their calculations are numerically more robust than those of Dorfi (1982). They considered the case in which the ambient medium had a density small compared to that of the cloud, but a field of the same magnitude. The assumption of an approximately uniform field implies that their calculation corresponds to Eq. (44); they confirmed the validity of this equation, as did Dorfi. On the other hand, the assumption of a low external density made the braking time quite long, comparable to the ambipolar diffusion time. It would be worthwhile to carry out such a calculation for the more realistic case in which there is a contrast in field strength as well as density between the cloud and intercloud medium.

How important then is rotation in molecular clouds? Observations are ambiguous, although they suggest that rotation is generally not very important. Theory is less ambiguous provided that the field topology is an open one; it predicts a braking time that is comparable to or less than the free-fall time t_{ff} , depending on the rate at which the field diverges from the cloud and on the density contrast with the ambient medium (Eqs. 44,45). Magnetically subcritical clouds evolve on the ambipolar diffusion time, which is much greater than t_{ff} (cf. Eq. 51 below), so such clouds should be slow rotators. For a dense, magnetically supercritical cloud on a cylindrical flux tube, Eq. (44) predicts that the contraction of the cloud would be limited by the rate of braking, so the cloud would be in approximate virial equilibrium. On the other hand, the field in molecular clouds is observed to be about an order of magnitude greater than that in the diffuse ISM, and the field in the gas collapsing onto a protostar is predicted to be greater still. In these cases, the magnetic braking should be sufficiently efficient that the angular momentum is transported outward at about the same rate that collapse occurs. Hence, a dynamical calculation is needed to determine the final angular momentum, which in turn determines the size of the protostellar accretion disk (Terebey et al. 1984) and whether a binary star forms (Mouschovias 1977). In principle, such a calculation should allow for the possibility of magnetic reconnection (Sec. V.C); existing calculations assume that the field in the cloud is fully connected with the ambient field, but the braking time probably would be greater if the field were partially closed (see Kulsrud 1971). Observationally, it would be worthwhile to study the topology of the field of clouds which appear to be relatively rapid rotators to see if there is any evidence for closed field lines.

V. THE PHYSICS OF AMBIPOLAR DIFFUSION AND FLUX REDISTRIBUTION

A. Time Scales for Ambipolar Diffusion

To this point, we have assumed that the magnetic field is frozen to the gas, which is generally a good approximation. In fact, under interstellar conditions the field is frozen only to the small number of ionized particles in the gas, and it can act on neutral particles only indirectly through collisions. As a result, the field slips through the neutrals at a velocity v_D , exerting a force per unit volume $\rho_n v_{ni} v_D$ on the neutrals, where ρ_n is the density of the neutral particles and v_{ni} is the neutral-ion collision frequency. This process is often referred to as “ambipolar diffusion” (Spitzer 1978). Neglecting the gas pressure for simplicity, we have for the equations of motion for the neutrals and charged particles

$$\rho_n \frac{d\mathbf{v}_n}{dt} = \rho_n v_{ni} \mathbf{v}_D + \rho_n \mathbf{g} \quad (46)$$

$$\rho_i \frac{d\mathbf{v}_i}{dt} = -\rho_n v_{ni} \mathbf{v}_D + \frac{(\nabla \times \mathbf{B}) \times \mathbf{B}}{4\pi} \simeq 0. \quad (47)$$

The low ion density renders the charged particle inertia negligible unless the frequency of the motion is so high that the charged particles are uncoupled from the neutrals; we do not consider such high frequencies here. In our applications, the ionization is sufficiently low that we can set the neutral density equal to the total density, $\rho_n \simeq \rho$.

Equations (46) and (47) imply that the drift velocity v_D varies inversely with the collision frequency $v_{ni} = n_i \langle \sigma v \rangle$. Numerically, the collision rate coefficient $\langle \sigma v \rangle \simeq 1.5 \times 10^{-9} \text{ cm}^3 \text{ s}^{-1}$ for molecular gas of cosmic abundances (Nakano 1984). At high densities ($n \gtrsim 10^8 \text{ cm}^{-3}$), grain drag increases this somewhat (Elmegreen 1979b; Nakano 1984), and at high velocities ($v_D \gtrsim 10 \text{ km s}^{-1}$), the cross section becomes geometric and $v_{ni} \propto v_D$ (Mouschovias and Paleologou 1981). The ionization of the gas is determined by balancing the rate at which the ions are formed, $\zeta_H n_H$, with the rate at which they are destroyed by recombination, which is generally proportional to n_i^2 . As a result, the ionization can be expressed as

$$x_i \equiv \frac{n_i}{n_H} \equiv \frac{K_i}{n_H^{1/2}} \quad (48)$$

where K_i is a constant. If the ionization is due to cosmic rays, then $\zeta_H \simeq 10^{-17} \text{ s}^{-1}$ (Spitzer 1978). For this value of the cosmic-ray ionization rate, and assuming that all grains have a size $0.15 \mu\text{m}$, Elmegreen (1979b) found $K_i \simeq 10^{-5} \text{ cm}^{-3/2}$; in general, $K_i \propto \zeta_H^{1/2}$. More recently, McKee (1989) found $K_{i-5} \equiv K_i / (10^{-5} \text{ cm}^{-3/2}) \simeq 0.5$ for an MRN grain distribution (Mathis et al. 1977) and for densities high enough that an ion such as HCO^+ , rather than H_3^+ , is the dominant molecular ion ($n_H \gtrsim 10^3 \text{ cm}^{-3}$). Lepp and Dalgarno (1988) find that the inclusion of a substantial concentration of large molecules

such as polycyclic aromatic hydrocarbons (PAHs) increases the ionization by up to a factor of ~ 2 . The presence of large molecules or small grains implies that the $n_{\text{H}}^{-1/2}$ scaling for the ionization will persist to higher densities than found by Elmegreen (1979*b*). Altogether, the value $K_{i-5} \simeq 1$ appears to be a fairly robust estimate for the ionization in dense molecular gas ionized by cosmic rays. The collision time is then

$$\tau_{ni} \equiv \frac{1}{v_{ni}} = \frac{6.7 \times 10^4}{K_{i-5} n_3^{1/2}} \text{ yr} \quad (49)$$

provided $v_D \lesssim 10 \text{ km s}^{-1}$. It should be noted, however, that much of the molecular gas in the Galaxy is photoionized by far-ultraviolet radiation, and for such gas the ionization is higher and K_i is no longer constant (McKee 1989). Models of photodissociation regions (Tielens and Hollenbach 1985) show that the ionization of gas in which the carbon is locked up in CO is due primarily to S^+ in regions of relatively low extinction, with $x_i \sim 10^{-5}$; for typical densities $n_{\text{H}} \sim 10^3 \text{ cm}^{-3}$, this gives $K_{i-5} \simeq 30$. At somewhat higher extinctions, the ionization is due to Mg^+ and Fe^+ , with $x_i \sim 10^{-6}$; this corresponds to $K_{i-5} \simeq 3$ at the typical density. Cosmic-ray ionization takes over for $A_V \gtrsim 4$ in the typical interstellar radiation field.

1. Ambipolar Diffusion Under the Influence of Gravity. Consider a magnetized cloud held together by its self-gravity. Because the neutrals do not directly feel the effects of the magnetic field, they fall at a rate limited by the friction with the charged particles, which are tied to the field. Under the assumption that the contraction is slow, the inertia is negligible and the drift velocity is simply $v_D = g\tau_{ni}$ from Eq. (46). For an oblate spheroid of semiminor axis Z parallel to the ambient field, the gravitational acceleration is $g \simeq GM/R^2 = (4\pi/3)G\rho Z$. The ambipolar diffusion time for the core of the cloud,

$$t_{\text{AD}} = \frac{Z}{v_D} = \frac{3}{4\pi G\rho\tau_{ni}} = \frac{3\langle\sigma v\rangle}{4\pi G\mu_{\text{H}}} x_i \quad (50)$$

is directly proportional to the ionization; here $\mu_{\text{H}} \equiv \rho/n_{\text{H}} = 2.34 \times 10^{-24} \text{ g}$ is the mass per hydrogen nucleus for a gas of cosmic abundances. Evaluation of Eq. (50) gives $t_{\text{AD}} = 7.3 \times 10^{13} x_i \text{ yr}$. This is quite close to the typical value for the time to core collapse found by Nakano (1984) in his numerical calculations, $\sim 8 \times 10^{13} x_i \text{ yr}$. Because the time for the entire cloud to undergo ambipolar diffusion is longer by a factor R/Z , which is typically of order 2 for Mouschovias's (1976*b*) clouds, a more characteristic value for the ambipolar diffusion time for the entire cloud, not just the core, is $1.6 \times 10^{14} x_i \text{ yr}$ (McKee 1989).

Because the ionization is proportional to $n^{-1/2}$, Eq. (50) implies that the ratio of the ambipolar diffusion time to the free-fall time t_{ff} is a constant (see, e.g., Mouschovias 1987*a*):

$$\frac{t_{\text{AD}}}{t_{\text{ff}}} = \left(\frac{6}{\pi^3 G\mu_{\text{H}}} \right)^{1/2} \langle\sigma v\rangle K_i \simeq 17 K_{i-5}. \quad (51)$$

The fact that for typical interstellar conditions the ambipolar diffusion time is long compared to the free-fall time is extremely important, because it ensures that magnetically subcritical clumps do indeed evolve quasi-statically. Had we adopted a cylindrical or slab geometry, we would have obtained the same result but with the coefficient of K_{i-5} reduced by a factor of ~ 1.5 and 2, respectively.

2. Ambipolar Diffusion in Hydromagnetic Waves. Ion-neutral friction is an important damping mechanism for hydromagnetic waves. The propagation of these waves in the absence of thermal pressure or gravity has been described by Kulsrud and Pearce (1969), while Ferriere et al. (1988) have included the effects of pressure, and Langer (1978) and Pudritz (1990) have considered the effects of gravity. The basic physics can be extracted from Eqs. (46) and (47) (with the gravitational term omitted). At sufficiently low frequencies or low wavenumbers, the charged and neutral components are well coupled and the wave speed (the Alfvén velocity), $v_A = B/(4\pi\rho)^{1/2}$, is determined by the mass density of the entire medium. Equation (46) then yields the drift velocity $v_D = \omega\delta v/v_{ni}$ in terms of the wave amplitude δv . Now the energy density of the wave, including both magnetic and kinetic energy, is $\epsilon = \rho\delta v^2$, and the rate of energy dissipation is $\dot{\epsilon} = \rho v_{ni} v_D^2 = \rho\omega^2\delta v^2/v_{ni}$. In terms of the damping rate for the amplitude of the wave Γ , we have $2\Gamma\epsilon = \dot{\epsilon}$, which implies

$$\Gamma = \frac{\omega^2}{2v_{ni}}. \quad (52)$$

This heuristic argument tacitly assumes that $\Gamma < \omega$. According to Eq. (52), the waves are critically damped (i.e., $\Gamma = \omega$) at $\omega = 2v_{ni}$. This frequency corresponds to a wavenumber $k = 2v_{ni}/v_A \equiv k_{\text{cut}}$, above which we expect very little power. A more precise calculation (Kulsrud and Pearce 1969) shows that the real part of the frequency actually vanishes at $k = k_{\text{cut}}$. On the other hand, if the waves are emitted from a source, such as a collision between two clumps (Sec. III.B), then the frequency is real and the wavenumber complex; the damping length is about a wavelength at $k = k_{\text{cut}}$.

Hydromagnetic waves in which δB^2 varies on the scale of the wavelength (i.e., linearly polarized or unpolarized waves, not circularly polarized waves) steepen as they propagate, and this leads to nonlinear damping at a rate

$$\Gamma_{\text{nl}} \simeq kv_A \left(\frac{\delta B}{B} \right)^{q_d} \quad (53)$$

where $q_d = 1$ for magnetosonic waves propagating perpendicular to the magnetic field, and $q_d = 2$ for Alfvén waves propagating along the field (Cohen and Kulsrud 1974; Zweibel and Josafatsson 1983). Nonlinear damping exceeds ion-neutral damping for

$$k < k_{\text{nl}} \equiv k_{\text{cut}} \left(\frac{\delta B}{B} \right)^{q_d} = \frac{2v_{ni}}{v_A} \left(\frac{\delta B}{B} \right)^{q_d}. \quad (54)$$

Thus, large amplitude waves evolve by steepening until ion-neutral collisions damp them when the wavenumber has increased to of order the cutoff wavenumber k_{cut} .

B. Ambipolar Drift as a Heating Process

Frictional heating is an inevitable consequence of ambipolar diffusion, and occurs in both steady and fluctuating magnetic fields. Recall that the magnetic force density $\mathbf{J} \times \mathbf{B}/c$ is the sum of the magnetic pressure gradient $-\nabla B^2/8\pi$ and the magnetic tension $\mathbf{B} \cdot \nabla \mathbf{B}/4\pi$. If we define the characteristic length scale for variations in the magnetic field, ℓ_B , by $|\mathbf{J} \times \mathbf{B}|/c \equiv B^2/(4\pi\ell_B)$, then the drift velocity becomes

$$v_D = \frac{B^2}{4\pi\ell_B\rho v_{ni}} = \frac{v_A^2}{\ell_B v_{ni}} \quad (55)$$

from Eq. (47), and the heating rate is

$$\dot{\epsilon} = \rho v_{ni} v_D^2 = \frac{B^4}{(4\pi\ell_B)^2 \rho v_{ni}}. \quad (56)$$

Equation (56) is provocative but difficult to evaluate, because of the sensitivity to the length scale ℓ_B , which is very difficult to measure, and to B .

Scalo (1977) was the first to consider ambipolar diffusion heating of clouds by the mean magnetic field. He took ℓ_B to be about equal to the cloud size R , and he then calculated the equilibrium temperature as a function of density assuming $R \propto n^{-1/3}$ and $B \simeq (1.5\mu G)(0.6n_H)^y$. The resulting cloud temperatures were too high to be consistent with $y = 2/3$ but marginally consistent with $y = 1/2$ (corresponding to field strengths of $110 \mu G$ and $37 \mu G$ at $n_H = 10^3 \text{ cm}^{-3}$, respectively). In our notation, the heating rate in a static magnetic field under Scalo's assumption that $\ell_B = R$ is

$$\dot{\epsilon}_s = 2.6 \times 10^{-25} \left(\frac{B_{1.5}}{M/M_\Phi} \right)^2 \frac{n_3^{1/2}}{K_{i-5}} \text{ erg cm}^{-3} \text{ s}^{-1} \quad (57)$$

where we have used Eqs. (22) and (49). This estimate is quite crude: in order that $\ell_B \sim R$, it is necessary for the mass M to be close to the critical mass M_{cr} ; on the other hand, calculations show that clouds become highly centrally concentrated as $M \rightarrow M_{\text{cr}}$ (see, e.g., Tomisaka et al. 1988b), thereby violating the assumption that the density and field are approximately uniform. If the parameters entering Eq. (57) are set equal to unity, this heating rate is comparable to the cosmic-ray heating rate estimated by Goldsmith and Langer (1978), which is $3.2 \times 10^{-25} n_3 \text{ erg cm}^{-3} \text{ s}^{-1}$.

Lizano and Shu (1987) have gone beyond the crude gradient length scale parameterization by calculating the heating rates in models of self-gravitating, magnetically supported slabs (Shu 1983). In the case studied by Lizano and

Shu, the pressure is assumed to be provided by both a static magnetic field and by Alfvén waves with an energy density that is a fixed fraction of the mean magnetic energy density. Under these conditions, the field is largest in the midplane, whereas the field gradients are steepest in the outer parts of the slab. The results of Lizano and Shu show that ambipolar diffusion heating is most important in models with large field strengths, but that in any given model the heating increases with distance from the midplane, so much so as to produce a temperature inversion. It is not clear that this inversion would persist in a spheroidal cloud, however.

Hydromagnetic wave damping also heats the gas (Elmegreen et al. 1978; Zweibel and Josafatsson 1983). Noting that $v_D = \omega \delta v / v_{ni}$ from Eq. (46), we find that the heating due to waves of wavenumber k is

$$\epsilon_w = \frac{2}{3} \rho \delta v^2 \left(\frac{k^2 v_A^2}{v_{ni}} \right) = \frac{2}{3} \left(\frac{\delta v}{v_A} \right)^2 (kR)^2 \epsilon_s \quad (58)$$

where we have assumed that the turbulence is isotropic and we have neglected gravity; only the components of $\delta \mathbf{v}$ perpendicular to \mathbf{B} contribute to the heating. Wave heating is more effective than the static heating considered by Scalo if the wavelength is small and the amplitude of the waves large. As Elmegreen et al. (1978) point out, the heating rate will increase if the gas is compressed, as, for example, by a shock, because the compression increases both B and k . As an example of wave heating, consider the heating due to a spectrum of waves extending from k_{\min} to k_{\max} with $(\delta v^2)_k = \delta v^2 (k_{\min}/k^2)$; this is consistent with Larson's (1981) relation that the line width on a scale of R is proportional to $R^{1/2}$. One can readily show that the heating rate is given by Eq. (58) with k^2 replaced by $k_{\min} k_{\max}$. For a minimum wavenumber given by $k_{\min} R = 1$, and a maximum wavenumber corresponding to a wave with a damping length equal to the cloud diameter, $k_{\max} = (v_{ni}/R v_A)^{1/2}$, one finds that the heating rate is a little more than twice the static value given in Eq. (57). As Goldsmith and Langer (1978) show, cosmic ray heating is of the right order of magnitude to account for the observed temperatures of dark clouds, and it appears that wave heating is of comparable importance. Carlberg and Pudritz (1991) have come to a similar conclusion. Ferriere et al. (1988) have shown that hydromagnetic wave damping is an important heating mechanism in the intercloud gas in the ISM, which has a temperature of order 10^4 K, and it is possible that this process can heat the interclump gas in molecular clouds to a similar temperature (McKee 1989).

C. Effects of Ohmic Dissipation and Magnetic Reconnection

Ambipolar diffusion preserves the topology of the magnetic field, because the field lines are frozen to the charged component of the medium. Yet, topological change is an essential aspect of star formation: it must occur at some point between the time a molecular cloud forms with a field that is well connected with that of the diffuse interstellar medium, and the time a

star forms out of the cloud with a field that is substantially detached from the interstellar field. At present, we have no direct observational evidence as to when this reconnection occurs, which poses a substantial observational problem for the future.

Reconnection can occur only if the medium is resistive. A lower limit to the rate of reconnection is set by pure ohmic diffusion, which occurs on a characteristic time scale $t_{OD} \equiv 4\pi\ell_B^2/\eta c^2$, where ℓ_B is the characteristic length scale over which the field reverses direction and η is the resistivity. In molecular clouds, η is determined by electron collisions with neutral molecules, $\eta \sim \langle \sigma v \rangle_{en} m_e / e^2 x_i$. With the ionization fraction x_i given by Eq. (48), we have, in years

$$t_{OD} \sim \frac{5.9 \times 10^{20} \ell_{B,18}^2}{(n_H T)^{\frac{1}{2}}} \quad (59)$$

which is extremely long at normal molecular cloud densities. In order for this process to be competitive with ambipolar diffusion, the density must be very high, $\gtrsim 10^{12} \text{ cm}^{-3}$ (Umebayashi and Nakano 1990). In reality, dynamics plays a crucial role in reconnection, and the rate is intermediate between the diffusion rate t_{OD}^{-1} and the dynamical rate $t_{Alf}^{-1} \equiv (\ell_B/v_A)^{-1}$. Reconnection may occur spontaneously in a sheared magnetic field, due to instability, or may be externally driven by a flow. If reconnection is initiated by magnetic tearing instabilities (Furth et al. 1963) when the field becomes sufficiently sheared, then the growth time t_{rec} of these instabilities is roughly proportional to the geometric mean of the Alfvén crossing time t_{Alf} and the ohmic diffusion time t_{OD} , where in this case the length scale ℓ_B is the characteristic size of the shear layer. Rapid tearing requires very short gradient length scales for the magnetic field. Such scales may develop naturally through the interaction of the field and motions of the gas, even if the structure in the flow is on much larger scales (Moffatt 1978; Parker 1979). Hewitt et al. (1989) have shown that if ℓ_B becomes less than a mean free path, then the reconnection proceeds extremely efficiently.

It is possible that GMCs with large magnetic fields ($\bar{B} \gg B_0$) already have undergone a significant amount of reconnection, as the concentration of the field \bar{B}/B_0 can be much greater in magnetically disconnected clumps (Strittmatter 1966; Zweibel 1990b). These authors modeled the cloud as a homogeneous, isothermal body of gas with a uniform internal field \bar{B} (in our notation) immersed in a medium with a field $q\bar{B}$; for the case in which the temperature of the gas is negligible, so that $M_{cr} = M_\Phi$, their results imply that the coefficient in the magnetic critical mass (Eq. 23) is

$$c_\Phi = \frac{\sqrt{10}}{3\pi^2} \max [(1-q)(1+3q)]^{1/2} = 0.123 \quad (60)$$

in close agreement with the result of Mouschovias and Spitzer (1976) and Tomisaka et al. (1988b). (The maximum occurs at $q = 1/3$, which is significantly smaller than the values of q in the numerical models, however.) They

showed that for q less than some critical value q_c , the field develops a partially closed topology. For spherical clouds, $q_c = 1/3$; for a flattened disk, $q_c \rightarrow 1$, so that a flattened cloud with $q = 1/3$ would have a substantially closed topology. For fixed q , the coefficient c_Φ is given by Eq. (60) without the "max." This suggests that a cloud with a substantially closed field topology has a magnetic critical mass close to that for a connected topology, although this should be verified by accurate numerical calculation. This conclusion is consistent with the result of Tomisaka et al. (1988*b*) that it is primarily the central-flux-to-mass ratio that determines the stability of the cloud.

In a prescient paper, Mestel and Strittmatter (1967) considered the resistive relaxation of a magnetic field which had been drawn in by rapid collapse (Mestel 1966*a*). The field evolves from fully connected to partially connected, and eventually returns to its initial uniform configuration. As they pointed out, the resistivity in interstellar clouds is too low for this process to be of importance there (their work was done prior to the discovery of molecular clouds, so they considered atomic clouds). It is now known that in the later stages of gravitational collapse, the resistivity becomes sufficiently large that the ohmic diffusion time becomes shorter than the dynamical time (Umebayashi and Nakano 1990), making their work of greater relevance than they foresaw.

Reconnection may also play a role in the internal structure of a molecular cloud. If the magnetic field of a GMC is weaker than the equipartition value of $(12\pi\bar{\rho}\sigma^2)^{1/2}$, and if the clumps which dominate the inertia are not so small that ambipolar diffusion rapidly removes the flux, then it appears inevitable that the field becomes tangled by the motions of the gas and thereby subject to reconnection. For example, Clifford and Elmegreen (1983) show sketches of misaligned magnetic flux tubes brought into proximity by the motion of the clumps to which they are attached. Magnetic reconnection in the interclump medium would have several important consequences: the field could be kept fairly smooth instead of progressively more tangled; the field would gradually become detached from the mean interstellar field; once a clump had a disconnected field, it would interact with the field of the rest of the cloud much more weakly; and magnetic braking, in which angular momentum is carried away along the interclump field lines (see Sec. IV.B above), would proceed quite differently (Kulsrud 1971). Reconnection could also lead to heating and particle acceleration. It is clear that magnetic reconnection remains one of the major problems of plasma astrophysics, and is crucial to our understanding of the evolution of magnetic fields in star-forming regions.

VI. AMBIPOLAR DIFFUSION AND FLUX REDISTRIBUTION: ROLE IN STAR FORMATION

As discussed in the Sec. I, magnetic fields are intrinsic to two of the classical problems of star formation, the magnetic flux problem and the angular momentum problem. The discussion in the Chapter by Heiles et al. and in Secs.

II–V has demonstrated the importance of magnetic fields in the structure of the molecular clouds out of which stars are born. However, once the stars have formed, magnetic fields are no longer energetically significant. To see this quantitatively, note that Eq. (25) indicates that the ratio of the mass to the magnetic critical mass, M/M_ϕ , is typically within an order of magnitude of unity for either diffuse atomic clouds with fields of order $3\ \mu\text{G}$, or molecular clouds with fields of order $30\ \mu\text{G}$. A star like the Sun, however, has a magnetic critical mass $M_\phi = 0.12\pi R^2 \bar{B}/G^{1/2} \simeq 3 \times 10^{-6} M_\odot$, even if the mean field is $10^3\ \text{G}$. Thus, for such a star $M/M_\phi \sim 10^{5.5}$, virtually all the flux in the initial molecular cloud has been lost, and the magnetic energy is negligible. There is general agreement that ambipolar diffusion is a significant mechanism for flux loss (Mestel and Spitzer 1956); reconnection may also be important (Mestel 1965*b*; Mestel and Strittmatter 1967). The question is, when does the flux loss occur—in the interstellar or in the protostellar stage? The answer to this question is essential if one is to solve the angular momentum problem, as it determines the efficiency with which the fields can remove the angular momentum of the contracting gas through magnetic braking.

A. Magnetically Subcritical vs Magnetically Supercritical Star Formation

For a frozen-in field, magnetically subcritical clouds (those with $M < M_\phi$) can never undergo gravitational collapse, whereas magnetically supercritical clouds ($M > M_\phi$) can never be prevented from collapse by the magnetic field (Sec. II). The evolution of these types of clouds is therefore quite different (Mestel 1985): magnetically subcritical clouds evolve on an ambipolar diffusion time scale, which is generally quite long (Sec. V.A), whereas magnetically supercritical clouds evolve on a dynamical time scale set by the rate of dissipation of the internal turbulence and the rate of loss of angular momentum. This distinction has led Shu et al. (1987*b*) to suggest that magnetically subcritical clouds are associated with low-mass star formation, which is observed to occur at a relatively low efficiency, whereas magnetically supercritical clouds form stars with a relatively high efficiency, and may preferentially form high-mass stars.

This distinction can be refined somewhat. Magnetically subcritical clumps evolve via ambipolar diffusion until their cores become magnetically supercritical. The subsequent “inside-out” collapse (Shu et al. 1987*b*) is supercritical, but it occurs around a well-defined core. As the core will have some angular momentum, it will form a disk upon collapse (Terebey et al. 1984) at the same time the star is forming. However, the collapse of a supercritical clump is quite different, particularly if the angular momentum is low. In this case, there is no well-defined initial core, so the collapse is like that considered by Zel’dovich (1970) for the formation of large-scale structure in the Universe: the clump will first collapse into a sheet (a “pancake”) and then fragment. In other words, disk formation precedes star formation in the supercritical case. Having the disk form before the star could resolve a difficulty in

forming massive stars (Nakano 1989*b*), because spherically symmetric models indicate that the radiation pressure on dust grains (assuming the standard dust-to-gas ratio) is too great to allow massive stars to form by spherical collapse (Wolfire and Cassinelli 1987). The formation of a ring of massive stars in W49A (Welch et al. 1987) is a possible example of supercritical star formation on a large scale.

B. Magnetic Flux Loss in Magnetically Subcritical Star Formation

Consider an isolated, magnetically subcritical clump in a molecular cloud. In view of the efficiency of magnetic braking (Sec. IV), assume that the cloud is not rotating. Under the influence of ambipolar diffusion, the clump will evolve toward greater densities until either it settles into a stable pressure-supported configuration (a “failed core” in the terminology of Lizano and Shu [1989], which is possible for $M < M_J$), or it begins a supercritical collapse leading to the formation of a star. Most studies of this problem have concluded that only a modest amount of magnetic flux can be lost in this “interstellar” stage of star formation (Nakano 1979, 1982, 1983; Nakano and Umebayashi 1986*a, b*; Umebayashi and Nakano 1990; Black and Scott 1982; Mestel and Paris 1984; Mestel 1985; Lizano and Shu 1989; Tomisaka et al. 1990). These studies indicate that there are several distinct stages in the evolution of the clump:

1. *Core Formation.* So long as $M < M_{cr}$, the clump contracts quasi-statically due to ambipolar diffusion. The flux leakage occurs primarily from the central region of the clump, redistributing the flux into the outer parts of the clump (Mouschovias 1976*b*; Nakano 1979). As a result M_ϕ , and therefore M_{cr} , drop, and a cloud core forms that is in approximate gravitational virial equilibrium. The mass of the core is approximately equal to the mass of the star (or stars) that will eventually form; the outer parts of the clump, being magnetically subcritical, cannot undergo collapse (Mouschovias 1976*b*; Nakano 1979). Because interstellar clouds typically have $M/M_\phi \gtrsim 0.1$, only a small fraction of the magnetic flux problem can be solved in this stage. Nonetheless, the long time scale associated with this stage has a major effect on the evolution of the cloud (Mouschovias 1977) and on the rate of star formation (Sec. VI.C).

2. *Dynamical Collapse.* Once M_{cr} drops below M , gravity exceeds the combined effects of gas pressure and magnetic fields and collapse ensues. So long as the ambipolar drift velocity is small compared to the infall velocity, the flux-to-mass ratio remains approximately constant. Now the free-fall velocity is $v_{ff} = (2GM_t/R)^{1/2}$, where $M_t \equiv M + M_*$ is the sum of the mass of the infalling gas M and the mass of a central protostar/disk if one has formed. The ratio of the free-fall velocity to the ambipolar drift velocity v_D is essentially the same as the ratio t_{AD}/t_{ff} given in Eq. (51), without the assumption of hydrostatic equilibrium. Setting the magnetic scale length ℓ_B

in Eq. (55) equal to R , we find

$$\frac{v_{ff}}{v_D} \simeq 11 \left(\frac{M}{M_\Phi} \right)^2 \left(\frac{M_t}{M} \right)^{1/2} \left(\frac{R}{Z} \right)^{3/2} K_{i-5}. \quad (61)$$

Insofar as any flux leaks out in the collapse stage, M/M_Φ increases and the field becomes more tightly coupled to the gas, reducing the rate of flux loss; in other words, a weaker field is less effective at driving the charged particles through the neutrals (see also Mouschovias 1989)

3. Magnetic Decoupling. Substantial flux loss can occur in the collapse only when the ionization parameter K_i drops below its normal interstellar value so that the drift velocity v_D becomes comparable to the free-fall velocity v_{ff} . Nakano and Umebayashi (1986*a, b*) find that this occurs only for densities $n_H \gtrsim 10^{12} \text{ cm}^{-3}$. For the cases they considered, such high densities are reached only after the gas is within a few AU of the protostar, i.e., the decoupling occurs at protostellar, rather than interstellar, densities. These densities are sufficiently high that ohmic dissipation is comparable to ambipolar diffusion: the field is no longer even well coupled to the charged particles. More recent calculations, including more accurate chemical reactions (Umebayashi and Nakano 1990) and allowing for the effect of a distribution of grain sizes (Nishi et al. 1991) show that the critical density at which the field decouples from the gas may be as low as $2 \times 10^{10} \text{ cm}^{-3}$.

4. Magnetic Recoupling. When the contracting core becomes opaque, the temperature rises, eventually re-ionizing the gas and trapping the flux. When allowance for rotation is made, much of the flux will be in the accretion disk surrounding the protostar, as discussed in the Chapter by Königl and Ruden.

An alternative view of magnetic flux loss in low-mass star formation has been given by Mouschovias and his collaborators (Mouschovias 1979; Mouschovias and Paleologou 1981; Mouschovias et al. 1985; Mouschovias 1987*a, b*; Mouschovias and Morton 1991). Much of this work focused on ambipolar diffusion in a slab with a magnetic field in the plane of the slab, and led them to the conclusion that the flux loss occurs at interstellar ($n_H \lesssim 10^7 \text{ cm}^{-3}$) rather than protostellar densities. That their solutions are basically correct has been verified analytically by Shu (1983). However, the relevance of their solution to the astrophysical problem has been questioned by Mestel (1985) and by Lizano and Shu (1989), who point out that gravity saturates in one dimension; i.e., the force on a given mass element is independent of its height above the midplane. Tomisaka et al. (1990) have also shown that the evolution of the mass-to-flux ratio in a planar geometry is quite distinct from that in a spherical geometry. More generally, the distinction between a spherical collapse on the one hand and a planar or cylindrical collapse on the other is that the latter two are always magnetically subcritical: in these cases, the magnetic forces (assuming a frozen-in field) will always exceed the gravitational ones under sufficient compression. To see this, recall that

the pressure due to gravity at the center of any of these configurations is $P_{\text{gr}} \sim G\Sigma^2$ from the equation of hydrostatic equilibrium. (Note that Σ for the cylinder is measured for a surface containing the axis.) Comparing this with the magnetic pressure $P_B = B^2/8\pi$, we have

$$\frac{P_B}{P_{\text{gr}}} \sim \frac{B^2}{G\Sigma^2} \propto \begin{cases} L^{-2}/L^0 = L^{-2}, & \text{slab} \\ L^{-4}/L^{-2} = L^{-2}, & \text{cylinder} \\ L^{-4}/L^{-4} = L^0, & \text{sphere.} \end{cases} \quad (62)$$

Hence, for both the slab and cylindrical geometries, the magnetic forces dominate at sufficiently small scales, so that they can never be truly supercritical; in the spherical case, the magnetic and gravitational forces scale in the same manner, which is what enabled us to introduce the magnetic critical mass in Sec. II. A spheroid which is very oblate is similar to a slab with the field perpendicular to the plane; in contrast to the slab with the in-plane field, there is a critical surface density $\propto B/G^{1/2}$ in this case, and the cloud can be supercritical. On the other hand, a spheroid which is very prolate behaves like a cylinder provided the contraction velocity along the field is not much greater than that in the perpendicular direction; such a prolate spheroid cannot be magnetically supercritical. The distinction between the planar and cylindrical geometries on the one hand and the spherical geometry on the other can be succinctly summarized: a cloud with a uniform magnetic field can be magnetically supercritical only if flow is permitted along field lines; in the absence of such flow, the magnetic pressure will eventually dominate the pressure due to self gravity as the cloud contracts.

The consequence of this distinction is that gravitational collapse cannot occur in one or two dimensions so long as flux freezing holds; as Mouschovias and Morton (1991) state, collapse in these cases can occur only as a result of ambipolar diffusion. As flux-freezing collapse *can* occur in three dimensions, calculations in one or two dimensions are of limited relevance to resolving the magnetic flux problem in star formation, a point acknowledged by Mouschovias (1989). Theoretical modeling of collapse in three dimensions demonstrates that the magnetic flux problem must be resolved at high densities (at least $\gtrsim 10^{10} \text{ cm}^{-3}$, and probably $\gtrsim 10^{11} \text{ cm}^{-3}$).

There is a further difficulty with the slab and cylindrical geometries, which has been pointed out by Nakano (1984). If the thermal pressure is small, then the Jeans length will be small compared to L and the cloud will fragment, losing its cylindrical symmetry; on the other hand, if the gas pressure is large enough to overcome this difficulty, then the rate of ambipolar diffusion is substantially reduced.

Numerical calculations of three-dimensional, axisymmetric collapse with ambipolar diffusion have been carried out by Black and Scott (1982). The simple form, Eq. (48), for the ionization breaks down at high density, so they adopted an ionization that varies as a power of the density, $x_i \propto n^{-q_i}$. To represent this case, the parameter K_i must vary as $n^{-(q_i-1/2)}$; recall that

$q_i = 1/2$ for the case of cosmic-ray ionization discussed in Sec. V.A above. Once the dynamical collapse has begun, the flux remains frozen so long as $v_{ff} \gg v_D$. If q_i exceeds $1/2$, however, K_i drops and eventually $v_D \simeq v_{ff}$. Now note that in Eq. (61), $M/M_\phi \simeq \Sigma/B$, where $\Sigma = M/\pi R^2$ is the surface density; then $v_{ff}/v_D \propto \Sigma^2 K_i/B^2$. If the drop in the ionization is slow enough that $\Sigma^2 K_i$ increases with density, then B will continue to increase as well, though perhaps more slowly than when the flux was frozen, and v_D will remain of order v_{ff} . On the other hand, if the ionization drops so rapidly that $\Sigma^2 K_i$ decreases with density, then the field is essentially completely decoupled from the neutrals and B will tend to remain constant as the density increases. (Equation [61] does not apply in this case because the magnetic scale length ℓ_B becomes much greater than R .) These three cases correspond qualitatively to the three types of solution found by Black and Scott (1982).

In summary, the controlling factors in magnetic flux loss are the geometry and ionization. For the idealized case of a planar contraction perpendicular to \mathbf{B} , the magnetic field will tend to prevent gravitational collapse; as a result, the flux loss will occur on the ambipolar diffusion time scale at relatively low densities. For the more realistic case of a three-dimensional collapse, the flux remains approximately frozen to the gas so long as the ionization varies as $n^{-1/2}$; in this case, the flux loss must occur at high densities.

C. Magnetic Fields and the Rate of Star Formation

In order for a clump of gas to collapse, it must overcome the combined effects of gas pressure (represented by M_J), magnetic fields (M_ϕ), and angular momentum (M_{rot}); in other words, its mass must exceed the critical mass M_{cr} given in Eq. (41). We have seen that angular momentum is generally rendered unimportant by magnetic braking, so we focus on M_J and M_ϕ . For a molecular cloud which is at a substantially higher pressure than its surroundings, we have argued that the mass must be close to M_{cr} and therefore must exceed both M_J and M_ϕ (see Sec. II). On the other hand, prior to ambipolar diffusion, stellar mass clumps inside molecular clouds are by and large magnetically subcritical—the magnetic mass M_B is typically of order $10^{2.5} M_\odot$ according to Eq. (27) with $n_H \sim 10^3 \text{ cm}^{-3}$ and $B \sim 30 \mu\text{G}$. Magnetically supercritical clumps ($M > M_\phi$, or, equivalently, $M > M_B$) may have subclumps and are therefore potential sites of both subcritical and supercritical star formation (Sec. VI.A).

Subcritical star formation is believed to be the dominant mode of star formation in the Galaxy (Shu et al. 1987a), and it proceeds via ambipolar diffusion. McKee (1989) has estimated the rate of star formation in molecular clouds on the basis that the rate is set by the ambipolar diffusion time in the typical molecular gas, which has a density $n_H \sim 10^3 \text{ cm}^{-3}$; the higher-density gas seen in molecular cloud cores has presumably already undergone ambipolar diffusion and is now close to forming stars. Penetrating far-ultraviolet radiation can photo-ionize metals such as magnesium and iron until the extinction exceeds a few, and the ambipolar diffusion time in this photo-ionized

gas is quite long. As a result, most of the star formation occurs in the shielded regions of the cloud where cosmic-ray ionization is dominant. For typical conditions in the Galaxy, McKee (1989) estimates that the star-formation time in a molecular cloud with a mean visual extinction \bar{A}_V is,

$$t_{g*} \equiv \frac{M}{\dot{M}_*} \simeq \frac{2 \times 10^7}{n_3^{1/2}} \exp(16/\bar{A}_V) \text{ yr} \quad (63)$$

where \dot{M}_* is the rate at which mass in the cloud is converted into stars. The star-formation time scale is exponentially sensitive to the mean extinction; cold molecular clouds with $\bar{A}_V \sim 2$ (Falgarone and Puget 1986) should have little star formation. On the other hand, typical warm molecular clouds with $\bar{A}_V \simeq 5$ to 7 should have $t_{g*} \sim 3 \times 10^8$ yr. If about half the molecular gas in the Galaxy is warm (Solomon and Rivolo 1989), corresponding to about $10^9 M_\odot$, this gives a galactic star-formation rate of $3 M_\odot \text{ yr}^{-1}$, consistent with observation.

Star formation can also be induced—triggered by a mechanism external to the clump—although this is believed to be less important than the spontaneous mechanism just described. Shocks, which can be due to supernovae or to cloud–cloud collisions, have been invoked frequently as a mechanism for inducing star formation. Elmegreen and Elmegreen (1989) have argued that, so long as flux freezing holds, magnetic fields can inhibit this process. For magnetically subcritical clumps, this conclusion is obvious, because compression, unless predominantly along the field, leaves M/M_ϕ less than unity so that the clump remains stable. For magnetically supercritical clumps, their argument can be strengthened as follows. The condition for star formation to be induced is that the ratio of the free-fall time t_{ff} to the dynamical time t_d must decrease as a result of the shock. For cloud–cloud collisions and for shocks striking clouds which are not too small, the dynamical time is simply $t_d = L/\sigma$, where L is the characteristic size of the compressed region (e.g., the thickness of the shocked layer for a one-dimensional compression). Now the velocity dispersion is $\sigma = (P/\rho)^{1/2} \propto \rho^{(\gamma-1)/2}$; if the compression occurs in ν dimensions, so that $\rho \propto L^{-\nu}$, then we have

$$\frac{t_{ff}}{t_d} \propto \frac{\rho^{-1/2}}{L/\sigma} \propto \rho^{\frac{\gamma}{2} + \frac{1}{\nu} - 1}. \quad (64)$$

For a magnetically supercritical clump, the gas pressure is dominant and $\gamma \sim 1$; three-dimensional contraction can lead to gravitational collapse, but in the more likely case in which the shock compression is primarily one dimensional, collapse usually will not occur. The only way that one-dimensional compression can lead to collapse is if the cloud is initially magnetically supported and if the compression along the field is sufficient to render the cloud magnetically supercritical while leaving $t_{ff}/t_d < 1$. If the cloud is initially supported by gas pressure ($M < M_J$ and $M > M_\phi$), and if $\gamma \gtrsim 1$, then

the compression must be approximately three dimensional to induce collapse. On the other hand, if the compression leads to a phase change (e.g., 100 K atomic gas to 10 K molecular gas), then γ is significantly less than unity and compression can lead to collapse over a wider range of conditions.

Under what conditions can induced star formation occur? In a classic paper, Elmegreen and Lada (1977) showed that ionization-shock fronts driven by associations of massive stars can drive gas along the mean field direction until it becomes magnetically supercritical and another generation of massive stars can form. This model fits the observations of Orion reasonably well, but the universality of the mechanism remains to be established. Scoville et al. (1987) have argued that the correlation of giant H II regions with molecular gas indicates that star formation can be induced by collisions between molecular clouds. The argument summarized in Eq. (64) suggests that the compression itself is not effective in accelerating the rate of star formation, because the hydrodynamic expansion time of two clouds which have collided is reduced more than the gravitational contraction time. What the collision does, however, is to increase dramatically the mass of molecular gas that is shielded from far-ultraviolet radiation; this can increase the rate of star formation by increasing the rate of ambipolar diffusion in the clumps comprising the combined clouds (McKee 1989). Pringle (1989c) has argued that the prevalence of binary stars can be best understood if most low-mass star formation is induced by collisions among weakly magnetized clumps that are close to gravitational collapse, in contrast to the canonical view of low-mass star formation summarized by Shu et al. (1987b).

Star formation can also be induced by the three-dimensional, radiation driven implosion of a clump of gas exposed to the ionizing radiation of one or more massive stars (Klein et al. 1983). Radiation-driven implosion is the first stage of cloud photoevaporation (Bertoldi 1989); if the clump is initially magnetically supercritical, as assumed by Klein et al. (1983), or if the core of the clump becomes supercritical as a result of ambipolar diffusion in the shocks compressing the clump (Bertoldi et al. 1991), then star formation can occur promptly. Possible evidence for the latter process has been found by Sugitani et al. (1989), who have observed molecular outflows in several bright-rimmed globules associated with H II regions.

In summary, low-mass star formation in the Galaxy appears to be due primarily to the gravitational collapse of clumps which are initially magnetically subcritical and become supercritical as a result of ambipolar diffusion. In principle, the formation of both low-mass and high-mass stars can be induced by shock compression, but only in certain cases. For a magnetically supercritical clump with $\gamma \sim 1$, the compression must be approximately three dimensional to induce collapse, as in the case of radiation-driven implosions. For a magnetically subcritical clump, induced star formation requires either compression along the field, as in the Elmegreen-Lada mechanism, or enhanced ambipolar diffusion as a result of increased density, reduced flux of ionizing radiation, or steeper gradients associated with shocks.

VII. MAGNETIC EVOLUTION OF MOLECULAR CLOUDS

We conclude our discussion of magnetic fields in molecular clouds by addressing a basic question: how did the fields in these clouds evolve from the much weaker field observed in the diffuse interstellar medium? As a first step, we may determine the volume of interstellar medium out of which the cloud formed, the accumulation volume (Mestel 1985; McKee and Lin 1988). For simplicity, we assume that the accumulation volume is an ellipsoid of radius R_0 normal to the field and length L_0 along the field. The mass $M = 2\pi R_0^2 L_0 n_0 \mu_H / 3$ and (assuming flux freezing) the flux $\Phi = \pi R_0^2 B_0$ are the same for the accumulation volume as for the actual cloud. Then the length of the accumulation volume is readily shown to be,

$$L_0 = 96 \left(\frac{B_{0\mu}}{n_0} \right) \frac{M}{M_\Phi} \text{ pc} \quad (65)$$

and the radius is

$$R_0 = 380 \left(\frac{M_6}{B_{0\mu}} \right)^{1/2} \left(\frac{M}{M_\Phi} \right)^{-1/2} \text{ pc} \quad (66)$$

where $B_{0\mu} = B_0 / 1 \mu\text{G}$ and $M_6 = M / 10^6 M_\odot$. Our value for L_0 is smaller than Mestel's (1985) because our value of M_Φ is smaller than his. Note that L_0 is independent of the size of the molecular cloud: the assumption of flux freezing implies that M/M_Φ is the same for the accumulation volume as for the final cloud, so that $M/M_\Phi \propto \Sigma/\bar{B} \propto n_0 L_0 / B_0$. For the typical case $n_0 = 1 \text{ cm}^{-3}$, $B_0 = 3 \mu\text{G}$, and $M = 2M_\Phi$, this length is about 600 pc. Under the same conditions, the radius is about $250 M_6^{1/2} \text{ pc}$, so that the accumulation volume of a $10^6 M_\odot$ cloud is roughly spherical. For such large molecular clouds this radius exceeds the scale height of the gas in the galactic disk, so the accumulation volume is actually triaxial for such clouds, with R being the geometric mean of the radii normal to the field. The accumulation volume is large enough to contain many diffuse interstellar clouds, which subsequently become the initial clumps in the molecular cloud (Elmegreen 1985a). These same equations apply to the accumulation volume for a clump in a GMC which originates as a diffuse interstellar cloud, as suggested by Elmegreen (1985a). As the magnetic field in a diffuse interstellar cloud is comparable to the mean interstellar field, the accumulation length L_0 for a clump is smaller than that for a GMC by the ratio of the initial density of the diffuse cloud to the mean interstellar density, and the mass of the clump is correspondingly smaller as well.

What is the physical process that causes the gas in the accumulation volume to condense into a molecular cloud? Elmegreen (1990a) has reviewed the various cloud formation mechanisms that have been proposed—cloud coalescence due to cloud-cloud collisions, gravitational instability in the gas, including the Parker instability (Parker 1966), and shock compression—and

he concludes that gravitational instability is the most promising explanation at present. The importance of the self-gravity of the gas in the process of cloud formation is demonstrated by the fact that the length scale for the Jeans instability is comparable to L_0 . Define the effective scale height of the gas in the disk, H_{eff} , by $\Sigma_d = 2\rho_0 H_{\text{eff}}$, where Σ_d is the total surface density of gas in the disk and ρ_0 is the gas density in the midplane. This scale height is less than the value it would have in the absence of other matter in the disk by a factor f_g :

$$H_{\text{eff}} = f_g \left(\frac{\sigma^2}{2\pi G \rho_0} \right)^{1/2}. \quad (67)$$

Because the density of the gas in the solar neighborhood is about 1/4 of the total density (Binney and Tremaine 1987), and its scale height is less than that of the stars, f_g is of order 0.5 in the galactic disk. In terms of this scale height, half the minimum wavelength for the Jeans instability is $\pi(\sigma^2/4\pi G \rho_0)^{1/2} = \pi H_{\text{eff}}/(f_g \sqrt{2})$. Now consider the accumulation length L_0 . Adapting Parker's notation, we write $B_0^2/8\pi = \alpha_B P_0$; it is then straightforward to show that

$$\frac{L_0}{H_{\text{eff}}} = 2.26 \frac{\alpha_B^{1/2}}{f_g} \left(\frac{M}{M_\Phi} \right). \quad (68)$$

For typical values $\alpha_B \sim 0.1 - 0.2$, $f_g \sim 0.5$, and $M \sim 2M_\Phi$, this result leads to an accumulation length $L_0 \simeq (3 \sim 4)H_{\text{eff}}$, in agreement with the Jeans length. Thus self-gravity must play a role in the formation of giant molecular clouds. This could have been foreseen: because the ratio M/M_Φ is constant as the cloud contracts from its initial state in the diffuse ISM, the fact that gravity is important in the final cloud implies that it was in the initial cloud as well.

When the rotation of the Galaxy is included, the normal criterion for gravitational instability is that $Q \equiv \kappa \sigma / (\pi G \Sigma_d) \lesssim 1$ (Toomre 1964), where κ is the epicyclic frequency. This condition ensures that there is a range of wavelengths which exceed the Jeans length, but are small enough that they are not stabilized by rotation. Elmegreen (1987c, 1989c), however, has suggested that magnetic fields render this criterion irrelevant, based on the fact that an arbitrarily weak magnetic field normal to the rotation axis eliminates rotational stabilization (Chandrasekhar 1961). Physically, this destabilization occurs because the field, given enough time, can prevent the gas from spinning up as it contracts. As we have seen in Sec. IV.B, this magnetic braking is highly efficient for observed field strengths. How then can one account for the observation that the criterion $Q \lesssim 1$ describes the onset of star formation in external galaxies extremely well (Quirk 1972; Kennicutt 1989)? In other words, why do not magnetic fields permit star formation to occur at lower surface densities, albeit more slowly? We conjecture that this is because galactic disks are differentially rotating: a perturbation with $Q > 1$ will be destroyed by shear unless the field is so strong that it can maintain

rigid rotation. Recent calculations by Elmegreen (1991a) demonstrate that fragmentation of shearing perturbations does in fact require $Q \lesssim 1$.

It appears, then, that regions of a galactic disk which accumulate enough gas so that $Q \lesssim 1$ will be subject to gravitational instability, perhaps aided by the buckling of the magnetic field as envisioned by Parker. As the gas in the accumulation volume contracts, the mean magnetic field will grow as $B \simeq 5\bar{A}_V$ for $M \simeq 2M_\phi$ (Eq. 25); the initial extinction of the accumulation volume is 0.6 mag for an initial field of $3 \mu\text{G}$. The field begins to deviate significantly from its interstellar value for $\bar{A}_V \sim 1$, which is also the point at which clouds become substantially molecular in the solar neighborhood. So long as the mean extinction is relatively low, star formation is inhibited (McKee 1989) and the clouds remain cold; Perault et al. (1985) have studied a population of such clouds with a mean extinction $\bar{A}_V \sim 2$. The energy dissipation in a magnetized cloud is relatively inefficient (Elmegreen 1985b), so that molecular clouds should contract gradually, over several free-fall times (Carlberg and Pudritz 1991). The morphology of the clumps in the cloud will evolve as the cloud contracts: on the one hand, the gradual increase in the mean field will tend to squeeze non-self-gravitating clumps out into filamentary structures, such as those observed by Bally et al. (1987); on the other hand, this tendency to form structures along the field will be counteracted by the increase in the density as the gas converts from atomic to molecular form and gradually cools to 10 K. Isolated molecular clouds will evolve with M/M_ϕ constant. If clouds coalesce (which should be relatively unimportant at typical cloud-cloud velocity dispersions according to Elmegreen [1990a]), M/M_ϕ will increase unless the two clouds are on completely separate flux tubes. As the cloud contracts, it becomes increasingly shielded from the interstellar radiation field, reducing the ionization and permitting more rapid star formation. When the mean extinction of the cloud reaches $\bar{A}_V \sim 6$ to 8, whether through contraction alone or through contraction abetted by coalescence, the energy injection from the bipolar flows of newly formed stars can slow, or perhaps halt, the further contraction of the cloud (Norman and Silk 1989a; McKee 1989); such clouds correspond to the warm molecular clouds studied by Scoville et al. (1987) and Solomon et al. (1987). At this stage, the mean magnetic field is ~ 30 to $40 \mu\text{G}$, ~ 10 times the interstellar value. Eventually, the cloud is disrupted by the formation of massive stars, and the cycle begins anew.

VIII. CONCLUSION

Substantial progress has been made toward the solution of the two classical problems of star formation, the angular momentum problem and the magnetic flux problem. Magnetic braking appears to be relatively efficient, although it would be worthwhile to have more extensive observations of cloud rotation in order to test the theory more precisely. For low-mass stars, the loss of magnetic flux is thought to occur in two stages. First, ambipolar diffusion permits a

clump which was initially magnetically subcritical to evolve to the point that it is magnetically supercritical and to begin its collapse. The second stage, in which most of the flux is lost, must occur at relatively high densities, but the details remain obscure because of uncertainties in the ionization associated with tiny grains and large molecules; direct observation of the ionization in cloud cores would represent a major advance. The formation of massive stars is less well understood. They may form from clumps which are initially magnetically supercritical, and in this case disk formation may precede star formation. Star formation can also be induced by an external mechanism, such as a shock, which acts to reduce the flux-to-mass ratio; this may occur directly, by driving gas along the field, or indirectly, by accelerating the rate of ambipolar diffusion.

There is a third problem, however, on which less progress has been made. For want of a better name, we shall term it the magnetic topology problem: how does the topology of the field evolve as a molecular cloud forms out of the ISM and as clumps within the cloud contract to form stars? This problem has several aspects. One of the most basic is the determination of when the field in a protostellar clump becomes disconnected from the field in the ambient molecular cloud. The topology of the field of the cloud as a whole is also uncertain; the observations summarized in the Chapter by Heiles et al. suggest that the ratio of mean field in a cloud to the ambient field (up to a factor 10) is well beyond that of any published theoretical models. This poses the observational challenge of determining if and how the cloud field joins up with the ambient interstellar field, perhaps in the H I envelope surrounding the cloud; and it poses the theoretical challenge of producing models which can match these observations. Given the rate at which the field is advancing, we anticipate substantial progress on these issues will have been made by the time that the "Protostars and Planets IV" book is written.

Acknowledgments. We wish to thank F. Shu for suggesting that we undertake this review and for helpful comments. We are grateful to F. Bertoldi, B. Elmegreen, E. Falgarone, L. Mestel, T. Mouschovias and R. Pudritz for useful remarks. The research of CFM on star formation is supported by a NASA grant to the Center for Star-Formation Studies; his research on the interstellar medium is supported by a grant from the NSF. EGZ acknowledges support also through an NSF grant to the University of Colorado and to the Institute for Theoretical Physics, where a portion of this chapter was written. AG is supported in part by a President's Fellowship at UC Berkeley. CH acknowledges with pleasure the hospitality of the Joint Institute for Laboratory Astrophysics. His research is supported in part by a grant from NSF.

STELLAR MULTIPLE SYSTEMS: CONSTRAINTS ON THE MECHANISM OF ORIGIN

PETER BODENHEIMER

University of Wisconsin

The discovery rate of pre-main-sequence binary and multiple systems has increased dramatically over the last few years, providing us with our first insights into the nature of such systems at young ages. The observational data derived from spectroscopic, occultation, speckle, visual, and other techniques are reviewed. Where possible, the pre-main-sequence binary population is compared with main-sequence systems. These results are interpreted in terms of binary formation mechanisms. While wide binaries ($P > 100$ yr) are ordinarily explained by a fragmentation process during the collapse of a rotating protostar, origin of some systems by capture is a possibility. The origin of close systems is not well understood: various processes, such as fragmentation during late stages of collapse, gravitational instabilities in disks, or orbital decay from a longer-period system are examined. Many important questions remain unanswered: (1) Can binary formation be explained by a single process for all separations? (2) What is the origin of the angular momentum of binary systems? (3) Under what circumstances do single stars rather than binaries form? (4) What is the relationship between disks and binaries? Speculations regarding these questions are discussed with reference to the evolution of the angular momentum distribution in collapsing protostars and circumstellar disks.

I. INTRODUCTION

The observational discovery of binary and multiple systems among young stars and the quest for clarification of the mode of origin of these systems is a complicated subject and one that has developed rapidly in the past few years. This review summarizes recent observational and theoretical results, concentrating on the solar mass range. Further information may be found in the reviews of observational material by Abt (1983), Reipurth (1988), Mathieu (1989) and Zinnecker (1989a) and in the reviews of theoretical material by

Tassoul (1978), Lucy (1981), Zinnecker (1984*a*), Boss (1988,1989), Miyama (1989*a*), Lebovitz (1989), Durisen et al. (1989*a*), Verbunt (1989) and Pringle (1991). The issue of the presence of low-mass companions is not dealt with at length, but recent discussions have been presented by Zuckerman (1989) and Latham (1989). In Sec. II we discuss the observational material. The main-sequence binary population in the solar mass range has been studied extensively, and the systematic behavior that is found must be explained by any theory of binary origin. Pre-main-sequence binaries provide information closer to the time of origin; observational searches are just now entering the phase of systematic surveys. Information has been obtained by several methods: spectroscopic, lunar occultation, speckle and slow slit scan techniques, and optical and infrared imaging. One purpose of the observations is to provide constraints on the mechanism or mechanisms of binary origin. Section III then considers the important question of the available angular momentum in the precursor material out of which the binaries form. The fate of a collapsing cloud depends strongly on the value and distribution of the angular momentum in the dense core of a molecular cloud where it originates. Observed rotation rates in molecular clouds and cloud cores are compared with the angular momenta in the orbits of binary systems and in the rotation of single stars. Physical mechanisms for the redistribution of angular momentum during protostellar evolution are discussed. Section IV then discusses formation theories, emphasizing the closely related processes of fragmentation during protostellar collapse, during disk formation, and after an equilibrium disk has been formed. Other processes, such as capture, orbital decay, and fission are also considered. Finally, Sec. V reviews the mostly speculative suggestions regarding the situations in which single stars rather than multiple systems are formed, and Sec. VI provides a summary with a view toward future work.

II. OBSERVATIONAL EVIDENCE

A. The Main-Sequence Solar-Mass Binary Population

Certainly some of the most valuable clues to the process of binary star formation lie in the nature of the product, that is, the main-sequence binary population. For more than a decade, the classic study of Abt and Levy (1976, henceforth AL; see also Abt 1983) has been the standard description of the main-sequence solar-mass binary population. Recently Morbey and Griffin (1987) have argued that a large fraction of the spectroscopic orbit solutions presented there are not statistically significant and that in most of these cases there is no evidence that the stars are binaries. Abt (1987) reanalyzed his results in light of these findings, noting that the description of the solar-mass binary population was nonetheless little changed. Recent technological advances (in particular in the realm of radial-velocity measurements and speckle interferometry) have permitted several extensive long-term surveys which will soon be ripe for analysis; we can expect an improved description of the main-sequence solar-mass binary population in the next few years. For example,

Duquennoy and Mayor (1991, henceforth DM) have reported on the Swiss study of 164 F7-G9, luminosity class IV–V, V and VI stars, selected from the Gliese catalog to be within a parallax-limited volume.

Given the rapidly changing state of the observations, here we only discuss several essential points of the main-sequence binary population, based on the revised AL sample and the DM study, unless otherwise noted.

1. In these surveys, approximately half of the stars are detected to be components of multiple systems. Due to detection biases, the true frequency of multiple systems is certainly substantially higher; for example, Abt (1983) argues that 78% of the AL sample has at least one stellar companion. Most (~85%) of the stars observed to be multiple are detected as binaries.

2. The orbital period distribution is continuous in the range $0 < \log \text{period (days)} < 9$, with a single maximum. DM argue for a median period of 180 yr, somewhat longer than that found by AL.

3. The mass-ratio q distribution has been the subject of much study with widely varying results. While it has generally been found that the secondary mass distribution of longer-period binaries rises continuously toward smaller mass (similar to the Van Rhijn distribution according to AL or to derived initial mass functions according to DM), an essential issue has been whether shorter-period binaries tend to have smaller primary-secondary mass ratios (closer to unity). AL and Abt (1987) have argued for such a trend, with the transition occurring at a period of ~100 yr. On the other hand, DM find no support for differing secondary mass functions between binaries with periods longer than or shorter than 100 yr. Historically, results derived from cataloged data have differed greatly, presumably due to selection biases. A recent careful analysis of cataloged data by Halbwachs (1987) showed a secondary mass distribution similar to that of DM with no evidence for a period dependence. This issue of the dependence of the secondary mass distribution on orbital period is critical; for example, a transition as suggested by AL may well imply separate formation mechanisms for short- vs long-period binaries, with the transition period perhaps related to the maximum size of circumstellar accretion disks. From the point of view of binary formation, resolution of this question is perhaps the most essential goal of the next generation of main-sequence binary surveys.

4. The orbital eccentricity distribution is clearly dependent on orbital period. The binaries with the shortest periods have circular orbits; DM find that the transition from circular to eccentric orbits occurs at a period between 10 and 13 days. Indeed, the transition is remarkably well defined, given that the sample includes stars of all ages. Longer-period binaries are found to have essentially all eccentricities. Heintz (1969) has argued that the mean orbital eccentricity is ~0.5, independent of orbital period between 1 yr and 500 yr. DM argue that for binaries with periods between 11 days and 1000 days, the eccentricity distribution is bell shaped with a maximum at ~0.3. For longer-period binaries, they find that the relative number of binaries having high eccentricity increases, and they suggest the distribution is more like the

dynamically relaxed distribution $f(e) = 2e$.

These main-sequence eccentricity distributions have significant implications for the processes of binary formation and evolution during the pre-main-sequence (PMS) phase. That the shortest period orbits tend to be circular has been recognized for some time; the long-standing explanation has been tidal circularization during the main-sequence phase of evolution (see, e.g., Zahn 1977; Koch and Hrivnak 1981). This interpretation was reinforced by the discovery of similar transitions in the Hyades and Praesepe open clusters (age ~ 0.8 Gyr) at a period of 5.7 days, in M67 (age ~ 5 Gyr, comparable to the expected mean age of the DM G-dwarf sample) at a period of 10 to 11 days, and in the halo of the Galaxy at a period between 13 and 18 days (Mayor and Mermilliod 1984; Mathieu and Mazeh 1988; Jasiewicz and Mayor 1988; Latham et al. 1988). Mathieu and Mazeh (1988) noted that this increase in transition period with binary age is consistent with effective tidal circularization on the main sequence.

Recently, however, Zahn (1989) has argued that viscous dissipation in stellar envelopes, and consequently tidal circularization, is less effective than previously thought. Subsequently, Zahn and Bouchet (1989) have done a theoretical analysis of the expected tidal circularization as binary components evolve from the birthline to the main sequence. They come to the important conclusion that the circularization of a binary orbit takes place almost entirely at the very beginning of the Hayashi phase, and that there is little further decrease of the eccentricity on the main sequence. For a variety of assumptions regarding initial conditions and binary component masses, they predict that transition periods between 7.2 and 8.5 days should be found for low-mass binaries of all ages. Recognizing that both shorter and longer transition periods have already been found in several systems of varying ages, they suggested alternative *ad hoc* explanations for those systems (such as mass transfer and evolution of the stellar interiors).

That the observed monotonic increase in transition period with main-sequence population age can be so easily explained away is not clear; the reader is referred to the review of Mazeh et al. (1990) for an alternative view. On the observational side, both the number of binary samples with detected transition periods and the number of stars defining the transition periods are small. In addition, in some samples counterexamples to the premise of a single transition period exist. The numbers of binary samples and orbits must be increased, particularly at ages of less than 10^9 yr. The theory of stellar tidal circularization, particularly in regard to the dissipation mechanism and consequently the circularization time scale, also remains uncertain (Tassoul 1987, 1988, 1990; Goldman and Mazeh 1991). Nonetheless, the work of Zahn and Bouchet is seminal in its attempt to quantify the evolution of binary orbits during the PMS phase. Future work must both clarify the role of tidal circularization and incorporate other relevant processes, such as associated disks and mass loss (see, e.g., Artymowicz et al. 1991).

Taking a broader view in orbital period, among main-sequence binaries

with periods longer than ≈ 10 days, the vast majority have eccentric orbits. Equally important, the observed eccentricity distribution shows a significant frequency over essentially the entire range of eccentricity. Thus any theory of binary formation or early orbital evolution must not overly tend toward either circular or high-eccentricity orbits. The challenge to the observers is to provide more precise definition to the eccentricity distribution, particularly as a function of period.

B. The Pre-Main-Sequence Low-Mass Binary Population

While the main-sequence binary population provides a valuable boundary condition on the processes of binary formation and PMS evolution, clearly the more direct approach is to observe binaries in the process of forming and evolving. Substantial advances in this regard have been made since the publication of *Protostars and Planets II* (Black and Matthews 1985). The field is young and still largely in the stage of collecting objects for analysis. As yet, no comprehensive study of the young binary population comparable in magnitude to those for the main-sequence binary population has been done.

The following review of the observed PMS binary population is organized by discovery technique. One important generalization should be made, however. Binaries of all periods have been found among PMS stars of all ages, including the very youngest. DF Tau and SVS 20 are examples of binaries very near the birthline (ages $\sim 10^5$ yr). Binary formation evidently can occur very early in the star formation process.

1. Spectroscopic Binaries. The first orbit for a low-mass PMS spectroscopic binary was that derived for V826 Tau by Mundt et al. (1983). At present, the roster of identified low-mass PMS spectroscopic binaries stands at more than 20. Those published at the time of writing are listed in order of increasing period in Table I, where the orbital periods, eccentricities, and the relevant references are presented. Arguably, EK Cep might not be considered a PMS binary as the primary is a $2.0 M_{\odot}$ star on the ZAMS. However, Popper (1987) argues that the $1.1 M_{\odot}$ secondary is still contracting to the main sequence, and hence we include it here. The high frequency of short-period binaries in the list of Table I reflects the fact that systematic monitoring of large samples of PMS stars has only recently begun.

Only the binaries discovered by Mathieu, Walter and Myers (1989, henceforth MWM) are the product of a comprehensive radial-velocity survey. The MWM study included an X-ray selected sample of some 50 PMS stars in the Taurus-Auriga, Ophiuchus and Corona Australis star-forming regions. For binaries in this sample with periods of less than 100 days, they find the detected PMS binary frequency to be $9\% \pm 4\%$, indistinguishable from the corresponding detected binary frequency among main-sequence stars ($\sim 12\%$).

Spectroscopic techniques have the advantage that they are sensitive to the shortest period binaries and hence often provide not only evidence of binarity but also orbital solutions; the only orbits yet determined for PMS binaries have been derived from spectroscopic data. Knowledge of the orbital

elements can provide important insights into the nature of the binary formation process itself. In the remainder of this section we highlight several of the more interesting discoveries to date.

i. Orbital Eccentricities. Examination of Table I shows that all binaries with periods of <4 days have circular orbits, while those with longer periods have eccentric orbits (with the one notable exception of GW Ori). In addition, Mathieu, Walter and Myers (in preparation) have found two additional PMS binaries of interest here, in particular a binary with a circular orbit having a period of 4.253 days and another with an eccentric orbit ($e = 0.26$) having a period of 7.46 days.

These data reflect directly on the issue of orbital evolution during the PMS phase. Taken straightforwardly, the binaries listed in Table I indicate a transition from circular to eccentric orbits occurring at a period of 4 days, the shortest transition period yet found. However, this conclusion rests on only one binary, EK Cep, so that a PMS transition period is not well established. Should enlargement of the PMS sample support such a short transition period, the indication would be that tidal circularization during the PMS phase is not as effective as Zahn and Bouchet (1989) suggest (or that other processes are also active in determining orbital eccentricity), and that significant tidal circularization occurs during the main-sequence phase. However, excepting EK Cep, the present sample is consistent with the predictions of Zahn and Bouchet (1989) for PMS tidal circularization. The existence of another PMS binary with an eccentric orbit at 7.46 days, when compared to transition periods of >10 days among both disk and halo solar-mass field stars as well as in M67, does suggest that tidal circularization progresses on the main sequence.

In any case, the complex evolution of internal stellar structure, circumbinary disk structure, and orbital separation prior to 1 Myr must ultimately produce the robust result of circular orbits for binaries with periods < 4 days. Given the variety of influences on a binary orbit between formation and the main sequence (e.g., disks, mass accretion, mass outflows, encounters), some or all of which may drive orbital eccentricity (Goldreich and Tremaine 1980; Artymowicz et al. 1991), the uniformly circular orbits among the shortest-period binaries suggests that these orbits are established relatively late in the orbital evolution of a young binary. The apparent sensitivity of the circularization mechanism to orbital period may indicate that stellar tidal circularization has the final word in these short-period systems.

The case of GW Ori may be an important counterpoint to this simple picture of the PMS eccentricity distribution. The spectral energy distribution of GW Ori indicates the presence of a circumprimary disk and possibly a circumbinary disk as well (Mathieu, Adams and Latham 1991, henceforth MAL; see discussion below). Thus GW Ori provides the rare opportunity to examine a young, short-period binary in a disk environment. Notably, MAL find an orbital eccentricity of 0.04 ± 0.06 , despite the rather long period of 242 days. Formally, the measured eccentricity is indistinguishable from zero, but the measurement error is large, so it would be premature to assert that the orbit is circular. Certainly, however, the eccentricity is small. Interestingly, Artymowicz et al. (1991) argue that disks should very rapidly drive a binary orbit to high eccentricities. Earlier work (Goldreich and Tremaine 1980; Ward 1988) also found that the orbital evolution would be rapid, but in the case of planetesimal companions the sense of the eccentricity evolution was very sensitive to the details of the disk structure. Thus, if GW Ori does presently have a circular orbit and will ultimately have an eccentric orbit, it may provide important insight into the details of disk evolution.

ii. Mass Determinations. To date the only double-lined eclipsing PMS binary discovered is EK Cep, which provides a dynamical mass determination for the secondary of $1.12 M_{\odot}$. A preliminary analysis by Popper (1987) finds the position of the secondary in the theoretical HR diagram to be between the $1.0 M_{\odot}$ and $1.25 M_{\odot}$ evolutionary tracks of Iben at an age of 20 Myr. This result is important, but the secondary is sufficiently near the main sequence that it would be remarkable indeed if the theoretical mass calibration were greatly in error.

The double-lined binary 162814–2427 is substantially younger with an age of 1 Myr (MWM). The system is notable in that the dynamical lower limit on the primary mass is $1 M_{\odot}$. However, MWM have placed the primary on the theoretical HR diagram and found theoretical mass estimates of $0.7 M_{\odot}$ and $0.8 M_{\odot}$ (using models of VandenBerg [in preparation] and Cohen and Kuhn [1979], respectively). This inconsistency may reflect on the validity of using these theoretical tracks for estimating masses of young low-mass stars (at least in short-period binaries). However, the uncertainty in the effective temperature of the primary permits theoretical values consistent

with the dynamical mass limit (although only marginally so in the case of the VandenBerg models).

Marschall and Mathieu (1988) have used the double-lined binary P1540 to test the relative mass calibrations of the theoretical tracks. They deconvolved the composite light, placing both the primary and secondary on the theoretical HR diagram. Using the PMS tracks of Cohen and Kuhi (1979) and assuming coeval formation, they could not find consistency between the theoretical and dynamical mass ratios. By relaxing the assumption of coevality, they could make the two mass ratios consistent, although only at the limits of the estimated errors for the secondary effective temperature and luminosity. Again, this binary raises doubts regarding either the mass and age calibrations of the theoretical tracks or the assumption of coevality. However, there is an interesting ambiguity with P1540, as the binary has a space velocity 3.5 times the velocity dispersion of the Trapezium cluster upon which it is projected. If the binary formed in the cluster, then it may have recently undergone a stellar encounter during which exchange of a binary component with the encountered star may have occurred. In this scenario, coevality of the binary components would no longer be expected.

Increasing the number of fundamental mass determinations, particularly for binary components with ages of 1 Myr or less, must be a primary goal of future spectroscopic binary work. While discovery of eclipsing systems is entirely a matter of fortune, analyses of double-lined PMS binaries similar to that for P1540 can provide critical tests of both relative mass calibrations and coevality of formation.

iii. Circumbinary Material. Spectroscopic binaries among PMS stars with significant infrared excesses or other diagnostics for the presence of substantial circumstellar disks represent important opportunities to study the evolution of disks in the binary environment. In fact, few spectroscopic binaries have been found among those T Tauri stars which show evidence for substantial circumstellar disks (see Mathieu [1989] and MWM for a more complete discussion of the observational situation). This paucity of detection is surprising (Herbig 1962*b*), given the amount of spectroscopic attention that has been given to these stars and the ease with which spectroscopic binaries have been detected among main-sequence stars and the naked T Tauri stars. It may be an important clue in understanding the interaction of binaries and circumstellar disks. Nonetheless, several PMS stars with substantial infrared excesses and line emission have been found to be spectroscopic binaries. Here we briefly discuss two of the more interesting cases, AK Sco and GW Ori.

The double-lined binary AK Sco has been studied extensively by Andersen et al. (1989), who found an orbit with a period of 13.6 days and an eccentricity of 0.47. Evidence for the existence of circumstellar material in the system rests largely on near- and far-infrared excesses. In addition, the star is variable at the 1 mag level, and H α has been observed in emission with a central reversal (although no other emission lines are present in the spectrum). Remarkably, Andersen et al. (1989) found the relative luminosities of

the stars to vary in the blue by as much as a factor 2 from one orbital cycle to the next. They ascribe both the infrared emission and the light variability to the presence of local dust clouds, in particular a cold (160 K) component with solar-system size scale and a hot (1600 K) component having a size scale comparable to the binary orbit. Alternatively, C. Lada (personal communication to Andersen) has suggested that the near infrared emission could as well be attributed to the power-law emission of a circumbinary disk. Perhaps the most exciting opportunity afforded by AK Sco is a relatively detailed map of the distribution of the circumbinary material; combining aperture photometry with the relative luminosities of each component throughout an orbit may permit determination of the extinction to each star at each point in the orbit.

GW Ori is a classic T Tauri star with strong H α emission and with excess infrared luminosity comparable to the photospheric luminosity. The star is also a single-lined spectroscopic binary with a period of 242 days, corresponding to a separation of slightly greater than 1 AU (MAL). The spectral energy distribution of GW Ori is shown in Fig. 1, as derived from the literature. The pronounced dip in the energy distribution between 2 μ m and 20 μ m and the presence of a strong silicate emission feature at 10 μ m are notable.

One intriguing explanation for the structure in the flux distribution is a nearly evacuated gap in an otherwise optically thick disk. Indeed, the presence of a companion is expected to create such gaps in circumstellar disks on size scales comparable to the orbital separation (Lin and Papaloizou 1986; see also their Chapter). In this picture, the near-infrared excess is provided by at least one circumstellar disk (likely circumprimary), while the far-infrared emission is attributed to a circumbinary disk. The silicate emission is attributed to optically thin hot dust between the two disks. The spectral energy distribution of such a configuration has been computed by MAL (Fig. 1). They find that a disk with a gap from 0.17 AU to 3.3 AU provides a reasonable match to the observed flux distribution; the model is consistent with the independent constraint that the gap location correspond to that of the companion orbit. However, the large disk luminosity, particularly in the far infrared, is difficult to produce through accretion mechanisms, as discussed in detail by MAL. This problem can be relieved somewhat if one attributes the far-infrared emission to re-processed photospheric light from a shell at distances greater than 200 AU from the binary (MAL). An appropriately flared disk is another possibility. In any case, the energy budget is such that the entire infrared luminosity cannot be explained as reprocessed photospheric light. Even a partial contribution from energy production in the disk through accretion raises fascinating questions regarding the dynamics of accretion in the binary environment.

2. *Spatially Resolved Binaries.* At present much of our knowledge garnered from spatially resolved pairs of PMS stars lies not in their binary properties *per se*, but rather derives from the fact that binaries consist of two stars which are presumed to have the same age and which typically have different masses. Spatially resolved binaries permit direct examination of the flux distributions and derived parameters (L_{bol} , T_{eff} , theoretical ages,

Figure 1. The spectral energy distribution (open boxes) of the binary T Tauri star GW Ori, as compiled from the literature. Particularly notable are the dip in the flux distribution at mid-infrared wavelengths and the prominent silicate emission feature at $10\ \mu\text{m}$. The solid curve is the spectral energy distribution of the primary star and a disk having a gap between $0.17\ \text{AU}$ and $3.3\ \text{AU}$. The dashed curve shows the spectral energy distribution of the same star-disk model without such a gap (figure from Mathieu et al. 1991).

infrared excesses, lithium abundances, etc.) for each star independently. Thus, resolved binaries represent laboratories in which to study the mass dependence of PMS stellar and circumstellar evolution directly, always given the caveat that as circumstellar disk length scales are often greater than or comparable to the binary separations, evolution in the binary environment may not reflect evolution in isolation.

i. Lunar Occultation. Occultation techniques are sensitive (at $2.2\ \mu\text{m}$) to binaries with separations from a few milli-arcseconds ($\sim 1\ \text{AU}$ at $150\ \text{pc}$) to of order $1\ \text{arcsec}$, to be compared with the diffraction limit of a $4\ \text{m}$ telescope of $140\ \text{milli-arcseconds}$. As such, lunar occultation observations are uniquely sensitive to binaries with periods at the peak of the main-sequence binary frequency distribution and overlap with both spectroscopic observations and

techniques with lower spatial resolution. By good fortune, two of the nearest star-forming regions, Taurus and Ophiuchus, lie on the lunar path.

The most extensive lunar occultation studies of PMS stars have been done by Simon and his collaborators (Simon et al. 1987; Chen et al. 1990; Chen 1990). Combining the Taurus and Ophiuchus regions, they have observed occultation events for 31 objects and have found 9 double systems, several of which have projected separations of 10 AU or less (Table II). This detected binary frequency (29%) is in fact comparable to the frequency of Abt and Levy (1976) in the same regime of projected semimajor axis. Direct comparisons of the *detected* binary frequencies must be interpreted with caution, however, because the selection effects associated with the two studies are very different; as yet no attempt has been made to make a comparison after correcting for these biases.

TABLE II
Roster of PMS Lunar Occultation Binaries

Object	D^a		$2\mu\text{m}$ Flux Ratio
	milliarcsec	AU	
HQ Tau	5	0.7	0.19
FF Tau	37	5.1	0.25
DI Tau	72	10.0	0.13
DF Tau	73	10.0	0.68
FW Tau	118	16.5	0.95
ROX 31	130	20.8	0.78
SR 12	186	29.8	0.85
FS Tau A	259	36.3	0.08
FV Tau	570	79.8	0.64

^a The angular separations D are the projections of the true angular separation on the direction of occultation; as such they represent lower bounds. The one exception is DF Tau, where multiple occultation events permit a determination of the true angular separation (Chen 1990), which is given here.

There is no preferred value for the detected secondary-to-primary flux ratios. The distribution is reasonably uniform over the range 0.1 to 1. Because selection effects bias against systems that have large flux differences, the true distribution may be more concentrated toward smaller flux ratios (Chen 1990). This result must be interpreted with caution since the observations were made only at K, and the contributions to the light in many cases do not arise solely from the stellar photosphere (Moneti and Zinnecker 1991). Consequently, conversions from flux ratios to mass ratios are uncertain (Chen 1990).

Several of the detected binaries are active T Tauri stars. DF Tau in particular has large ultraviolet and infrared excesses, a veiled optical spectrum, and strong Balmer lines in emission. With a projected separation of only 10 AU the orbital period is likely to be only a few tens of years. Thus DF Tau, along with GW Ori and V4046 Sgr, show that the short-period binary environment does not necessarily preclude T Tauri activity. These

T Tauri diagnostics are often interpreted as deriving from the presence of active circumstellar accretion disks. For example, Bertout et al. (1988) have argued that the ultraviolet excess of DF Tau is indicative of an accretion rate of a few times $10^{-7} M_{\odot} \text{ yr}^{-1}$ into a boundary layer at the stellar surface. If this interpretation is correct, it is in contrast to the theoretical work of Artymowicz et al. (1991), who find that the formation of a binary in an accretion disk terminates accretion onto the binary components.

ii. Speckle/Slit Scan. Fittingly, the application of high-resolution techniques to PMS stars was stimulated by speckle observations of T Tau itself. Dyck et al. (1982) used one-dimensional near-infrared speckle interferometry to detect a companion at a separation of 0.61 arcsec (~ 100 AU). A positional ambiguity was resolved by Schwartz et al. (1984), the companion being south of T Tau. The companion is substantially cooler than T Tau, fainter at all wavelengths shorter than $4.8 \mu\text{m}$ and brighter at radio wavelengths, perhaps due to a mass outflow. Shortly thereafter, Nisenson et al. (1985) reported an optical companion 0.27 arcsec north of T Tau. Dynamically the discovery of this third component with a projected separation from T Tau comparable to that of the infrared companion is intriguing; if the true separations are similarly distributed, the triplet is unstable. However, Ghez et al. (1990) have done two-dimensional imaging at optical and near-infrared wavelengths and one-dimensional slit scans at $10 \mu\text{m}$. They do not confirm the presence of the third (northern) component.

The discovery of the companion to T Tau augured the importance of using infrared techniques for the discovery of PMS binaries. In the last few years infrared speckle and slow slit-scan techniques have uncovered several infrared companions to low-mass young stellar objects (e.g., SVS20: Eiroa et al. 1987, Eiroa and Leinert 1987; DoAr24E [alias Elias 22] and Glass I: Chelli et al. 1988; Sz 30: see Reipurth 1988; Haro 6–10: Leinert and Haas 1989; DK Tau: Weintraub et al. 1989c; XZ Tau: Haas et al. 1990; MWC 863 [alias Elias 49]: see Zinnecker 1989a).

In some cases the companions are more luminous at infrared wavelengths than the optical component of the binary. One such binary, Glass I, is particularly intriguing. In Fig. 2 we show the flux distributions in the West-East direction at 1.25, 1.63, 2.19 and $3.61 \mu\text{m}$; the infrared component is substantially brighter than the optical component at wavelengths greater than $2 \mu\text{m}$ (Chelli et al. 1988). More significantly, attributing the IRAS fluxes to the infrared companion, one finds that the infrared component has a higher bolometric luminosity ($4 L_{\odot}$) than the optical component ($0.75 L_{\odot}$). Haro 6–10 and XZ Tau show similar properties.

The interpretation of these three binaries is not clear. Chelli et al. (1988) linked the infrared luminosity of the more luminous component of Glass I to the reprocessing of a dust envelope, noting that it was unusual that the less luminous object had first dispersed its envelope. Nonetheless, given the youth indicated by the extreme T Tauri characteristics of the optical component, they find both components to be of comparable age. Zinnecker (1989a) suggests

Figure 2. Slit scans of the binary Glass 1 in the East-West direction at wavelengths of (a) $1.25\ \mu\text{m}$, (b) $1.63\ \mu\text{m}$ (c) $2.19\ \mu\text{m}$ and (d) $3.61\ \mu\text{m}$ (figure from Chelli et al. 1988.) The bolometric luminosity of the infrared companion is greater than that of the optically visible star.

that higher accretion rates onto the infrared companions might lead to an oversized, cooler star or substantial contribution to the luminosity from the disk accretion itself. He also notes that non-coplanarity of the disks might lead to differing extinctions, perhaps indicative of a capture origin. In any case, the discovery and detailed study of more binaries with such unexpected relative spectral distributions may provide substantial insight into the formation of binary companions and the evolution of disks in the binary environment.

The detection rate of infrared companions is accelerating; indeed at the time of writing the number of unpublished detections likely exceeds the number referenced above. While infrared observations have several important advantages, optical speckle work has also proven effective (see, e.g., Baier et al. 1985). Finally, the application of similar techniques to embedded massive stars has been equally fruitful in uncovering pairs of infrared sources (see, e.g., Dyck and Howell 1982; Dyck and Staude 1982; McCarthy 1982; Castelaz et al. 1985), although typically at much larger physical separations. In general, the application of high-resolution techniques to PMS stars is about to yield a wealth of important results.

iii. Visual Binaries. By their very nature, “visual” pairs (including infrared pairs with separations similar to classical visual pairs) are often discovered serendipitously. In his classic review of T Tauri stars, Herbig

(1962*b*) tabulated 29 pairs in which at least one star was a T Tauri and commented that Joy had noted the presence of pairs in his discovery studies (Joy and van Biesbroeck 1944). Cohen and Kuhi (1979) listed 34 pairs serendipitously discovered with the Lick acquisition TV during the course of their spectroscopic survey. Reipurth (1988) reports the discovery of 28 pairs found during a systematic CCD survey of southern low-mass PMS stars, with an increase in frequency with smaller separation. Walter et al. (1988) find six visual pairs of naked T Tauri stars among 37 such systems in Taurus-Auriga. While some chance projections are certainly present in these samples, clearly visual companions to low-mass PMS stars are a common phenomenon. Time scale arguments show that systems with projected separations within tens of arcseconds at 150 pc are likely to be bound when considered in isolation, although the evolution of such systems in the molecular cloud environment remains to be investigated.

Despite this long history of visual pairs among young low-mass stars, little systematic analysis of the population has been done to date. However, at present array detectors (both optical and near-infrared) are being used at many observatories for imaging surveys of the PMS stellar population. Near-infrared imaging in particular holds great promise; it has proven effective in detecting companions to optically visible young stars, the companions often being of later spectral type and faint in the optical (see, e.g., Reipurth and Gee 1986; Sandell et al. 1987). Also, near-infrared imaging has permitted surveys for binaries in embedded regions (see, e.g., Rieke et al. 1989; Barsony et al. 1989*a*; Zinnecker 1989*a*). Finally, Wootten (1989) has found a candidate protobinary star (separation of 5 sec or 750 AU) with centimeter continuum maps of IRAS 16293–222 obtained with the VLA. The nature of the wide binary population should be substantially clarified in the very near future.

Wide pairs can be used to test the consistency of the assumption of coeval formation and the theoretical evolutionary tracks and to examine standard techniques for estimating PMS stellar ages. When analyzed independently, each component of a wide pair should fall on the same theoretical isochrone under these assumptions. Walter et al. (1988) have performed this test with five naked T Tauri pairs in the Taurus-Auriga region and found good agreement in the estimated ages for each pair of stars. Unfortunately, the youngest of the pairs has an age somewhat in excess of 1 Myr, so that none are young enough to be sensitive tests of the earliest stages of PMS evolution. In fact, there may be fundamental limitations to performing such a test upon the youngest stars, for the presence of disks and accretion produces substantial uncertainty in defining the photospheric parameters (Hartmann and Kenyon 1990; Kenyon and Hartmann 1990).

Recently, Moneti and Zinnecker (1991) have completed a near-infrared imaging study of nine PMS multiple systems. They find that the K brightness ratios range from 0.05 to 0.5 (median 0.1), somewhat smaller than the ratios found for the lunar occultation binaries. In nearly all cases the brighter component at K is the redder at J–K. Moneti and Zinnecker attribute the

excess flux at K to disk luminosity and find that the ratio of disk to stellar luminosity increases with stellar luminosity. As they find a similar color-magnitude distribution for isolated T Tauri stars, they argue that in these wide binaries the two stars (and associated circumstellar disks) do not interact. This may suggest that the disks are smaller than about half the minimum separation of the binaries (~ 200 AU in radius).

In a similar vein, Beckwith et al. (1990) and Beckwith and Sargent (see their chapter, especially their Fig. 5) have found an indication that the existence of a binary companion may act to limit the mass of associated disks. These investigators have observed at 1.3 mm a sample of 17 PMS binaries, most having projected separations between 1 AU and 1000 AU. Their observations permit estimates of disk masses; intriguingly, they find detectable disk masses only among those binaries with projected separations of $\gtrsim 100$ AU. This transition point is significant in that 100 AU is a typical value deduced for the outer radii of circumstellar disks; the result suggests that companions embedded within such disks act to reduce the total disk mass. As they note, the upper limits on the disk masses of those binaries with projected separations < 100 AU are only slightly smaller than the detected masses. In addition, the expected number of detections among these closer binaries is only a few, so small-number statistics are a concern. Nonetheless, the result is reasonable theoretically and, if confirmed by future work, critical to our understanding of disk evolution in the young binary environment.

To conclude, we summarize those findings which most directly constrain the processes of binary formation and early evolution. Approximately half of main-sequence solar-mass stars are detected as binary systems; the actual binary frequency must be substantially higher (e.g., $\sim 80\%$; Abt 1983). Thus binary formation is the *primary* branch of the star formation process. The binary period distribution ranges over 10 orders of magnitude and is continuous with a single maximum. For longer-period binaries, the mass distribution of the secondary stars rises to smaller masses, similar to field initial mass functions. Whether the secondary mass distribution for the shortest-period binaries follows the same distribution is not yet settled and forms a critical gap in the observational picture. The vast majority of Population I main-sequence binaries with orbital periods longer than ~ 10 days have eccentric orbits, while shorter-period systems have circular orbits. The transition period from circular to eccentric orbits depends on age.

Binaries have been found among stars very near the stellar birthline, so that binaries can form at ages of $< 10^5$ yr. Observations to date suggest that binary components form coevally within an accuracy of ~ 1 Myr. The first studies suggest that the PMS binary frequency and orbital period distribution are similar to those of main-sequence binaries (excepting a possible deficiency of short-period binaries among classical T Tauri stars); however, rigorous comparisons have yet to be done. PMS binaries have circular orbits for periods of less than 4 days and eccentric orbits for longer periods, with the one notable exception of GW Ori, a binary-disk system which has a circular

or near-circular orbit at a period of 242 days. These orbital period and eccentricity distributions are likely the result of evolution prior to and during the PMS stage due to coupling with circumstellar disks, mass redistribution, and stellar tidal interaction. Tantalizing evidence for the evolution of disks in the binary environment may be found in the flux distribution and very low orbital eccentricity of GW Ori, in the lack of detection of 1.3 mm emission among binaries with separations of less than 100 AU, and in the lack of detection of the shortest-period binaries among classical T Tauri stars. These results suggest that the amount of disk material is substantially reduced at scale lengths comparable to the binary separation. Nonetheless, observations indicate that accretion near the stellar surface(s) can continue in the binary environment. Young binaries are observationally accessible analogs to planetary systems, and the study of binary-disk systems will be a particularly fruitful forefront for observers in the near future.

III. ANGULAR MOMENTUM IN PROTOSTELLAR MATERIAL

We inquire here whether the orbital angular momentum of a binary or multiple system can reasonably be associated with the remnant of the angular momentum of the molecular cloud core from which the stellar system formed. In this section we summarize observational data on rotation of molecular cloud material, discuss the turbulent nature of the rotation of cloud cores, and mention mechanisms of angular momentum redistribution at the different stages of star formation.

A. Rotation Rates in Molecular Clouds and Cloud Cores

Observations reveal that large molecular clouds are quite inhomogeneous and clumpy. Frequently they show inhomogeneities down to the smallest resolvable scales, which are smaller than the likely Jeans length in the clouds. Stars of roughly solar mass or less form in the small-scale (≤ 0.1 pc) densest region of molecular clouds, which are referred to as cloud cores. The chaotic internal motions suggest that it is reasonable to consider the clouds as turbulent, taking into account that turbulent flows actually consist of a hierarchy of small-scale irregularities superimposed on larger-scale more systematic motions such as rotation or expansion (Larson 1981; Dickman 1985; Kleiner and Dickman 1987).

The turbulence in the idealized incompressible fluid of classical laboratory hydrodynamics is characterized by a hierarchy of vortices on a range of length scales down to the scale where dissipation becomes important. However, the interstellar turbulence may be quite different and more complicated. The observed internal velocities could refer to the independent motions of clumps, filaments and other wispy condensations superimposed on a background of warmer less-dense matter. Such motions could, in principle, be vortex free, for example, if the motions result from fragmentation of an initially hydrostatic nonrotating cloud. The random motions of fragments in this

case could describe motions of clumps under the action of mutual gravitation of the system of clumps. Such a system slowly contracts at the rate set by dissipation due to clump collisions and drag, but the kinetic energy of clumps is continually extracted from the gravitational field of their parent cloud rather than from shear motion on a larger scale as in incompressible turbulent flow (Scalo and Pumphrey 1982). Furthermore, the turbulence in the interstellar medium is affected by energy deposition and energy sinks on several scales at once. It is not surprising therefore that the real interstellar turbulence in molecular clouds has much smaller characteristic rotational velocities on large scales than would be expected for Kolmogoroff turbulence, based on the velocity dispersion on the small scales (Scalo 1984; Kleiner and Dickman 1985). Thus the velocity dispersion in the cloud is not a direct measure of rotation, which must be measured independently.

The rotation of interstellar clouds or their subregions is usually determined by observation of systematic shifts in the velocity of the centroid of a spectral line along a cut through the cloud (Goldsmith and Arquilla 1985). Naturally the shift must be not too small compared with the width of the spectral line. Therefore the lower limit on the rotational rate which can be measured depends on the dimension of the cloud and its temperature or turbulent velocity. If a cloud possessed a highly ordered velocity field, the observation of a gradient of the radial velocity across the cloud would be sufficient proof of the presence of rotation. However, in fact, different types of mass motion can produce gradients more or less similar to those resulting from rotation. Therefore additional information (such as detailed velocity field, mass distribution, structure of the magnetic field) is needed to assess the probable validity of the rotation model. Arquilla and Goldsmith (1986) have undertaken a detailed study of the velocity fields of eight clouds, six of which were previously referred to in the literature as fast rotators. They analyze the radial-velocity distribution using well-filled maps of ^{13}CO spectra, generally more coarsely sampled ^{12}CO maps, and extensive star counts. Kinematic models of the sources were developed from the examination of the relevant spatial velocity diagrams and ^{13}CO column-density maps. The data strongly supported the presence of rotation in only three program clouds (B361, L1253, L1257). One object (CRL 437) has been removed from the list of rotating clouds, and the rotational model is in difficulty for the globules B163 and B163 SW. As most of these clouds were known to have large velocity gradients across them, these results imply that rapid rotation in dark clouds may be less common than hitherto suspected, because in most other measurements of rotation, such a detailed analysis was not applied. In general, there is a range of deduced values of the rotational velocity at each size scale, and the mean specific angular momentum clearly decreases at smaller scales (Goldsmith and Arquilla 1985). Typical results indicate that clouds with radius 0.5 to 1.0 pc and a few hundred solar masses rotate with $\omega \sim 3$ to $11 \times 10^{-14} \text{ rad s}^{-1}$. The typical specific angular momentum of the clouds that rotate is therefore $j \sim 10^{23} \text{ cm}^2 \text{ s}^{-1}$. Most of the clouds seem to rotate rigidly, although the outer

envelope of B361 shows evidence for differential rotation.

Similar difficulties occur in the measurement of rotation of cloud cores. Bipolar outflows from embedded low-mass young stars could create the observable shift across some cores; recent observations reveal a high fraction of outflows in cores with stars. Therefore the measured velocity gradient can be considered only as an upper limit on the rotational velocity projected onto the line of sight (Fuller and Myers 1987; Mathieu et al. 1988). In small cores, the velocity gradients are less than the observational limit in approximately half of studied cases (Myers and Benson 1983; Ungerechts et al. 1982; Heyer 1988). In Heyer's (1988) work on cores in Taurus the mass range is 0.3 to $38 M_{\odot}$, the range in radius is 0.1 to 0.5 pc, the mean density range is 0.1 to $2.6 \times 10^4 \text{ cm}^{-3}$, and the observed velocity gradients are 0.2 to $1.5 \text{ km s}^{-1} \text{ pc}^{-1}$. Corresponding angular velocities, Ω are 0.6 to $5 \times 10^{-14} \text{ rad s}^{-1}$, and values of j (at the outer edge) fall in the range 1 to $45 \times 10^{21} \text{ cm}^2 \text{ s}^{-1}$, increasing on the larger scales. The small (0.1 pc) cores, which represent initial conditions for star formation, have $j \sim 10^{21} \text{ cm}^2 \text{ s}^{-1}$, if they are observed to rotate. Similar results were found in earlier work (Myers and Benson 1983; Ungerechts et al. 1982; Harris et al. 1983; Wadiak et al. 1985). It is worth noting, however, that the observational limit at this scale is $\Omega \sim 2 \times 10^{-14} \text{ s}^{-1}$ or $j \sim 10^{21} \text{ cm}^2 \text{ s}^{-1}$. Therefore the observations do not exclude the existence of cores with much slower rotation. The cores are usually centrally condensed in density: $\rho \sim r^{-p}$ with $1 \leq p \leq 2$ (Myers et al. 1987). It is not known whether differential rotation is present.

The typical angular momenta observed in cloud cores may be compared with those in binary systems and single stars (Table III). This table emphasizes a number of points. First, the angular momentum associated with orbital motion in binaries is considerably larger than that associated with rotation of individual stars. Second, the orbital angular momenta in long-period binaries have the same order of magnitude as those inferred from observations of cloud cores. However, it is not known whether some cloud cores have angular momenta consistent with those of the systems with the shorter periods. These close systems do have far too much angular momentum to be explained by fission of (now slowly) rotating T Tauri stars. Third, the value of j in the solar nebula, as deduced from Jupiter's orbit, is comparable to that of binary orbits of intermediate period, raising the question of whether the solar system formed from a very slowly rotating cloud ($j \leq 10^{19}$) with outward transport of angular momentum occurring into a small amount of mass at a later stage, or from one with $j \sim 10^{20}$. This question is further discussed in Sec. V.

B. Physical Nature of Rotation in the Cloud Cores

Interstellar turbulence (Cameron 1962) and galactic differential rotation (Hopper and Disney 1974) were considered to be the main mechanisms causing cloud rotation. The absence of a preferred orientation for the rotational axes of single stars or the orbital planes of binaries (Kraft 1970) or, in fact, the rotational axes of molecular clouds themselves (Goldsmith and Arquilla 1985),

TABLE III
Characteristic Values of Specific Angular Momentum

Object	J/M (cm ² s ⁻¹)
Binary (10 ⁴ yr period)	4×10^{20} – 10^{21}
Binary (10 yr period)	4×10^{19} – 10^{20}
Binary (3 day period)	4×10^{18} – 10^{19}
T Tauri star (beginning of contraction phase)	5×10^{17}
Jupiter (orbit)	10^{20}
Present Sun	10^{15}
Molecular cloud (scale 1 pc)	10^{23}
Molecular cloud core (scale 0.1 pc)	10^{21}

means that the rotation of the cores in molecular clouds is probably caused by interstellar turbulence. Larson (1981) pointed out that in the scale range $0.05 \leq L \leq 60$ pc the turbulent velocity is v_t (km s⁻¹) = $1.1 L^{0.38}$ (pc). The Kolmogoroff spectrum, which describes a dissipationless cascade of vortices, has a power-law index of 1/3. Subsequent studies have shown, however, that there is appreciable scatter in the data and that the power-law index in different clouds ranges from 0.3 to 0.6, implying that the energy content of random motions does not depend on the length scale in some clouds (as in Kolmogoroff turbulence) but increases with length scale in others. Thus (see also Sec. III.A) the turbulence in molecular clouds probably does not represent the single dissipationless cascade from the scale determined by the cloud dimension to the scale in which the turbulence is dissipated due to molecular viscosity. The similarity with the Kolmogoroff spectrum, however, is more likely on the intermediate length scales where the turbulence is subsonic and where there is no significant dissipation. If so, the turbulence in molecular clouds could be considered as a superposition of cascades with randomly distributed energy sources on several length scales. One could expect that under such circumstances the interstellar turbulence would have an intermittent character (Ruzmaikina 1986,1988). The intermittency means that turbulent vortices are distributed nonuniformly in time and space, i.e., small regions of intense rotational motions, whose locations change with time, are separated by extended quiet regions.

Laboratory investigations of turbulence in an incompressible fluid show that intermittency is most marked in strong turbulence at high Reynolds numbers on the dissipative length scale $l_d = (v^3/\epsilon)^{1/4}$, where v is the kinematic viscosity and ϵ is the energy dissipation rate per unit mass (Stewart and Townsend 1951; Kuo and Corrsin 1971). If applied to the turbulence in molecular clouds, the intermittency suggests the existence of a number of regions with relatively small turbulent velocities on the length scales in which dissipation is important.

In magnetized molecular clouds there are two dissipative length scales: one is associated with the molecular viscosity and the second with magnetic

viscosity. The magnetic viscosity ν_{ad} is produced by ambipolar diffusion, which is the most effective mechanism of dissipation of the magnetic field and turbulence. It is much larger than the molecular viscosity as long as an equipartition exists between turbulent and magnetic energy for $l \geq l_d$, that is, $H^2 \sim 4\pi\rho v_t^2$, where H is the intensity of the magnetic field and ρ is the density. The degree of ionization is defined by n_i/n_n , where n_i and n_n are the particle densities of ions and neutrals, respectively. It is governed by ionization of gas by cosmic rays (with rate $\zeta = 10^{-17}$ to 10^{-18} s^{-1}) and by recombination of ions on the dust particles. The velocity of ions relative to neutrals $v_{in} = v_i - v_n$ is of the order of the turbulent velocity on the length scale of dissipation l_d . Then

$$\nu_{ad} = \frac{v_t^2 m}{2\mu_{in} \langle \sigma u \rangle_{in} n_i} \quad (1)$$

where μ_{in} is the reduced mass of ions and neutrals and $\langle \sigma u \rangle_{in}$ is the mean rate of collisions between ions and neutrals. The dissipation length scale l_{ad} associated with ambipolar diffusion is

$$l_{ad} = \frac{v_t m}{2\mu_{in} \langle \sigma u \rangle_{in} n_i} = 0.08 \left(\frac{\zeta}{10^{-17} \text{ s}^{-1}} \right) \text{ pc}. \quad (2)$$

For parameters typical for the dense regions of molecular clouds, this formula gives values comparable to the dimension of the small cores containing only one or a few solar masses.

The laboratory intermittent turbulence obeys a log-normal distribution of energy dissipation rate ϵ . If the vorticity on the length scale l_d in molecular clouds follows the same distribution, then the probability for a cloud core to have an angular momentum per unit mass notably different from the average is much larger than for normal turbulence (Ruzmaikina 1986, 1988). The log-normal distribution of the angular momentum J means that a probability to have a given $J = \psi < J >$ is

$$P(\psi) = \frac{1}{\sqrt{2\pi D\psi}} \exp \left[-\frac{(\ln \psi + \frac{D^2}{2})^2}{D^2} \right] \quad (3)$$

where $D^2 = \langle (\ln J - \langle \ln J \rangle)^2 \rangle$. Unfortunately, there are few measurements of the gradient of radial velocity across dense cores with dimensions $\leq 0.1 \text{ pc}$ and mass of about $1 M_\odot$. Assuming the measured velocity gradient is entirely caused by rotation and that a typical value for the cases when no rotation was observed is one-half of the upper limit, then $\langle J \rangle = 7.8 \times 10^{53} \text{ g cm}^2 \text{ s}^{-1}$ and $D = 0.934$ according to the observational data. Then the fraction of slowly rotating dense cores could be large (Ruzmaikina 1989). This argument, although not strongly confirmed by observations, suggests that the turbulent

motions of the interstellar gas could produce the angular momenta of the full range of binary orbital periods and possibly also of the single stars. However, the picture is undoubtedly more complicated than a simple one-to-one mapping between initial cloud rotation rate and final binary period, as both fragmentation and redistribution of angular momentum must be taken into account.

C. Mechanisms for Redistribution of Angular Momentum

The importance of the redistribution of the angular momentum at the stage of star formation is connected with a significant enhancement of density and decrease in the moment of inertia of the collapsing cloud. For example, if a sphere containing $1 M_{\odot}$ contracts from an initial density of $10^{-24} \text{ g cm}^{-3}$ to the average density of the Sun (1 g cm^{-3}), then the radius decreases by a factor 10^8 and the moment of inertia by a factor 10^{16} . It is clear, therefore, that if the sphere contracts with local conservation of angular momentum, then even negligible initial rotation could be dynamically important during contraction and could stop the contraction in the direction perpendicular to the rotation axis, resulting in fragmentation. The redistribution of angular momentum could be a crucial factor in determining what kind of system is produced.

The efficiency of redistribution depends strongly on the stage of protostellar evolution. It definitely could be high at the early stages at molecular cloud densities ($\sim 10^3 \text{ cm}^{-3}$). If the typical magnetic field in a cloud is $\sim 10^{-5}$ gauss and if the magnetic field is frozen into the material, then the field is effective in braking the rotation of the cloud and in redistributing the angular momentum inside the cloud (Mouschovias 1977; Mestel 1985; Ruzmaikina 1985; Shu et al. 1987; Chapter by McKee et al.). The time scale for these effects is 10^6 to 10^7 yr, which is shorter than the evolution time of the cloud as long as the coupling between the field and gas is maintained. However, this coupling decreases because of ambipolar diffusion as the density approaches the values for the dense cores of molecular clouds (Mestel and Spitzer 1956; Lizano and Shu 1989; Ruzmaikina 1981a, 1985). Magnetic braking becomes less effective, but ambipolar diffusion itself can still be effective in redistributing the angular momentum because of the relatively large effective viscosity ν_{ad} associated with the drag of the ionized component moving through the neutral component (Sec. III.B).

During the protostellar collapse itself, the evolution time is comparable to the dynamic time, and there will not be appreciable angular momentum transport by any process, unless initial nonaxisymmetric perturbations are especially large. The magnetic field is dynamically unimportant on the time scale of collapse because of the effects of ambipolar diffusion, which restricts the enhancement of the magnetic field during collapse and decouples the field from the matter. The redistribution of angular momentum associated with ν_{ad} has a time scale longer than that of collapse. Similarly, turbulent velocities are not likely to exceed the sound speed because of greatly increased dissipation at supersonic speeds. Numerical simulations show, however, that the collapse

is supersonic at most stages. The time scale for angular momentum transport by turbulent viscosity is larger than the collapse time as long as the turbulent velocity $v_t < v_{\text{collapse}}$. Also, nonaxisymmetric perturbations will not produce appreciable transfer by gravitational torques because the perturbations do not grow appreciably with respect to the collapsing background until the collapse has been slowed considerably by rotational and pressure effects. After about one free-fall time, when the cloud has become rather disk-like and is approaching equilibrium, the perturbations can grow and fragmentation can occur; the process involves conversion of spin angular momentum of the cloud into orbital motion of the fragments (Sec. IV).

If the critical condition for fragmentation is not reached, however, then the outcome is likely to be a central object plus a disk. A number of transport processes now become possible—turbulent, magnetic and gravitational torques produced by spiral density waves (see review by Larson 1989). The question arises whether the disk can ever become unstable to the formation of a binary if it has not already fragmented during its formation. The answer will depend on the time scales of the various processes.

The disk is very likely to be turbulent because of the high Reynolds number $Re \sim (GMR)^{1/2}/\nu \geq 10^{10}$, where ν refers to the molecular viscosity. Mechanisms which could, in principle, result in turbulence include shear motion due to differential rotation (Zeldovich 1981), relative motion of accreting material with respect to the disk (Cameron 1962), and thermal convection (Lin and Papaloizou 1980). At present the best developed theory is that of turbulent viscosity arising from convective instability in the vertical direction. The results of such calculations are approximately represented by the viscosity parameter α (Shakura and Sunyaev 1973) which is $\sim 10^{-2}$ (Lin and Papaloizou 1980) or 10^{-2} to 10^{-4} (Cabot et al. 1987*a, b*). The corresponding time scale t_r for redistribution of the angular momentum over a length scale of the order of the present-day size of the solar system ranges from 10^5 to 10^7 yr. Estimates of the turbulent viscosity in the disk arising from shear between accreting material and the disk give $\alpha \sim 10^{-2}$ and $t_r \sim 1$ to a few times 10^5 yr (Ruzmaikina 1982). The shear flow will definitely induce turbulence near the surface of the disk, but it is also possible that turbulence can be generated throughout the entire thickness of the disk. This statement is supported by measurements of turbulence in the ocean, where the turbulence is excited at the surface by wind. In spite of a stable density stratification, intermittent turbulence is measured down to depths of several km. Finally, turbulence associated with differential rotation can proceed through development and interaction of global nonaxisymmetric unstable modes (Sekiya and Miyama 1988*b*). The growth time is $\sim 10^3$ to 10^4 yr, but the evolution time t_r is uncertain.

Conditions for the occurrence of axisymmetric gravitational instability in a disk have been investigated by Safronov (1960) and Toomre (1964). Numerical calculations of a disk with a central point mass (Cassen et al. 1981) indicate that nonaxisymmetric effects in the form of trailing spiral waves

develop, which result in transfer of angular momentum if $M_{\text{disk}} > M_{\text{central}}$. A disk of moderate mass $M_{\text{disk}} \sim M_{\text{central}}$ can be unstable to nonaxisymmetric disturbances having growth rates comparable to the orbital frequency at the outer edge (Adams et al. 1989). Lin and Pringle (1987) derived a time scale $t_r \sim 10\Omega^{-1}$. However, it is not clear whether angular momentum is transported over large radial distances. Vertical temperature stratification in the disk can refract waves with azimuthal wave number $m \geq 2$ to high altitudes, where they may steepen and dissipate (Lin et al. 1990). Adams et al. (1989) suggest that spiral waves with $m = 1$ may be most effective at transporting angular momentum over large radial distances. These are eccentric modes in which the star and the disturbance orbit around their common center of mass. The unstable modes can encompass the entire disk and be driven nonlinearly by these eccentric motions. In general, the gravitational instabilities result in transport of angular momentum through spiral waves on a near-dynamical time scale. However, it is possible that under special conditions the $m = 1$ instability could result in the formation of a binary (Sec. IV).

Magnetic fields amplified during the collapse of a cloud or generated by a hydromagnetic dynamo can result in angular momentum transport in the inner part of the disk (Lüst and Schlüter 1955; Hoyle 1960; Alfvén and Arrhenius 1976; Levy and Sonett 1978; Ruzmaikina 1981a, 1985; Hayashi 1981; Stepinski and Levy 1988). The central region is hot enough for the evaporation of dust particles and thermal ionization of the alkaline metals ($T \geq 1600$ K). According to some models of protostellar evolution the radius of the region where the field is coupled sufficiently to the gas changes from a few tenths to about 1 AU (Makalkin 1987; Ruzmaikina and Maeva 1986). At larger distances it is generally thought that the degree of ionization near the central plane would be much lower because the thermal ionization is negligible and the disk is opaque to external sources of ionization such as cosmic rays.

However, non-negligible magnetic effects can occur also in those regions that are transparent to galactic cosmic rays—at high altitudes above the mid-plane and in the outer regions of the disk where the surface density is $< 10^2$ g cm $^{-2}$. From data on molecular clouds, one can expect that the cosmic ray ionization rate $\zeta \sim 10^{-17}$ s $^{-1}$, which makes possible a moderate enhancement of the magnetic field.

The maximum intensity of the azimuthal magnetic field B_ϕ that can be generated from an axially symmetric poloidal component B_p is limited by Ohmic dissipation to $B_\phi \leq R_m B_p$ (where R_m is the magnetic Reynolds number associated with the differential rotation), or by ambipolar diffusion (Levy et al. 1991). In a Keplerian disk the limiting value is

$$B_\phi^2 \leq 10^{11} \rho \left(\frac{\xi}{10^{-17} \text{s}^{-1}} \right) \sqrt{R/1 \text{AU}} \sqrt{M/1 M_\odot} \text{ gauss}^2. \quad (4)$$

In the case when the solar nebula is turbulent, the hydromagnetic dynamo could generate both B_ϕ and B_p . Ambipolar diffusion restricts the maximum

intensity of the field to (Levy et al. 1991)

$$B_\phi \sim 4\alpha^{1/4} \left(\frac{\xi}{10^{-17} \text{ s}^{-1}} \right) \sqrt{R/1 \text{ AU}} \sqrt{M/1 \text{ M}_\odot} \text{ gauss.} \quad (5)$$

In general, B_p is less than B_ϕ by a factor of \sqrt{D} , where D is the dynamo number ($\propto \alpha^{-1}$; α is the turbulent viscosity parameter). The time scale of redistribution of angular momentum has the lower limit $t_r = \rho \sqrt{GMR} / (B_p B_\phi) \sim 10^8$ to 10^{10} s in the region beyond several AU where the matter is transparent to cosmic rays. Even if the field in the outer part of the nebula is just a remnant of the compressed interstellar field, t_r can be short compared with accretion times. Then $t_r \sim (\rho/10^{-11}) \times 10^9 / (B_p B_\phi) \sim (\rho/10^{-11}) \times 10^9 / B^2$ is less than the accretion time (10^5 yr) if $B \geq 1.7 \times 10^{-2}$. If $B \propto \rho^\gamma$ during collapse and the interstellar field in a cloud core is 10^{-5} gauss, then the required value for γ is 0.4; if the initial field is as high as 10^{-3} gauss, the value of γ is only 0.125. Thus only a modest enhancement of the interstellar field can have significant consequences once the disk stage is reached.

To summarize, the magnetic field could be an effective mechanism for redistribution of angular momentum both in the early stages of star formation and in a disk. Magnetic transport probably accounts for the difference of 2 orders of magnitude in the specific angular momentum of molecular clouds themselves and their cold, dense cores. In a disk, magnetic effects can be important except in the dense, cold, essentially un-ionized region at intermediate distances from the central object (e.g., 1 to 10 AU for central mass $M_c = 1 \text{ M}_\odot$ and disk mass $M_d \sim 10^{-2}$ to 10^{-1} M_\odot). The time scale in the inner warm region can be as short as 10 times the orbital frequency (Hayashi 1981). In the outer regions the times could fall in the range 1 to 10^5 yr. Gravitational instability, generally in a relatively massive disk, can also result in rapid transport, on time scales again ~ 10 orbital periods. Turbulent shear flow during the infall phase is estimated to give transport times of $\sim 10^5$ yr. Turbulent convection is likely to be present in the 0.5 to 20 AU region where grain opacity dominates and where the nebula is optically thick. The resulting transport times fall in the range 10^5 to 10^7 yr. If a binary is to form in a disk, its formation time must not be much longer than that of the fastest applicable mechanism for angular momentum transport; the appropriate conditions have not been determined.

IV. THEORIES OF BINARY FORMATION

Theoretical work at the present time is still in the stage of identifying the primary mechanism for binary formation. Theory is not yet able to clarify the important questions concerning the binary frequency and the distributions of orbital periods and mass ratios. It is also not clear under what circumstances single stars form (see Sec. V). In fact, for a cloud of given mass and total angular momentum, it is energetically favorable to form a single star with

a low-mass disk or a binary with a very large mass ratio (Lynden-Bell and Pringle 1974). One might expect that most stars would be found in such systems, but observations show otherwise. Presumably, the angular momentum redistribution required to produce them is in many cases not effective enough to prevent fragmentation at a relatively early phase of protostellar evolution. In this section we discuss, first, binary formation by fragmentation during the hydrodynamic collapse of a protostar; second, fragmentation after a relatively massive disk has formed; and third, other binary formation processes such as capture and fission.

A. Fragmentation During Protostellar Collapse

The theory of fragmentation was introduced by Hoyle (1953) but without the crucial element of rotation. Recent work on fragmentation during the protostar phase has concentrated on numerical calculations of hydrodynamical collapse with rotation in three space dimensions. The evolution of the protostar may be divided into the earlier optically thin isothermal phase and the later adiabatic phase, which sets in when the density ρ has increased to values above 10^{-13} g cm⁻³. The three-dimensional calculations generally start out with uniform density, uniform angular velocity, and small nonaxisymmetric perturbations in the density. The importance of rotation is measured by the ratio β of rotational to gravitational energy. If angular momentum is conserved locally, then $\beta \propto \rho^{1/3}$ in the limit of slow rotation. During the first free-fall time the cloud collapses, becomes centrally condensed, and develops rotational flattening; however little growth of the perturbations occurs, relative to the collapsing background. The collapse then slows down because of pressure effects parallel to the rotation axis and rotational effects perpendicular to it. During the process of the formation of a disk-like structure, the system fragments, generally through a nonaxisymmetric pattern, into two or more orbiting subcondensations. The properties of the fragments depend on the initial perturbation. An $m = 2$ perturbation will generally result in fragments of roughly equal mass, with a total mass of about 15% of the original cloud mass over the time scale of the calculations, which are generally run only 1 to 1.5 initial free-fall times (Boss 1986a). A perturbation closer to $m = 1$ will result in highly unequal-mass fragments (Boss 1990). The typical fragment has a residual spin angular momentum per unit mass which is an order of magnitude or more smaller than that of the original cloud.

Extensive calculations have been carried out for the isothermal case. If rotational effects are to become important while the gas is still isothermal, the degree of collapse must be relatively mild, and therefore the initial angular momenta must be relatively large; wide systems are produced. Exploratory calculations with $m = 2$ perturbations of relatively large amplitude produced binaries (Bodenheimer et al. 1980; Boss 1980; Bodenheimer and Boss 1981); more recent calculations with small perturbations have produced larger numbers of fragments. If we define α_i and β_i to be the initial ratios of thermal and rotational energy, respectively, to the absolute value of the gravitational

Figure 3. Fragmentation of an isothermal cloud with $\alpha_i = 0.2$, $\beta_i = 0.3$ (Miyama et al. 1984). Projected particle positions are plotted in the equatorial (x,y) plane, after 2.19 initial free-fall times. R_o is the outer radius.

energy, then we find that the number of fragments increases as α_i decreases, as was demonstrated by Larson (1978) with a simple particle core. Figure 3 shows the result of Miyama et al. (1984) with $\alpha_i = 0.2$ and $\beta_i = 0.3$, starting with density fluctuations $\delta\rho/\rho \sim 0.05$, in which about 8 fragments formed. The numerical method is a modification of the smoothed-particle hydrodynamic scheme originally developed by Lucy (1977). The individual fragments, which have roughly equal mass, also have low enough α_i and β_i so that they can collapse and fragment again, forming hierarchical multiple systems (Larson 1972; Bodenheimer 1978). A recent calculation by Monaghan and Lattanzio (1991), including molecular cooling in the optically thin phase, shows similar results. Their smoothed-particle calculations were carried out with up to 30000 particles, starting with random initial density perturbations

with typical initial amplitudes of 14%. With $\alpha_i = 0.47$ and $\beta_i = 0.3$, the system evolved, after cooling, into 6 fragments in a roughly ring-like configuration (Fig. 4).

Figure 4. Fragmentation of a cooling cloud with $\alpha_i = 0.25$, $\beta_i = 0.04$ (Monaghan and Lattanzio 1991). Projected particle positions are plotted in the equatorial (x,y) plane at two different times (given in units of $R^3 M^{-1} G^{-1}$, where R and M are the initial radius and mass of the cloud, respectively). The resolution length H is given in terms of R .

For values of the initial angular momentum that are small enough to produce a close binary, the central part of the cloud becomes opaque before rotational effects become significant in promoting fragmentation, and fragmentation will tend to be suppressed (Safronov and Ruzmaikina 1978; Ruzmaikina 1988). Calculations of fragmentation in the adiabatic phase are more difficult, because the cloud develops a large density contrast before the central density reaches $10^{-13} \text{ g cm}^{-3}$, and the inner regions, which contain only a small fraction of the total mass, must be adequately resolved. Calculations for purely adiabatic collapse (Boss 1980) and for the transition between the optically thin and thick regions (Boss 1986a) give the general result that if α_i is high at the beginning of adiabatic collapse, fragmentation is suppressed. For $\alpha_i \sim 0.05$ to 0.1 , fragmentation can occur. Figure 5 shows a calculation of Boss (1986a) with $\alpha_i = 0.25$ and $\beta_i = 0.04$, starting in the isothermal phase and including radiative transfer. In this particular case, fragmentation into a binary occurs just before the adiabatic phase sets in. The distance between the orbiting fragments is 110 AU and the period is ~ 1000 yr, emphasizing the fact that fragmentation in the isothermal phase can explain only the longer-period systems. The reason is related to the fact that the central part of a protostar becomes optically thick on a scale of 100 AU because of grain opacity. In a low-angular-momentum cloud rotational effects become important in promoting fragmentation only in the optically thick region, where nearly adiabatic heating and the consequent increase in pressure tend to smooth out perturbations. However, when the central region reaches a temperature of

2000 K, molecular dissociation occurs, the adiabatic Γ 's of the gas decrease to values close to those appropriate for the isothermal phase, and conditions again become favorable for fragmentation (Larson 1972). The scale of this region is <1 AU, and the possibility of forming close binary systems at this stage exists but has not been adequately tested. Problems with this suggestion that must be considered include (1) the amount of mass initially present in the unstable region is very small, (2) later addition of material of higher angular momentum from the outer part of the cloud will tend to separate the system, and (3) generation of spiral waves in the cloud by the binary will tend to bring the components closer together.

Figure 5. Fragmentation calculation including radiative transfer with $\alpha_i = 0.25$, $\beta_i = 0.04$ (Boss 1986a). Contours of equal density in the equatorial plane are plotted after one freefall time. Sample values of $\log \rho$ are indicated; the initial density was $2 \times 10^{-18} \text{ g cm}^{-3}$. The length of one side of the box is 360 AU.

Alternate modes of fragmentation have been suggested, for example, in the collapse of cylindrical nonrotating clouds (Bastien 1983; Rouleau and Bastien 1990). A related mechanism involves elongated, prolate filamentary fragments rotating end over end (Zinnecker 1989a), in which, after fragmentation, the components first move almost directly toward each other until they reach the centrifugal barrier. Numerical calculations by Bonnell et al. (1991) indicate the formation of multiple systems by this process. Such elongated dark clouds are commonly observed in star-forming regions. Finally, it has been argued (Boss 1988) that fragmentation can occur on all scales and can explain the full range of binary orbital angular momenta. To explain the formation of close binaries by this process he relies on first, orbital decay of longer-period binaries by gravitational torques, and second, hierarchical fragmentation in which low- α initial conditions are provided in the adiabatic phase by previous fragmentation near the end of the isothermal phase. His numerical results (Boss 1986a) show that fragmentation in the adiabatic phase can produce systems with separations as small as 1 AU, given suitable initial conditions.

General criteria for the fragmentation of rotating collapsing clouds have been developed. For isothermal collapse, Miyama et al. (1984) have shown that fragmentation occurs if $\alpha_i \beta_i < 0.12$. Above this limit, nonfragmenting equilibria or disk systems are formed. For an adiabatic gas with $\gamma = 1.4$, fragmentation occurs if $\alpha_i < 0.09 \beta_i^{0.2}$ (Miyama 1989a; Hachisu et al. 1987; Tohline 1981; Boss 1981). This criterion is not necessarily useful for protostars, which begin their collapse in the isothermal phase and evolve into the adiabatic phase only in their central regions at a later time. Thus wide binaries (those with relatively high angular momentum) can be understood to have been formed by fragmentation in the isothermal phase. But a major problem remains concerning the origin of close binary systems. A further possibility, apart from fragmentation during dissociation or hierarchical fragmentation during the adiabatic phase, is that clouds with relatively low angular momentum collapse through the adiabatic phase without fragmenting, then evolve to a central object plus a relatively massive equilibrium disk. Gravitational instability in such a disk could then result in a close binary.

B. Disk Fragmentation

The standard indicator for the occurrence of gravitational instability in a thin disk, which could, under the right conditions, lead to fragmentation, is the Toomre (1964) $Q = \kappa c / (\pi G \sigma)$, where κ is the epicyclic frequency, c is the isothermal sound speed, and σ is the local surface density. Axisymmetric perturbations are stabilized if $Q > Q_c$, where $Q_c \sim 1$. Larson (1985) generalized this condition to thin gaseous disks which are not necessarily isothermal, obtaining the same formula with c evaluated at the midplane. Values of Q_c range from 0.53 to 0.68, depending upon the equation of state. Hachisu et al. (1987, 1988) develop a revised formulation of the criterion. They give convincing arguments that the condition for occurrence of an axisymmetric

ring instability in the equilibrium configuration also gives the condition for instability to fragmentation. Two conditions must be met if the disk is to fragment. First, the ratio $t_{ff}/t_s < f_J$, where t_{ff} is the free-fall time at mid-plane, t_s is the sound travel time around the circumference of the disk, and $f_J \sim 0.1$. Second, $t_{ff}/t_{ep} < f_R$, where $t_{ep} = 2\pi/\kappa$, and $f_R \sim 0.15$. The second criterion is generally the governing one, and it can be expressed as $\frac{\kappa^2}{\pi G \rho} < 1$ for instability. The improvements in this criterion include the fact that it is not limited to thin disks, it is independent of the equation of state and the rotation law, and that it gives a criterion for *instability*, while Q is actually a stability indicator. Their results show that a collapsing cloud which conserves angular momentum is likely to fragment if the axisymmetric equilibrium configuration towards which it is collapsing is ring-like. This suggestion is consistent with three-dimensional numerical simulations. For example, in the isothermal case (Miyama et al. 1984) the criterion for fragmentation ($\alpha_i \beta_i < 0.12$) is also the criterion for ring formation in the equilibrium isothermal disk with the same angular momentum distribution.

Investigations of the nonaxisymmetric gravitational instability of thin disks have been performed by Adams et al. (1989) and Shu et al. (1990). This effect has been referred to as the “sling instability,” meaning “stimulation by the long-range interaction of Newtonian gravity.” They concentrate on the $m = 1$ (one-armed spiral) mode and find that eccentric distortions can grow on a time scale comparable to the orbital frequency at the outer edge of the disk. Growth times become shorter if the mass of the disk, relative to the central object, increases or if the temperature decreases. More precisely, growth times can be shorter than the 10^7 yr lifetimes of disks around T Tauri stars (Strom et al. 1989*d*) if $Q \leq 3$ at the corotation radius. Thus disks that are stable to axisymmetric modes (that is, those with $Q > 1$) according to the Toomre criterion can be unstable to nonaxisymmetric modes. Because of the eccentric nature of the unstable mode, they speculate that binary formation in the disk is a possible outcome. An important result of the linear analytic and numerical calculations is the determination of the so-called maximum-mass solar nebula. The disk is found to be stable to all gravitational disturbances below a critical value of its mass (which depends also on the temperature in the disk). The critical ratio of disk mass to total mass (disk plus central object) is found to be 0.24 if the Toomre Q value at the outer edge of the disk is 1. The speculation is that disks with lower mass can form planetary systems while those with greater mass may transport angular momentum through spiral waves or may develop a binary companion. Nonlinear calculations are necessary to verify this suggestion and to provide further insight into the question of the origin of close binaries. The first of such calculations (Yang et al. 1991), shows that star-disk systems resulting from the collapse of cloud cores become dynamically unstable to the generation of spiral modes right at the time of formation. It was not determined whether fragmentation of the disk occurred. Future work along these lines is necessary to predict, for

example, the expected mass-ratio distribution from a disk instability.

C. Other Possibilities

The classical fission theory, involving the breakup of a rapidly rotating equilibrium object into two or more pieces in orbit as a result of dynamical instability to nonaxisymmetric perturbations, has often been suggested as a mechanism for the formation of close binary systems. However, there are numerous difficulties (reviewed by Tassoul 1978). For example, (1) pre-main-sequence single stars have too little spin angular momentum to be consistent with that of a typical close binary orbit (Table III); (2) angular momentum considerations (see Pringle 1989*c*) indicate that the mass ratio q of the binary would have to be small, ~ 0.1 , contrary to observations; (3) the required initial condition may never be attained; and (4) numerical three-dimensional simulations of the process show that breakup does not occur. To consider the last two points, it is known that the classical Maclaurin spheroid becomes unstable to nonaxisymmetric perturbations when the ratio β of the rotational energy to the absolute value of the gravitational energy exceeds 0.27. Similar critical values of β hold for polytropes. However, in a rapidly rotating stellar-like object with polytropic index $n \geq 0.8$, the critical value of β will not be reached if a mechanism for angular momentum transport, such as the magnetic field, is efficient. The transport tends to result in uniform rotation in the interior and outflow in the equatorial plane to form a disk (Ruzmaikina 1981*b*). Even if the critical condition for instability can be reached (Fig. 6), numerical simulations (Durisen et al. 1986; Williams and Tohline 1988) for polytropes with $\beta = 0.3$ to 0.4 show that a bar-like structure forms in the center, then spiral arms form, angular momentum is transferred outward, and the end result is a ring surrounding a central bar that is stable to nonaxisymmetric perturbations. No fission occurs.

Related numerical studies have been performed for polytropic equilibrium toroidal configurations (Tohline and Hachisu 1990). These structures can be dynamically unstable for values of β as low as 0.16; however, in the range $0.17 \leq \beta \leq 0.27$, they do not fragment but instead develop ellipsoidal shapes and transfer angular momentum outward. It is not excluded, however, that fragmentation of tori could occur for other values of β or for other equations of state (see, e.g., Norman and Wilson 1978). Lebovitz (1989) has recently defended the fission theory, suggesting but not proving that other initial conditions from those chosen for the numerical simulations could lead to fission.

Capture (Stoney 1867) is often mentioned as a binary formation mechanism. The process requires either (1) the presence of a third object to carry off the excess energy; (2) tidal dissipation in a close two-body encounter; or (3) the presence of a dissipative medium in the system. The likelihood of the first two processes in the galactic disk or in associations and the effectiveness of the third process in protostellar envelopes has been shown to be negligibly small (Boss 1988). However, three-body encounters and tidal captures may

Figure 6. Fission calculation for an equilibrium polytrope with index $n = 0.8$ and $\beta_i = 0.31$. A time series of isodensity surfaces with $\rho/\rho_c = 10^{-3}$ is shown, where ρ_c is the central density. Times are given in terms of the central rotation period (Williams and Tohline 1988).

be of importance in the dense cores of globular clusters (Verbunt 1989; see Abt 1983). Larson (1990) has suggested that protostellar disks can provide the dissipation needed to promote capture in dense young clusters such as the Trapezium cluster associated with the Orion Nebula, although calculations by Clarke and Pringle (1991a) raise difficulties with this mechanism.

An important variant on the capture scenario involves the gravitational and dissipative interactions of a system of loosely bound fragments within a dense molecular core, in analogy to binary production in the disintegration of systems with a small number of stars (see, e.g., van Albada 1968a, b). The formation of the systems could either be induced by cloud collisions (Pringle 1989c) or occur by fragmentation during collapse, as illustrated in Figs. 3 and 4. Clarke and Pringle (1991b) have performed dynamical calculations for triple-star systems, including dissipation induced by the associated disks.

They find that a wide variety of binary orbital periods and eccentricities are possible outcomes, depending on only small changes in the initial conditions. A key concern here is that the orbital time scale of these interactions is comparable to the fragment collapse time scale. Thus, Boss (1986a) in a numerical study of fragmentation, shows that some of the incipient binaries have orbital decay times (by loss of angular momentum to trailing spiral arms) shorter than the contraction time of the components. He suggests that this process would lead to mergers, but it is also possible that close binaries would result. However, the numerical calculations have not been carried out long enough to prove this conjecture, and several physical processes have not been considered, such as H_2 dissociation and the accretion of material with higher specific angular momentum.

V. CRITERIA FOR THE FORMATION OF SINGLE STARS

Numerous suggestions have been made concerning the formation of single stars. For example, they could form as a result of fragment interactions in an incipient multiple system, resulting in the ejection of one member. Or, they could result from the spiralling together, as a result of gravitational torques, of binary components that have formed by fragmentation (Boss 1986a). This section concentrates, however, on direct formation of a single star as a result of the collapse of a rotating cloud, for various values of the specific angular momentum.

Note that the maximum possible angular momentum of a $1 M_\odot$ star is about $10^{51} \text{ g cm}^2 \text{ s}^{-1}$ (Ruzmaikina 1981b), if it has the present solar structure and is rotating at breakup. Most T Tauri stars rotate significantly slower than the breakup velocity (Vogel and Kuhi 1981; Hartmann et al. 1986; Hartmann and Stauffer 1989). However, even a minimum-mass solar nebula adds a considerable amount of angular momentum. Reconstruction of the nebula by adding sufficient H and He to the present planets to recover the solar chemical composition (Weidenschilling 1977b), and adding a comparable mass to allow for ejection of material by the gravitational effects of the giant planets, gives a minimum mass M and angular momentum J of $0.02 M_\odot$ and $5 \times 10^{51} \text{ g cm}^2 \text{ s}^{-1}$, respectively (for radius $R = 10 \text{ AU}$). For this reconstituted disk model, M and J increase as $R^{1/2}$ and R , respectively, resulting in $M = 0.04 M_\odot$ and $J = 2 \times 10^{52} \text{ g cm}^2 \text{ s}^{-1}$ for the solar nebula with radius 40 AU. Therefore it is reasonable to consider a cloud core with specific angular momentum $j \sim 10^{19} \text{ cm}^2 \text{ s}^{-1}$ as an initial condition for the formation of the solar system.

If this core has uniform rotation and uniform density, then the centrifugal radius to which it will collapse is $\sim 0.05 \text{ AU}$. Formation of a single star is plausible in this case because the rotation is slow enough so that a stellar core in hydrostatic equilibrium can form before fragmentation can occur (Ruzmaikina 1981a, b). The initial mass, radius and central density of the core will be similar to those in the nonrotating case (Larson 1969): $M_c \sim 10^{-2} M_\odot$,

$R_c \sim 3 \times 10^{11}$ cm, $\rho_c \sim 10^{-2}$ g cm $^{-3}$. The temperature is high enough so that there is substantial ionization. This core accretes from the surrounding cloud and develops differential rotation, with angular velocity increasing inward. It is likely to possess a magnetic field of strength 10 to 10^3 gauss, resulting from intensification of the interstellar magnetic field (Ruzmaikina 1985). The outward transport of angular momentum by magnetic torque prevents the core from becoming unstable and produces an outflow of gas from the core equator to form an embryonic disk (Ruzmaikina 1981a, 1985). Another mechanism that might inhibit core fragmentation and produce outward angular momentum transport is the generation of a spiral density wave in the envelope by a nonaxisymmetric core (Yuan and Cassen 1985). This model, therefore, involves accretion of most of the infalling material onto the star, and ejection of a disk during the later stages of infall.

Crude estimates of the mean radial density profiles of molecular cloud cores give $\rho \propto R^{-p}$ with $1 < p < 2$, in the radial range from 0.1 to 0.5 pc. More detailed information on density and velocity distributions within small cloud cores is still lacking (Myers et al. 1987). For the purpose of making estimates in the following discussion, we use two limiting descriptions of cloud cores:

$$\Omega = \text{const for } \rho = \text{const} \quad (6a)$$

$$\Omega = \text{const for } \rho \propto R^{-2}. \quad (6b)$$

Relation (6a) could result from the initiation of collapse by external sources, such as a fast contraction behind a shock front. On the other hand, a cloud which evolved through a slow nonhomogeneous contraction while being supported primarily by a magnetic field could have had effective redistribution of angular momentum to result in relation (6b), which corresponds to the uniformly rotating singular isothermal sphere (Shu 1977).

We estimate here the maximum angular momentum J_c consistent with the formation of a single star in this scenario. The absence of low-mass (10 to 80 Jupiter masses) binary companions to main-sequence stars (Campbell 1989; Marcy and Benitz 1989) is consistent with a relatively low (1 to 5×10^{52}) value for J_c (Ruzmaikina 1989). For $J < J_c$ one would expect the formation of a single star with a low-mass disk that is stable to fragmentation. For $J > J_c$, fragmentation during the stage of dynamical collapse is likely, resulting in roughly equal masses.

For the formation of a single star, we assume the following conditions must hold: first, a star-like core of $\geq 10^{-2} M_\odot$ must form. Second, the mass of the disk cannot exceed, roughly, the mass of the star; otherwise the disk is likely to be unstable to binary formation. Third, the maximum centrifugal radius for the accreting envelope must be relatively small in radial extent (1 to a few AU) so that it will be hot, the magnetic Reynolds number will be $\gg 1$, and the field can efficiently transport angular momentum.

In case (6a), the first condition is not well determined but falls in the

range (Ruzmaikina 1981*b*)

$$4 \times 10^{51} \left(\frac{M}{M_{\odot}} \right)^{5/3} < J_c < 2 \times 10^{52} \left(\frac{M}{M_{\odot}} \right)^{5/3}. \quad (7)$$

The relation between the core mass and the total mass is given by $M_c = 0.36M(R_c GM^3/J^2)^{1/3}$, where R_c is the core radius, in the limit $R_c \ll R_k$, where the centrifugal radius $R_k = j^2/GM$ (Levy et al. 1991). It follows from this relation that $M_{\text{disk}} \sim M_c$ at the end of accretion when $R_c GM^3/J^2 \sim 1$. Using $R_c = 3 \times 10^{11}$ cm (Stahler et al. 1980), we obtain $J < 1.3 \times 10^{52}$ g cm² s⁻¹ for $1 M_{\odot}$. This result is similar to that given by Eq. (7). Thus the first and second conditions give comparable values of J_c in this case, and they restrict J_c more strongly than does the third condition.

For case (6b), the first condition gives a high value of $J_c \sim 2 \times 10^{54} (M/M_{\odot})^3$ (Levy et al. 1991), so in fact the second and third conditions provide stricter limits. In this case, the ratio of M_c to M is given by $M_c = 0.5M(R_c GM^3/J^2)^{1/3}$ (Levy et al. 1991). It follows that $R_c GM^3/J^2 \sim 1$ as in Case 6a, so $J_c = 1.3 \times 10^{52}$ g cm² s⁻¹, from the second condition. On the other hand, the third condition states that the centrifugal radius $R_k < R_d$, where R_d is one to a few AU. At the end of accretion, $j = 9/2(J/M)$, from which we find that $J_c \sim 2 \times 10^{52}$ g cm² s⁻¹ for $R_d = 1$ AU and $M = 1 M_{\odot}$. If $R_d > 1$ AU, then $J_c \propto (R_d/1\text{AU})^{1/2}$. Thus the second and third conditions give comparable values of J_c . The argument indicates, therefore that $J/M \sim 10^{19}$ is the upper limit for formation of a single star.

For a cloud with $J = 2 \times 10^{52}$ and $1 M_{\odot}$, $R_k = 0.3$ AU or 1 AU for distributions (6a) and (6b), respectively. The evolution of the system depends, in this case, on the relative time scales of infall (t_a) and angular momentum redistribution (t_r). If redistribution is inefficient, then the final radius of the disk $R_d \sim R_k$. But if $t_r < t_a$ then $R_d > R_k$. In that case, M_d will be small, $\sim 10^{-2}$ to $10^{-1} M_{\odot}$. For example, with $J = 2 \times 10^{52}$ and $R_d = 40$ AU and with $\sigma \propto R^{-3/2}$, $M_d = 0.08 M_{\odot}$. This relatively low mass is consistent with angular momentum transport by magnetic fields for $R < 1$ AU and in the transparent outer regions. In the intermediate weakly ionized region some other transport mechanism must be effective, such as turbulence or gravitational torques. In summary, the low angular momentum case ($j \sim 10^{19}$) can result in single star formation as a consequence of angular momentum transport outward after most of the matter has fallen into the central star.

However, two-dimensional simulations of the formation of the solar nebula from collapse of a rotating cloud (Tscharnuter 1989; Bodenheimer et al. 1990) often assume higher values of j . For example, $j \sim 10^{20}$ seems to be required for agreement between calculated and observed spectra of a number of infrared sources (Adams et al. 1987). In this case, the central part of the collapsing protostar will become opaque before fragmentation occurs (Safronov and Ruzmaikina 1985), and it is not immediately clear whether or not fragmentation can occur at a later stage (for example, during dissociation

of H_2 ; see above). According to Boss (1987) a cloud with $j \sim 10^{20}$ with distribution (6a) is likely to fragment during collapse, but a cloud with a centrally condensed distribution will evolve into a single star. The numerical calculations have probably not been carried out for sufficient time or with sufficient resolution in the central regions to prove this hypothesis. However, if true, the (6b) distribution with this value of j will evolve into a central star with a disk with $R_d \sim 100$ AU. Then, inward transport of mass from disk to star is required, rather than outward transport for disk formation in the case of $j \sim 10^{19}$. However, if there is no angular momentum transport during accretion, the disk is likely to be massive and gravitationally unstable. The instability could be an advantage if it promoted rapid angular momentum transport; on the other hand, it could prove to be a difficulty if binary formation resulted. A further problem lies in the difficulty of removing the excess mass in the disk after the presumed planetary system has formed. Further evolutionary calculations are necessary to determine the effectiveness of angular momentum transport and radiative cooling on the stability of the disk.

Even higher angular momenta are possible, as Miyama (1989*b*) proposes. Single stars could form from clouds with j near the observed value of $\sim 10^{21} \text{ cm}^2 \text{ s}^{-1}$ if α_i and β_i are in the range where the cloud core is stable to fragmentation ($\alpha_i \beta_i > 0.12$). Such a cloud will tend to evolve first into a rotationally supported isothermal equilibrium. With a proper choice of α_i and β_i the cloud will be unstable to nonaxisymmetric perturbations ($\beta > 0.27$) although stable to fragmentation. The instability would result in the formation of a bar-like structure and transport of angular momentum out of the central region by gravitational torques (Durisen et al. 1986). When sufficient angular momentum has been removed from the central regions, they will collapse from a centrally condensed initial condition, and the result will be similar to that of one of the previously discussed cases ($j \sim 10^{19}$ to $10^{20} \text{ cm}^2 \text{ s}^{-1}$). The angular momentum is transferred to the outer parts of the core which then do not collapse.

VI. SUMMARY AND CONCLUSIONS

Observations show that a significant fraction of stars form as binary systems; the observational constraints on binary formation are summarized at the end of Sec. II. The origin of the orbital angular momentum in those systems is most likely associated with the turbulent motions in molecular clouds from which the stars form. Observational information on velocity gradients across many cores is consistent with rotation, and the specific angular momenta are comparable with those of the wider binary systems. However, in some cases, the angular momenta may have been overestimated because velocity gradients can also be produced by other dynamical effects, such as inclined bipolar outflows. Further detailed observations with improved spatial and velocity resolution and improved dynamical analysis are required. These observations would also help to determine the fraction of cores with relatively low angular

momenta in the range necessary to form single stars or close binaries. They could also help to provide radial distributions of angular momentum within individual cores and thereby constrain initial conditions for protostar collapse.

Many different processes could account for the origin of binary systems; these can roughly be classified as capture, fission, and fragmentation mechanisms. Here we summarize the observational and theoretical arguments that apply to each of these processes.

Binary formation by capture of independently formed stars could occur by the three-body process, by tidal capture, or in the presence of a dissipative medium. However, current estimates indicate that such events are far too rare in the low stellar densities of the galactic field or even of associations to be solely responsible for the present field binary population. (Such captures may occur in very compact young clusters, such as the Trapezium Cluster, or in the cores of globular clusters.) Furthermore, three-body capture would tend to produce very wide orbits and tidal capture very close orbits; neither distribution (nor likely their union) would be in agreement with the observed period distribution. Capture processes do produce a wide range of orbital eccentricities, as observed. A more critical observational test would be the nonalignment in binaries of the stellar spin axes with each other and with the orbital plane. This test represents a very challenging but critical observational program. Finally, noncoevality of binary components would favor the capture theory. However, at present there is no evidence for such noncoevality on time scales >1 Myr. Thus if capture is a significant mechanism in binary formation, it must occur soon after the formation of each star.

Fission is traditionally associated with nonaxisymmetric instabilities in a centrally concentrated object, which is in equilibrium and is rotating more rapidly than a critical rate. The mechanism would produce close binaries; however, a stellar core with angular momentum low enough to form a close binary will probably transport angular momentum outward, resulting in a single star plus a disk, before it has a chance to reach the critical condition for fission. Even if the critical condition is reached, numerical calculations indicate that fission does not occur. Observationally, pre-main-sequence stars are not observed to rotate rapidly. Furthermore, fission theory predicts large mass ratios ($q \sim 0.1$) while the great majority of the observed systems have higher values of q .

Fragmentation during the isothermal stage of protostar evolution could serve as the initial step toward producing binaries with a wide range of periods, as observed. Calculations indicate that such fragmentation can straightforwardly produce systems with periods greater than a few hundred years. Earlier simulations of fragmentation tended to produce circular orbits. However, recent work suggests that fragmentation will typically produce a moderate number of fragments (Figs. 3 and 4), possibly followed by gravitational and dissipative disk interactions leading to captures and ejections. A key issue here is the time scale of these interactions compared with the fragment collapse time scale. For rapidly collapsing fragments, these processes can produce a

wide distribution of orbital eccentricities as well as some short-period systems, although if there are many fragments an excessive number may be ejected as single stars (Clarke and Pringle 1991*b*). Another possibility for short-period systems is hierarchical fragmentation, involving subfragmentation during the adiabatic phase or during the collapse induced by molecular dissociation. An argument in favor of fragmentation as a formation mechanism is that it naturally produces hierarchical multiple systems, as commonly observed. Also, Zinnecker's (1984) hierarchical fragmentation theory is consistent with the observed gaussian-like distribution of periods. Finally, fragmentation may occur at a much later stage in a moderate-mass disk, perhaps through an $m = 1$ gravitational instability, which also would produce eccentric orbits.

In conclusion, we mention another important problem for future work. Recent observations indicate a deficiency of low-mass (0.01 to 0.08 M_{\odot}) companions to main-sequence stars of spectral types G, K and M. This fact may be significant for the question of single-star vs binary-star formation. One possible explanation could be the following. If the angular momentum of a cloud is below a relatively low J_c , a star-like core can form, and the result would be a single star with a relatively low-mass disk that could not fragment. But above J_c , fragmentation would occur during dynamic collapse, and the formation of comparable masses would be favored.

PRE-MAIN-SEQUENCE EVOLUTION AND THE BIRTH POPULATION

STEVEN W. STAHLER

Massachusetts Institute of Technology

and

FREDERICK M. WALTER

State University of New York at Stony Brook

We present an overview of what is known, both theoretically and observationally, concerning the evolution of stars prior to their ignition of hydrogen. We concentrate on the optically visible phase of pre-main-sequence contraction, when the star has already emerged from its parent cloud of gas and dust. This subject has a venerable history, and the classical model developed thirty years ago remains the basis of current theoretical treatments. Accordingly, we first review these historical developments, then discuss the modifications now in progress. There has been a wealth of observational data on pre-main-sequence stars obtained in recent years. In our treatment of the observational issues, we stress the morphological distinction between various classes of young stars, and the possible evolutionary link between these classes. The subject of pre-main-sequence evolution is a broad one, encompassing results from a large number of investigators over many years. We cannot hope in this limited space to present a comprehensive treatment. Our discussion is pedagogical, and our choice of topics is largely a reflection of individual taste and expertise.

I. THEORETICAL FOUNDATIONS

A. Classical Theory and Its Applications

1. Quasi-Static Contraction. The theory of pre-main-sequence (PMS) evolution attempts to provide a comprehensive physical account of optically visible stars prior to the onset of hydrogen burning. Over the last ten years, it has become clear that the classical theory first established by Hayashi and his contemporaries (Hayashi et al. 1962; Iben 1965; Ezer and Cameron 1967) is inadequate when confronted with the observations. While the shortcomings of this theory are well known to all workers in the field, it is nevertheless true that many of the basic features of the earlier models will continue to provide a framework for future endeavors. For this reason, and because the current ideas have not yet cohered into a unified account, we begin by reviewing the classical model of pre-main-sequence evolution.

The extraordinary longevity of stars is made possible by a delicate balance between the expansive effect of thermal pressure and the attractive force

of gravity. In main-sequence stars, the pressure is derived from the heat supplied by nuclear reactions near the star's center. This heat diffuses slowly through the stellar interior and is ultimately lost by radiation at the surface. In a star too young to burn nuclear fuel, the heat loss leads to gravitational contraction. The use of the word "contraction" is deliberate, and is meant to describe a process slow compared to the dynamical, or "free-fall," time scale. That is, the shrinking of the star that is the primary characteristic of pre-main-sequence evolution is controlled by the rate at which the stellar surface radiates away internal thermal energy. In true free-fall collapse, on the other hand, gravity itself sets the time scale, which is exceedingly brief (about an hour) for an object of typical stellar density. To emphasize this difference, the contraction of young stars is also said to be "quasi-static." At any instant, the approximation of hydrostatic equilibrium is an excellent one, but the star nevertheless shrinks over the heat-leakage, or "Kelvin-Helmholtz," time scale.

A quantitative expression for the Kelvin-Helmholtz time is obtained by first estimating the total thermal energy content of the star. By the virial theorem, the energy contained in thermal kinetic energy is one-half the gravitational potential energy. The latter is given, within a factor of order unity, by GM_*^2/R_* , for a star of mass M_* and radius R_* . Thus, t_{KH} , the Kelvin-Helmholtz time, is given by

$$t_{KH} \equiv \frac{GM_*^2}{R_*L_*} \quad (1)$$

where L_* is the stellar luminosity. To get a feel for this quantity, we may substitute solar values for M_* , R_* , and L_* , obtaining 3×10^7 yr. This is the time it took for the Sun's radius to shrink by roughly a factor of 2 immediately prior to hydrogen ignition. Since the main-sequence lifetime of the Sun is about 10 Gyr, the entire phase of pre-main-sequence evolution is exceedingly brief in comparison, and the relevant candidate stars are correspondingly rare.

The virial theorem may be used also to estimate the internal temperatures of pre-main-sequence stars. Applying the perfect gas law, which is appropriate for the interiors of stars of ordinary mass, we find that the thermal energy can be written as $M_*\mathcal{R}\langle T \rangle/\mu$, where $\langle T \rangle$ is the mass-averaged interior temperature and μ is the mean molecular weight. Since both the thermal and gravitational energies grow larger in magnitude as the radius shrinks, we see that $\langle T \rangle$ increases in the course of contraction. Thus pre-main-sequence stars are beautiful examples in Nature of objects with negative heat capacity—their temperatures rise as a result of the loss of heat. It is the relentless, compressive force of gravity which underlies this seemingly paradoxical effect.

2. The Role of Convection. Historically, the basic idea of quasi-static contraction was fully accepted by the beginning of this century. Nevertheless, it was not until the early 1960's that adequate interior models of pre-main-sequence stars were constructed. The difficulty lay in deciding the mode of

energy transport through the stellar interior, radiation vs convection. This issue turns out to depend in a subtle manner on the properties of the star's subphotospheric layers.

The physical quantity of key importance is the entropy per unit mass. Figure 1 shows schematically the distribution of this quantity in the outer layers of a young star of roughly solar mass. As the entire region of interest comprises a negligible amount of mass, the specific entropy is shown as a function of pressure; the star's center lies to the right. The layers just inside the stellar photosphere have such low opacity that they are always radiatively stable against convection. For the rather low surface temperatures of pre-main-sequence stars, the opacity in this region is provided by H^- ions, which obtain their electrons from easily ionized metals. The supply of electrons, and hence the opacity, increases dramatically with temperature. At temperatures near 10^4 K, another opacity source comes into play—the photoionization of hydrogen. The combined opacity therefore climbs steeply as we move inward from the photosphere. Eventually, at the pressure marked P_{rc} in Fig. 1, the temperature gradient needed to push out the interior luminosity is so high that the material is convectively unstable.

Figure 1. Specific entropy in the surface layers of a PMS star (schematic). Beginning at the photospheric pressure P_{phot} , the entropy falls from s_{phot} to s_{rc} , its value at the radiative-convective interface. The entropy then climbs the super-adiabatic gradient until it levels off at the interior value s_{int} .

Going from P_{phot} to P_{rc} , the specific entropy falls steeply because of the sharp increase in pressure. Inside this point, Schwarzschild's criterion dictates that the entropy must rise, so that s_{rc} , the entropy at P_{rc} , is a local minimum. The onset of hydrogen ionization leads to a very rapid entropy rise at first. Once ionization is complete, the rise is slowed to the characteristically tiny entropy gradient needed for convective transport in stellar interiors (see, e.g., Clayton 1968). Hence, the specific entropy quickly reaches the asymptotic value denoted s_{int} in the figure. This value must be matched by the outer limit of the star's interior entropy distribution. Finally, we note that the high-temperature sensitivity of the opacity implies that the entire entropy scale in the figure would be moved upward appreciably if the transported luminosity, or, equivalently, the value of effective temperature, were to increase by only a modest amount.

It was Hayashi (1961) who first realized that this outer entropy structure implies that the interiors of young stars can be *fully* convective. To show this, he first demonstrated the important result that any star of fixed mass and radius has a *minimum effective temperature*. Imagine a sequence of such stars with outer convection zones of varying depth. The requirement of fixed radius, together with the sensitivity of the radius to internal entropy, implies that the mass-averaged entropy in all models must be very similar. Thus, models with thin outer zones have correspondingly high values of s_{int} to compensate for the lower entropy values throughout their radiative interiors. It follows that the *minimum* value of s_{int} in this sequence is attained for that model with the fully convective interior. Since, as we have already noted, the value of s_{int} increases steeply as a function of T_{eff} , the existence of a minimum T_{eff} is established. The same temperature sensitivity of the opacity which plays a key role in this proof also implies that these minimum temperatures do not vary greatly as a function of stellar mass and radius. For solar-type stars, the "Hayashi temperature" is in the range from 4000 to 5000 K.

The fact that stars have a minimum surface temperature implies that sufficiently young ones will be fully convective, and hence will have surface temperatures equal to the minimum value. Young stars have large radii, so that their emitted surface luminosity, L_{surf} , is also large:

$$L_{\text{surf}} = 4\pi R_*^2 \sigma T_{\text{eff}}^4. \quad (2)$$

On the other hand, L_{rad} , the luminosity which can be transported by radiation in a star, is given by

$$L_{\text{rad}} = L_0 \left(\frac{M_*}{M_\odot} \right)^{11/2} \left(\frac{R_*}{R_\odot} \right)^{-1/2} \quad (3)$$

where L_0 is a luminosity of order $1 L_\odot$ (Cox and Giuli 1968). Thus, if we consider progressively younger and larger stars of fixed mass, we inevitably reach the point where L_{surf} exceeds L_{rad} . For larger radii, the energy transport which the star needs to replenish the loss from its photosphere must be achieved by convection.

The solid curve in Fig. 2 shows schematically a typical pre-main-sequence track, as derived by Hayashi and his contemporaries. The shaded portion of the figure represents the region in which the star would have an effective temperature below Hayashi's minimum value; this region is thus "forbidden" to the evolving star. The heavy dotted line shows how the border of the forbidden region intersects the zero-age main sequence (ZAMS). It is seen that the true evolutionary track departs from this border and approaches the ZAMS along a more horizontal path. Along this portion of the track, the star is no longer fully convective, but has developed an inner core that is radiatively stable. For historical interest, the dashed curve labeled "HLL" is the older pre-main-sequence track of Henyey et al. (1955), which ignored convection entirely in the evolving young star.

Figure 2. A theoretical PMS track (schematic). A star of a fixed mass is first convective and descends a nearly vertical path, eventually turning onto the more horizontal radiative track discovered by Henyey et al. (1955). The vertical path and its downward extension (dotted line) form the border of the forbidden region of Hayashi (1961).

The fact that young stars tend to be convectively unstable is of key importance in the interpretation of their observed properties. Moreover, the interior structure and contraction of fully convective stars can be described in a mathematically simple and elegant fashion. Since the interior specific entropy is nearly uniform, the stars can be modeled as polytropes of index

$n = 3/2$ (Clayton 1968). The distribution of all physical variables in stars of arbitrary mass and radius can be obtained by proper rescaling of the solution to the dimensionless Lane-Emden equation. One finds that the star's contraction is "homologous," i.e., that the run of pressure, temperature, etc. at one instant can be related to the run at another time through multiplication by a spatially-independent scale factor. In physical terms, the rapid and efficient homogenization by convection of the interior entropy implies that the star looks the same at any time, but is compressed globally as its evolution proceeds.

3. *Nuclear Burning.* The classical model provides a simple account of the onset of main-sequence hydrogen burning. We have seen that the internal temperature of a young star paradoxically increases as it radiates heat into space. At early times, the central temperature is simply too low for hydrogen to ignite, but sufficient contraction inevitably raises the temperature to the requisite 10^7 K. As the nuclear burning in the central core gradually increases, its energy input begins to resupply the energy continually lost from the surface. Concurrently, the rate of gravitational contraction slows. For a brief time, in fact, the nuclear-generated luminosity is *greater* than the surface value, and the star temporarily expands. Soon, however, the star settles into a thermally stable state in which the nuclear and surface luminosities are essentially identical, and the rate of internal entropy change is extremely low. At this point, the star has joined the ZAMS. The details of this transition were followed numerically for a large range of stellar masses by a number of authors, most notably Iben (1965) and Ezer and Cameron (1967). The theoretical ZAMS found by these authors agreed very well with the observational results from color-magnitude diagrams (see the review by Iben 1967). It is hardly surprising, therefore, that the classical pre-main-sequence tracks in the HR diagram have formed a basis of research for almost three decades.

Stars that reach the point of hydrogen ignition all have nearly the same central temperature, and hence, similar values of the ratio $M_* R_*^{-1}$. Therefore, as we consider successively lower-mass stars along the ZAMS, the average internal density *rises* as M_*^{-2} . For stars of sufficiently low mass, the internal density is so high that electron degeneracy becomes the dominant mode of pressure support. One finds, for such stars, that T_c first rises during contraction, reaches a maximum value *below* 10^7 K, then falls to zero as the contraction proceeds and degeneracy takes over. Kumar (1963) first established that, as a result of this effect, stars below $0.08 M_\odot$ would never reach the ZAMS. Such objects are known as "brown dwarfs." Their possible presence in space has been the subject of intense inquiry and debate in recent years.

Other authors have repeated the contraction calculations, often obtaining noticeably different Hayashi temperatures (see, e.g., Cohen and Kuhi 1979; Vandenberg et al. 1983). Most of these differences can be attributed to the treatment of opacity in the subphotospheric layers. For example, Cohen and Kuhi were the first to display the effect of including molecular lines, which

are important in lower-mass stars. Because the actual value of the surface temperature depends somewhat on the opacity (see Fig. 6-6 of Clayton 1968), the effect is to shift the tracks by modest amounts. There has also been interest, because of the possibility of disk accretion (see below), in including the effect of mass addition. Unfortunately, current knowledge of the disk accretion process is too poor to predict the physical condition of matter as it flows onto the stellar surface. As we have seen, it is the *specific entropy* of this gas which counts the most. Until the quantity can be calculated, the effect of disk accretion on PMS evolution cannot be gauged accurately.

Even before the completion of the first detailed evolutionary calculations, it was realized that other nuclear processes prior to main-sequence hydrogen burning could be of importance. In a brief but prescient contribution, Salpeter (1953) pointed out that appreciable concentrations of the light nuclei D, Li, Be and B would temporarily halt gravitational contraction, and that their ignition would occur at central temperatures not far above 10^6 K. Soon after the publication of the results of Iben, Bodenheimer (1966) performed a series of numerical calculations that followed this early burning. In the case of deuterium, which is by far the most abundant of these species in interstellar matter, the predicted slowdown of contraction indeed occurred. Grossman et al. (1974) followed Bodenheimer's study with a more detailed account of deuterium burning. By careful consideration of kinetic and thermodynamic effects at relatively high densities and low temperatures, they were able to describe accurately stars of a few tenths of a solar mass or less, for which deuterium ignition actually stalled contraction until the fuel was exhausted. They found that for M_* less than $0.01 M_\odot$, the onset of electron degeneracy pressure during contraction prevented the central temperature from even rising to the point of deuterium ignition. In the HR diagram, they pointed to the existence of a "deuterium main sequence," found by joining the points on individual pre-main-sequence tracks where deuterium is able to halt the contraction temporarily.

The early investigators of deuterium burning all assumed that $[D/H]$, the interstellar ratio by number of deuterium to hydrogen, was close to the terrestrial one of 2×10^{-4} (Hageman et al. 1970). Within a short time, however, direct observations of the interstellar medium were lowering this value by an order of magnitude (York and Rogerson 1976). Mazzitelli and Moretti (1980) redid the calculation of pre-main-sequence burning with the updated ratio of 2.5×10^{-5} . Not surprisingly, the decreased deuterium had less effect on contraction, so that the upper mass limit of the deuterium main sequence was effectively lowered. The curious fact was also noted that few, if any, observed young stars appeared to lie above this curve in the HR diagram. Although a smaller number of more luminous stars was naturally expected as a result of their faster contraction rates, there was no reason for the apparent cutoff. Mazzitelli and Moretti concluded that the appearance of the deuterium main sequence as the upper boundary in the distribution of young stars was a "coincidence" that was "probably accidental." As explained

below, the coincidence has now found a satisfactory explanation in terms of the protostellar origin of pre-main-sequence stars.

Other studies of nuclear processes have focused on lithium as a possible diagnostic of stellar youth. The idea is that lithium should only be depleted in stars in which the base of the outer convection zone attains a temperature exceeding the ignition value of 3×10^6 K. This condition is never met in the relatively massive stars where the radiative-convective interface retreats to the surface before attaining the critical temperature. Indeed, it was observed that early F stars retained their primordial abundance ($[\text{Li}/\text{H}] \approx 10^{-9}$), while later G and K-type stars, with deeper convective envelopes, showed evidence of depletion (Wallerstein et al. 1965). For these cooler stars, Bodenheimer (1965) found a good correlation between the calculated lithium depletion during pre-main-sequence contraction for different masses and the observed abundances as a function of spectral type along the main sequence in the Hyades. More recent observations both in the Hyades and younger clusters, however, have clouded the picture, with an apparent spread in depletion among stars of similar mass and age (see, e.g., Strom et al. 1989b). It has been suggested that meridional mixing associated with stellar rotation could underly this puzzling result (Pinsonneault et al. 1989). Rotational mixing could also explain the remarkable *dip* in the lithium abundance as a function of spectral type discovered in Hyades F stars by Boesgaard and Tripico (1986).

4. *Rotation.* The classical studies of Hayashi and his contemporaries avoided entirely the issue of angular momentum in their contracting stars. It was recognized, of course, that appreciable angular momentum in the youngest, most distended configurations implied severe spinup and possibly mass loss during the subsequent evolution, but lack of observational evidence deprived the theorists of any strong motivation for detailed calculations. Two significant exceptions are Bodenheimer and Ostriker (1970) and Moss (1973), who followed the contraction of rapidly rotating, centrifugally distorted configurations. Moss, in particular, advocated that the equatorial mass shed during contraction would orbit the star as a circumstellar disk. His study, now largely forgotten, foreshadowed the current high level of interest in pre-main-sequence disks.

The angular momentum issue immediately came to the fore with the discovery by Vogel and Kuhl (1981) that solar-type pre-main-sequence stars (i.e., T Tauri stars) are *slow rotators*, in the sense that their surface speeds are a minor fraction (typically less than 0.1) of breakup (see also Hartmann et al. 1986). This finding, together with the earlier discovery of massive winds from T Tauri stars (Kuhl 1964), supplied the needed impetus to the theorists. Hartmann and McGregor (1982), following the seminal work on the solar wind torque by Weber and Davis (1967), suggested that centrifugally driven winds, coupled through ionization to a stellar magnetic field, could provide efficient braking in young stars. Endal and Sofia (1982) used the Weber-Davis mechanism to follow numerically the spindown of a solar-type star, assuming that the magnetic torque acted directly on a convective envelope in a state of

rigid rotation. They also considered the effect of rotational instabilities on redistributing angular momentum in the radiative interior.

Other workers have offered similar parameterized treatments of the problem, but a self-consistent incorporation of rotation into pre-main-sequence theory has yet to be achieved. The original Weber-Davis picture of magnetic braking remains uncontested as a general framework, but its detailed implementation is formidable. In the slow rotation limit, the three-dimensional configuration of the magnetic field has been calculated by Suess and Nerney (1973), but determination of the field structure for rapid rotation, the stellar mass loss rate, and the influence on the field of the depth of convection are all unsolved problems.

Meanwhile, improvements in detector sensitivity and spectral analysis have resulted in a wealth of observational data. The original upper limits of Vogel and Kuhi have now been replaced by firm measurements of rotation velocities for dozens of stars (Hartmann et al. 1986, Bouvier et al. 1986a). To date, there is no convincing evidence for any systematic variation of rotational velocity along pre-main-sequence tracks. On the other hand, the new observations have revealed a population of rapid rotators (with velocities exceeding 100 km s^{-1}) in the Pleiades and Alpha Persei clusters, among stars thought to be just joining the ZAMS (Van Leeuwen et al. 1983; Stauffer et al. 1984). These stars appear coincident in the diagram with other slow rotators, and it is not clear if this fact indicates a corresponding age or angular momentum spread in the initial population. Nevertheless, it is encouraging that such a spinup, prior to final main-sequence spindown, is obtained naturally as the result of the formation of the relatively dense radiative core (Endal and Sofia 1982).

B. Recent Developments

1. Protostellar Origins. In classical pre-main-sequence theory, the initial configuration of a star was essentially arbitrary. As long as the star was assumed to be fully convective, it had to be a member of the unique sequence of homologous models corresponding to the given mass. Different choices of initial radius, therefore, merely shifted by a fixed amount the elapsed time to any subsequent state. Cameron (1962) and Hayashi (1966) argued that the relevant starting radii were very large, e.g., about $50 R_{\odot}$ for a $1 M_{\odot}$ star. If this were the case, then the corresponding Kelvin-Helmholtz time would be exceedingly brief (see Eq. 1). The contraction time to a state with much smaller radius would therefore be virtually independent of the initial value. In addition, Bodenheimer (1965) and Von Sengbusch (1968) relaxed the assumption of a fully convective interior. For solar-type stars with large initial radii, they showed that even fully radiative configurations quickly become convectively unstable and rejoin the standard vertical evolutionary tracks.

It had long been recognized that the quasistatic evolution appropriate for pre-main-sequence evolution could not describe the earlier, more diffuse

configurations. Gaustad (1963) showed that the cloud fragment destined to become a star must collapse dynamically as long as it was optically thin to its own cooling radiation. In this “protostar” phase, the relevant time scale replacing Eq. (1) is the much shorter free-fall time, defined as

$$\begin{aligned} t_{ff} &\equiv (\rho G)^{-1/2} \\ &= 7 \times 10^5 \left(\frac{n}{10^4} \right)^{-1/2} \text{ yr} \end{aligned} \quad (4)$$

where ρ and n are the cloud’s mass and number density, respectively, and where the numerical estimate is for a typical cloud composed of molecular hydrogen. Although the details had not been worked out, it was assumed that this cloud collapse would end with the formation of a nearly hydrostatic object that became the pre-main-sequence star. The large initial radii advocated by Cameron and Hayashi were based on the belief that negligible energy was radiated away during the brief collapse phase.

The modern theory of protostars began when Larson (1969) first followed numerically the collapse of a protostellar cloud. Assuming for simplicity that the collapse was spherical, Larson integrated the equations of hydrodynamics and radiative transfer for a temporal sequence of cloud models, beginning with a diffuse, marginally unstable configuration. The most important result he obtained was that the collapse was distinctly *nonhomologous*. The region of highest density near the center collapsed first, while the outer layers remained temporarily static. The freely falling region spread outward at the speed of sound, reaching the cloud boundary at a time close to that in Eq. (4). [Note that the sound travel time and the free-fall collapse time are nearly equal in any cloud initially close to hydrostatic equilibrium.] As material within this region reached the center, it was arrested in a strongly radiating shock front. Inside the shock, this material settled slowly onto a growing *hydrostatic core*, which was the object destined to become a pre-main-sequence star. The photons emitted at the shock must diffuse through the dust in the infalling envelope before they can be detected; in the process, they are degraded into the infrared. Thus protostars, unlike their pre-main-sequence descendents, are optically invisible.

Larson’s simulation demonstrated that considerable energy is lost at the shock during the protostar phase. Thus, the assumption of large initial radius was incorrect, and the early properties of pre-main-sequence stars were seen to depend critically on their prior history. Throughout the 1970s, many researchers attempted to refine Larson’s calculation, but failed to arrive at consistent quantitative results for the hydrostatic outcome of the collapse. The issue was finally resolved by careful numerical treatment of the hydrostatic core and the bounding shock (Winkler and Newman 1980; Stahler et al. 1980). The final outcome was that the starting radius of a $1 M_{\odot}$ star was a mere $5 R_{\odot}$, a full factor of 10 smaller than the old result. This difference is a direct and dramatic manifestation of the severe energy loss associated with the accretion shock front.

2. *Deuterium and the Birthline.* The old issue of deuterium burning gained new attention when it was realized that protostars could readily attain the critical ignition temperature of 10^6 K (Stahler et al. 1980). Such high interior temperatures are a result of the relatively small radii reached during accretion. Prior to ignition, the protostar is built up by the low-entropy material that has cooled and settled inside of the shock. Once deuterium ignites, typically when the star has reached a few tenths of a solar mass, this intense heat source quickly turns the star convectively unstable.

As seen in Fig. 3, the burning progresses through a number of distinct phases. When the protostar is still fully convective, fresh deuterium that is continually landing on the surface can be rapidly swept into the center by turbulent eddies. In this manner, the star reaches a state of steady-state burning, in which the fuel is ignited at the same rate it is added. For a representative protostellar accretion rate of $1 \times 10^{-5} M_{\odot} \text{ yr}^{-1}$, steady-state burning generates a luminosity of $15 L_{\odot}$.

Figure 3. Deuterium burning in protostars. (a) At low masses, accreted deuterium is fed in a steady-state fashion to the burning center by convective eddies. (b) Eventually, a radiative barrier appears, cutting off the supply to the center. (c) The central region soon exhausts its deuterium and reverts to a radiatively stable state. (d) At higher mass, deuterium ignites as a shell source just outside the depleted central region (figure from Palla and Stahler 1990).

As the mass of the star grows, its internal temperature climbs slowly, leading to a drop in the average opacity. At some point, the luminosity generated by deuterium is insufficient to drive convection. The entire star does not turn radiatively stable at once. Instead, a localized region, whose exact location depends on the detailed evolution, becomes stable and acts as a *radiative barrier*. Inside the barrier, the freshly accreted deuterium can no longer reach the center. The interior of the star quickly exhausts its fuel and reverts to radiative stability. Deuterium continues to pile onto the outside until the temperature at the original location of the barrier climbs to the ignition point. When this happens, a shell-burning phase ensues. With further increase in stellar mass, the shell gradually retreats toward the surface.

While the protostar is undergoing steady-state burning, deuterium acts effectively as a thermostat, keeping the star's central temperature close to the ignition value of 10^6 K. As the central temperature is proportional to the stellar mass divided by the radius, the thermostatic effect also implies a linear mass-radius relation for protostars. The physical basis for the deuterium thermostat can be easily understood. If the stellar radius increased so slowly that the central temperature rose appreciably, the deuterium burning would increase dramatically, because the energy generation rate of the fusion process varies roughly as T^{12} (Harris et al. 1983). The extra energy input would, of course, swell the radius back to its proper value.

The existence of a mass-radius relation for protostars implies that pre-main-sequence stars should first appear along a well-defined locus in the HR diagram (Stahler 1983a). Recall that, in the classical theory, the star's initial configuration was represented by an essentially arbitrary point somewhere on the vertical portion of its evolutionary track. The mass-radius relation can now be used to eliminate this arbitrariness and establish a stellar "birthline." For low-mass stars, the resulting curve corresponds essentially to the old deuterium main sequence. Along the birthline, stars of various masses first appear as optically visible objects. They then slowly contract to the ZAMS, each star following the remaining portion of its classical track. According to this theory, observed pre-main-sequence stars should be found on the birthline or below it, but never above. As shown in Fig. 4 for the case of the well-studied Taurus-Auriga molecular cloud complex, this prediction is in good agreement with current observations of T Tauri stars.

The deuterium thermostat is effective as long as the nuclear energy supply is comparable to the star's gravitational binding energy. This condition begins to fail for higher masses. However, with the ignition of the *deuterium shell source*, the protostellar radius swells once more (Palla and Stahler 1990). This swelling is only temporary, as the increasing influence of gravity soon creates rapid contraction. If the protostellar mass-radius relation is again used to predict the initial positions of visible stars in the HR diagram, the resulting birthline is found to intersect the ZAMS at a stellar mass of about $8 M_{\odot}$ (see Fig. 5). *For stars with masses above this critical value, there is no optical pre-main-sequence phase, because the rapid gravitational contraction in these*

Figure 4. The birthline for low-mass stars (from Stahler 1988). The hatched region shows the variation in the birthline for protostellar mass accretion rates from 2×10^{-6} to $1 \times 10^{-5} M_{\odot} \text{ yr}^{-1}$. The lighter solid curves are the PMS tracks of Iben (1965), each track labeled by the corresponding mass in solar units. Open circles are observations of CTTS in Taurus-Auriga by Cohen and Kuhi (1979), while filled circles are NTTS from Walter et al. (1988).

objects leads to hydrogen ignition during the accretion phase. Figure 5 shows that the pre-main-sequence stars of intermediate mass, the Herbig Ae and Be stars, also have an upper H-R boundary consistent with the extended birthline.

3. *Outflows.* Observations of the molecular cloud clumps that appear to be forming low-mass stars show that they typically contain more gas than will be present in the final star (Myers and Benson 1983). Hence, it is generally believed that the protostar itself must somehow provide the means for ending its accretion of the infalling envelope. It is now known that a large fraction of embedded infrared sources are associated with strong outflows of molecular gas (Terebey et al. 1989) and that the cloud clumps in these cases have higher internal velocity dispersions (Myers et al. 1988). In light of these and similar findings, there is a growing consensus that the end of protostellar accretion and

Figure 5. The birthline for intermediate-mass stars (from Palla and Stahler 1990). The birthline is the heavy curve cutting across the lighter PMS tracks of Iben (1965). Each track is labeled by the corresponding mass in solar units. The squares are observed Herbig Ae and Be stars from Finkenzeller and Mundt (1984), and the filled symbols (circles and squares) are the outflow sources from Levreault (1988*b*).

the dispersal of the parent cloud are due to a powerful stellar wind, and that the molecular outflows are caused by the impact of these winds on surrounding cloud material. This view has recently been strengthened by the finding that those optically visible stars which have associated molecular outflows appear to lie along the stellar birthline (Levreault 1988; Palla and Stahler 1990; see also Fig. 5).

Within the context of spherical accretion, there is no likely source of energy for such winds. Deuterium does represent, as we have seen, a large energy reservoir. This energy is not available near the surface, because it is almost entirely absorbed by internal layers. Moreover, the thermostatic nature of deuterium burning places a severe constraint on any process dependent on it (Stahler 1988). For example, in the picture of Shu (1985), the wind energy is derived from differential rotation of the protostar. Once deuterium turns the star fully convective, a lower-energy state of rigid rotation can be attained, with the extra released in the form of internal magnetic fields that buoy upward to the surface. The problem with such a picture is that the released energy,

if it is to be as large as needed, will swell the star. This swelling will lower the central temperature and immediately cut off the deuterium triggering mechanism.

Any models in which the star draws on the rotational motion of accreting matter for generating the wind must also face the fact that even the youngest pre-main-sequence stars, those on the birthline, are rotating relatively slowly. Hence, if the winds are created by centrifugal ejection during the protostar phase (Hartmann and McGregor 1982; Shu et al. 1988), there must follow a period of rapid braking in which the stellar mass loss is driven by a different process. This braking must be so efficient that it is completed by the time the star is fully revealed on the birthline, a period as brief as 10^4 yr (Fuller and Myers 1987). Wind models employing centrifugal ejection from circumstellar disks (Pudritz and Norman 1986; Konigl 1987) face a similar problem, because the extraction of angular momentum from the orbiting material allows it to spiral onto the star and spin it up. Once again, a brief period of efficient braking is required.

II. OBSERVATIONAL OVERVIEW

A. Basic Stellar Properties

1. Classical T Tauri Stars. Historically, the first stars identified as pre-main-sequence objects were those of the T Tauri class (Joy 1945). It is now known that these "classical T Tauri stars" (CTTS) are also of *low mass*, i.e., $\sim 2 M_{\odot}$ or less. Mass determination has, in most cases, been made by comparison with theoretical pre-main-sequence tracks, but surface gravity measurements have also been used as confirmation (McNamara 1976). In this section, we offer an abbreviated summary of CTTS properties. The literature here is vast, and the reader interested in more detailed discussion is referred to recent, more extensive reviews, such as the Chapter by Basri and Bertout.

The general characteristics of the CTTS class are: (1) Infrared and ultraviolet excesses in the continuum spectrum; these excesses are measured with respect to a "normal" star of the same spectral type; (2) strong emission lines associated with low-excitation atomic species, chiefly the hydrogen Balmer lines, Ca II, and Fe II; (3) copious mass loss, as evidenced by P Cygni profiles and forbidden line emission (see Edwards and Strom 1987); (4) a stellar spectrum in which the absorption lines often appear partially filled in, or veiled; (5) irregular variability of the continuum and line fluxes, and of the line profiles. The T Tauri stars are generally found in loose clusters known as T associations, analogous to the higher-mass OB associations.

From their bolometric luminosities and effective temperatures, the CTTS are located above the main sequence, with ages ranging from 10^5 to 10^7 yr. These ages must, of course, be measured with respect to the birthline, but the reduction in age from the traditional figure using large initial radii is only appreciable for the youngest objects (Stahler 1983a). It is important to keep in mind that not all CTTS exhibit every characteristic listed here. Furthermore,

both spectral and photometric properties of these stars are highly variable. Brightness variations of up to 5 magnitudes can occur on time scales of days to years, often in conjunction with changes of color (cf. Appenzeller and Mundt 1989). Emission line profiles can also change on similar time scales (e.g., Brown 1985).

In recent years, it has become popular to identify the continuum excess emission as arising from a circumstellar disk (see, e.g., Bertout et al. 1988). The infrared component is thought to arise in the dust of the cooler, outer regions of this disk, while the ultraviolet excess is attributed to a hot star-disk boundary layer, where disk matter is slowed from its rapid orbital motion to join the slowly rotating stellar surface. Thus, in the current paradigm, CTTS are characterized by optically thick disks, which can be either *passive* or *actively accreting*. In a passive disk, the accretion luminosity is dwarfed by the luminosity of starlight absorbed and reradiated at longer wavelengths by the disk. There exists, unfortunately, a significant gap between this phenomenological model and pre-main-sequence theory. Thus, there is no generally accepted account of the structure of the disks, for the mechanism of their accretion, or for the cause of the rotational braking in the boundary layer. Nevertheless, the accretion-disk picture has proved useful as a working hypothesis.

As CTTS eventually become normal main-sequence objects, it is natural to search for evolutionary trends. Thus, one might expect to see a decline in the infrared excess among progressively older stars. To date, quantitative evidence for such a trend is still lacking. Simon et al. (1985), Walter and Barry (1991), and Feigelson and Kriss (1989) show that the class of CTTS displays more surface activity than older low-mass stars, but there is no firm indication of variation with age within the CTTS class itself. A complicating factor here is that the ages of the most active CTTS, the so-called continuum stars, are difficult to determine. Their photospheric absorption lines are partially filled in ("veiled") by circumstellar emission, with the consequence that neither stellar luminosities nor effective temperatures can be determined accurately. Using recent techniques for separating the photospheric and circumstellar components of the luminosity, it should be possible to make better estimates of CTTS ages, and thus to re-examine this important issue.

2. *Naked T Tauri Stars.* From their location in the HR diagrams of populous T associations, such as Rho Ophiuchus and Taurus-Auriga, it is apparent that most T Tauri stars cluster in age between 10^5 and 3×10^6 yr. However, we have seen from Eq. (1) that the total contraction time to the ZAMS is of order 10^7 yr for solar-mass stars. Because of the steep decline of luminosity, this time is even longer for stars of lower mass. Herbig (1978) pointed out that these figures imply a population of "post T Tauri" objects which would easily outnumber the CTTS in cloud complexes which have been producing stars for a sufficiently long time.

Until about 1980, there was little evidence for another type of low-mass pre-main-sequence star. However, X-ray observations of regions of

star formation by the Einstein Observatory revealed many stellar sources, only a few of which corresponded to catalogued CTTS (Ku and Chanan 1979; Montmerle et al. 1983a; Walter 1986; Feigelson et al. 1987). Further spectroscopic and photometric observations of the optical counterparts (see, e.g., Walter et al. 1988; Strom et al. 1990) confirmed the pre-main-sequence nature of these stars, but showed them to lack the defining characteristics of CTTS. From their positions in the HR diagram, the CTTS and a substantial fraction of the naked T Tauri stars (NTTS) have similar masses and ages (Fig. 4). However, the NTTS population, at least in Taurus-Auriga, also includes an older component (see Sec. II.B).

The general characteristics of the NTTS, in addition to their X-ray emission, are:

1. A normal stellar photospheric flux distribution, with no significant excesses in the optical and near-infrared. Ultraviolet excesses are similar to those in stars with very active chromospheres.
2. Modestly strong emission lines of Ca II H and K, and H α . Except for late K and M stars, the H α emission is generally insufficient to fill in the photospheric absorption and appear as a distinct line above the continuum.
3. Symmetric emission line profiles, with no evidence for forbidden-line emission.
4. A normal photospheric absorption line spectrum, with no evidence for veiling.
5. Periodic photometric variability.

The physical basis for the differences between the CTTS and NTTS can be addressed within the disk paradigm. The lack of infrared excess and continuum veiling has been taken to imply the absence of an active accretion disk, and, in most cases, the absence of an optically thick passive disk, as well (Skrutskie et al. 1990). The emission line fluxes from NTTS are consistent with active solar-like chromospheres, and the X-ray emission is similarly indicative of a solar-like corona (Walter and Kuhi 1984; Walter and Barry 1991). The absence of forbidden-line emission and the symmetric line profiles suggest a low level of mass loss. Finally, the periodic variability most likely arises from the rotation of an asymmetric distribution of dark starspots (Rydgren and Vrba 1983), as is common among active, late-type stars, including the RS CVn and BY Dra systems (see, e.g., Vogt 1983).

Herbig and Bell (1988) use the term "weak-lined T Tauri stars" (WTTS) to indicate low-mass PMS stars with H α equivalent widths $< 10 \text{ \AA}$. All NTTS are WTTS, but the converse is not true. This fact has led to some confusion in the community. The equivalent width of H α is a useful observational characteristic, but not a meaningful physical parameter when discussing stars with a wide range of photospheric temperatures. The equivalent width in a line is proportional to the surface flux in that line, and inversely proportional

to T_{eff}^4 . Thus, G-type CTTS with active disks, such as SU Aur, are WTTS, but are very different from the NTTS. Similarly, there are cooler WTTS with large near-infrared excesses; these also are quite distinct from NTTS. The distinction between NTTS and WTTS is further illustrated in Fig. 2 of Walter and Barry (1991).

3. *The Herbig Ae/Be stars.* The Herbig Ae and Be stars (Herbig 1960) are the intermediate-mass analogs of the classical T Tauri stars. They are stars of spectral types A and B with strong T Tauri-like emission lines, and are found in regions of star formation. By definition, a Herbig Ae/Be star must illuminate a nebulosity. After Herbig's original identification of this class, their position above the main sequence was confirmed through measurements of their surface gravity (Strom et al. 1972). It has recently been shown that they also lie near, but below, the theoretical birthline (Palla and Stahler 1990; see also Fig. 5). Their inferred ages range from 10^5 to 10^6 yr.

A catalog of 57 Herbig Ae/Be stars has been compiled by Finkenzeller and Mundt (1984). These authors noted the common appearance of P Cygni profiles, indicative of strong stellar winds. The width of the H α line indicates typical velocities of 500 km s^{-1} . These wind properties appear comparable to those of the high-mass loss CTTS (Mundt 1984). Stars earlier than spectral type A0 often have double-peaked emission, as is typical also of the classical Be stars. However, these stars are clearly distinguishable from classical Be stars in an infrared two-color diagram (see Fig. 5 of Finkenzeller and Mundt 1984). A catalog of line profiles of 26 Ae and Be stars was prepared by Finkenzeller and Jankovics (1984).

A majority of Herbig Ae/Be stars exhibit at least 5% variability of their continuum luminosities. This variability tends to be more pronounced among the later-type stars, but the data are insufficient to establish whether the fluctuations are periodic. Finkenzeller and Mundt suggest that the appearance of P Cygni profiles and significant variability may be indicative of vigorous surface convection. As is apparent from Fig. 5, however, these stars are on the *radiative* portion of their evolutionary tracks, and hence have no outer convection at all in the classical theory (Iben 1965). The resolution of this paradox may be provided by the shell-burning of deuterium left over from the protostar phase (Palla and Stahler 1990).

Garrison (1979) showed that the Herbig Ae/Be stars tend to exhibit near-infrared excesses and 3650 Å Balmer discontinuities that are smaller than expected for their spectral types. These shallow discontinuities could be created by emission from a star-disk boundary layer, the mechanism currently believed responsible for putting the Balmer jump into emission in the CTTS. The near-infrared excesses could, in principle, be caused by the same hydrogen continuum, but thermal emission from warm dust, as in the CTTS, is the preferred explanation. The light from these stars is often significantly polarized, as expected if the extinction arises in circumstellar material (Vrba et al. 1979). The 10- μm Si absorption feature has been observed in some cases, as have dust-related near-infrared emission features (see references in

Finkenzeller and Mundt 1984).

Praderie et al. (1982) and Felenbock et al. (1983) find that there are many similarities between the circumstellar emission of AB Aur, the brightest of the Herbig Ae stars, and that of the CTTS. In general, the Herbig Ae/Be stars share the following characteristics with the CTTS: circumstellar gas and line emission, variability, strong stellar winds, and association with dark clouds. As in the lower-mass case, individual objects exhibit a range of characteristics. Finally, there are at least a dozen X-ray bright late-B stars lacking H α emission associated with the Orion Nebula (Caillault and Zoonematkermani 1989), and similar late-B stars associated with the Taurus, Corona Australis, and L1641 clouds (Walter et al. 1988; Strom et al. 1990). It is tempting to identify these stars as the intermediate-mass equivalents of the NTTs.

B. Observed Initial Stellar Populations

1. The Taurus-Auriga Complex. The low-mass population in Taurus-Auriga consists of the two observationally distinct groups described above: the CTTS and the NTTs. About 100 CTTS have been catalogued (Herbig and Bell 1988), and it is unlikely that significant numbers of CTTS associated with the Taurus clouds remain undiscovered. Any uncatalogued CTTS remaining in Tau-Aur are probably highly reddened. The number of NTTs is less well known. Walter et al. (1988) discussed the X-ray selected NTTs, and Herbig et al. (1986) discussed a sample of optically selected NTTs. In all, about 40 NTTs have been catalogued in the region (This figure excludes several stars previously catalogued as CTTS, such as V410 Tau or DI Tau). The difficulty in determining the number of NTTs is that, unlike the CTTS, there are no extreme characteristics which are easily detected in surveys. The characteristic most amenable to large-scale surveys appears to be the coronal X-ray emission (Walter et al. 1988), although the presence of Li I 6707 absorption must be used to confirm youth. Walter et al. (1988) estimated the true number of NTTs in Taurus-Auriga by extrapolating from the X-ray selected sample. Correcting for instrumental factors and accounting for the observed level of X-ray variability, they estimated an average 30% completeness. This result assumes that the observed X-ray luminosity function is the true luminosity function; a large population of less X-ray-luminous NTTs would decrease the assumed completeness. This 30% completeness corrects only those regions which have been observed in X-rays; about 90% of the Taurus-Auriga region was not observed by EINSTEIN. On the assumption of a uniform spatial distribution of NTTs across the entire region, Walter et al. extrapolated the total number of NTTs to be $35 \times 3 \times 10$, or about 1000.

The ratio of NTTs to CTTS in Taurus-Auriga thus seems to be about 10. Such a result is in general agreement with expectations if (a) star formation has been proceeding in the region for at least 10^7 yr, and (b) the NTTs indeed represent the "post-T Tauri" population of Herbig (1978). From the HR diagram in Fig. 4, it is indeed apparent that the NTTs exist at lower luminosities, and hence greater ages, than the CTTS. However, the fact that both types

of stars can be found close to the birthline is a puzzling complication. It is also significant that the CTTS and NTTS populations exhibit different spatial distributions. The CTTS tend to be concentrated near the dark clouds. The younger NTTS are co-spatial with the CTTS, but there is an older population of NTTS west of the main Taurus clouds (Walter et al. 1988), which may represent an earlier episode of star formation associated with the Cas-Tau OB association (Blaauw 1956). After correction for the X-ray incompleteness, the ratio of NTTS to CTTS, integrated over the whole of the complex, is unity at a stellar age of ~ 1 Myr. The oldest (least luminous) CTTS appear to have ages of order 10 Myr, while the old population of NTTS is on radiative tracks, close to the ZAMS, with typical ages of 30 Myr.

2. *Low-Mass Stars in OB Associations.* The Taurus-Auriga region is an example of a star-formation region dominated by the low-mass stars. A number of researchers have cited evidence that star formation is "bi-modal," i.e., that high- and low-mass stars form in different locations under different physical conditions (see, e.g., Larson 1986). If this view is correct, the initial mass function (IMF) inferred from counting field stars must represent the juxtaposition of many unrelated IMF. In any specific star-formation region, there should be no correlation between the numbers of high- and low-mass stars. One can examine this hypothesis by directly observing the stellar mass spectrum in regions of star formation, prior to merger with or dilution by the field. The result of such studies, conducted using X-ray data, is that large numbers of low-mass stars appear to be associated with nearby OB associations.

Walter (1987*b*) reported preliminary results from X-ray observations of 4 square degrees of the II Scorpio OB association. In this small area, 30 NTTS were discovered, along with one new CTTS. There are 9 B-star members of the OB association with ages of 5 to 8 Myr (de Geus 1988) within these fields. The properties of the NTTS are similar to those in Taurus-Auriga, as are the distances, so the completeness of the X-ray data should be comparable. Accounting for the completeness, there should be about 100 NTTS in these 4 square degrees, with a ratio of NTTS to CTTS of ~ 50 . The projected space density (stars per square parsec) is three times that in Taurus-Auriga. The ratio of B stars to low-mass stars in this OB association is consistent with a Salpeter (1955) IMF from 0.3 to $10 M_{\odot}$.

A similar result is found in the Orion OBI association, where Walter et al. (in preparation) have identified some 150 low-mass NTTS based on X-ray images of fields near Lambda Orionis, the B35 dark cloud, the belt of Orion, and the periphery of the Orion nebula. Furthermore, some 200 low-mass stars associated with the belt of Orion have been identified in the $H\alpha$ survey of Kogure et al. (1989). Strom et al. (1990) find a 3:1 ratio of NTTS to CTTS in the L1641 dark cloud (presumably, this figure is lower than the 10:1 ratio in Taurus-Auriga because L1641 has not been producing stars as long). Throughout Orion, the numbers of NTTS greatly exceed those of CTTS. The Orion OBI association is 3 times more distant than either II Scorpio or Taurus-

Auriga, so the X-ray surveys are less complete. The observed space density of NTTS is about 3 times that in II Scorpio; correction for the distance and the larger incompleteness implies that the projected space density of NTTS is somewhat larger than in II Scorpio.

3. High-Mass Stars in T Associations. The results for low-mass stars in OB associations indicate the possible presence of high-mass stars in regions traditionally thought to be producing only low-mass objects. Walter and Boyd (1991) reasoned that, if the extrapolation of 1000 NTTS in Taurus-Auriga is correct, then there should be a significant number of B stars near this association. The exact number depends on the choice of IMF, ranging from ~ 30 for a Salpeter function to 60 for a Miller-Scalo (1979) IMF. That so many B stars could be hidden so close to the Sun would be surprising. However, the Taurus-Auriga association is projected on the Cas-Tau OB association (Blaauw 1956). The OB association has an age of ~ 30 Myr, and the nearest part is within 200 pc of the Sun. In fact, the kinematics of the Cas-Tau association's subgroups 6 and 7 are very similar to those of the T Tauri stars, and Cas-Tau and the T associations may well be physically related.

Walter and Boyd (1991) examined the space motions of the B stars in the Bright Star catalog, and found that 29 B stars in 21 systems are possible kinematic members of the T association, within the observational errors in the space motions. They conclude that the Taurus-Auriga complex is not devoid of high-mass stars. The estimated B star age of 30 Myr is similar to that of the oldest NTTS. There are a few younger high-mass stars associated with the 1 Myr old T Tauri stars, including the embedded B2 star HK Tau/G1 (Cohen and Kuhl 1979) and the B7V star 72 Tau (Jones and Herbig 1979). The T association may thus be the most recent episode of star formation in a larger complex which spawned the Cas-Tau OB association and the older NTTS 10 Myr ago.

C. Comparison of Observation with Theory

1. Distributions in the HR Diagram. Theoretical models of pre-main-sequence stars predict the stellar luminosity, effective temperature, and radius as a function of age. Because it is impossible to witness the evolution of these quantities in individual stars, the correctness of the models must be tested indirectly from the distribution of stars in the HR diagram.

The survey of Cohen and Kuhl (1979) showed that the more luminous CTTS lie in the region of the HR diagram predicted for young stars on convective tracks, while many of the higher-mass CTTS appeared to be on radiative tracks. Walter et al. (1988) placed the NTTS on the HR diagram of Taurus-Auriga. While some of the NTTS were coincident with the CTTS, many were found to lie on radiative tracks closer to the ZAMS, as seen in Fig. 5. Although the location of many CTTS and NTTS on convective tracks is consistent with their observed surface activity, direct evidence that the stars actually follow the theoretical tracks was first provided by the agreement of the theoretical birthline with the observed upper boundary of the stellar

distribution (Stahler 1983a, 1988). As the construction of the birthline uses both a protostar mass-radius relation and the pre-main-sequence tracks, this agreement provides strong support for both aspects of the theory. The mass-radius relation was constructed with a simplified treatment that ignored any rotation in the accretion flow or in the central protostar. The success of this relation in predicting the birthline can in part be attributed to the fact that the youngest optically visible stars are in fact slow rotators (Durisen et al. 1989b).

The recent discovery of a number of pre-main-sequence binaries has provided an opportunity for verifying the theoretical ages and masses of young stars. Walter et al. (1988) show that the NTTs in wide binary systems lie on similar isochrones, as would be expected if the stars form coevally. To date, few spectroscopic binaries, and no eclipsing binaries, are known among the low-mass PMS stars (Mathieu et al. 1989). In the cases of the two known double-lined spectroscopic binary NTTs, the inferred masses and ages are consistent with the evolutionary tracks, but only marginally so in the case of the system P1540 (Marschall and Mathieu 1988).

In comparing theory with observation, it is necessary to keep in mind that there are substantial systematic uncertainties that plague any empirical determination of the stellar luminosity. These include the errors associated with assigning a precise distance to an individual star, in separating the photospheric from the nonstellar components of the luminosity, and in evaluating the reddening corrections. In Taurus-Auriga, the depth of the clouds contributes an approximately 20% uncertainty in distance, which translates to a 40% uncertainty in luminosity. de Geus (1988) estimates a depth of 90 pc for the Ophiuchus dark clouds, which translates into a greater luminosity uncertainty. Corrections of the observed flux distribution for disk and boundary layer contributions, as well as for shadowing of the photosphere by the disk, are highly model dependent. The proper consideration of extinction in star-forming regions must be done with care, since R , the ratio of total to selective absorption, is frequently greater than the standard 3.1 (Mathis 1990) in star-forming regions. Moreover, visual extinctions can vary widely, even on close lines of sight (Cohen and Kuhi 1979). The net effect of these systematic uncertainties is to make the luminosity of any particular star rather uncertain, although the mean parameters of a large sample should be reasonably accurate.

2. Observational Constraints on Star and Disk Evolution. It seems reasonable to assume that as stars first become visible at the birthline they exhibit the properties of the CTTS. In fact, one would like to go a step further and argue that the most extreme CTTS, the continuum stars, are the youngest and least evolved of the low-mass stars. Unfortunately, as we have emphasized, this simple picture is complicated by the presence of NTTs near the birthline.

The topic of how the evolution of the circumstellar material proceeds has attracted interest of late. In terms of the disk paradigm, the transition from CTTS to NTTs involves the dissipation of the circumstellar disk. Depending

on the dissipation mechanism, one might expect to see some low-mass stars with characteristics of both classes. Such stars would yield important insights into time scales for disk dissipation, and perhaps provide constraints on how rapidly planets must form (if planetary formation is the rule).

Before one can attempt to quantify such considerations, a clear empirical distinction must be established between those stars which are believed to possess active disks and those which do not. Traditionally, the defining characteristic has been the presence or absence of excess emission at near-infrared wavelengths. Strom et al. (1989*b*) discussed the near-infrared colors of NTTS, and concluded that a significant fraction had excess emission from circumstellar material. Walter et al. (1989) analyzed the same data, and concluded that the near-infrared colors of NTTS were due to starspots with filling factors of up to 30%, similar to those observed in RS CVn systems and other active stars (see, e.g., Vogt 1983). The color temperature of the excesses is 2000 to 3000 K, far too high for circumstellar dust, but reasonable for starspots. The existence of starspots is confirmed by the periodic photometric variability (see, e.g., Rydgren and Vrba 1983). Among the stars first identified as NTTS in Tau-Aur, only V836 Tau and IP Tau show evidence for emission from warm dust at ~ 1000 K.

As a useful first step toward quantifying disk evolution, Strom et al. (1989*b*) have introduced the concepts of disk "survival" and "transition" times. The survival time measures the interval since the star's appearance at the birthline at which the disks disappear. Walter et al. (1988) have argued that this interval is difficult to pin down, at least in the Taurus-Auriga complex, because of the co-existence of NTTS with ages < 1 Myr and CTTS with ages of nearly 10 Myr.

The transition time, defined as the interval over which the disk ceases to be detectable, may represent the time required for dust in the inner disk to clump into macroscopic agglomerations prior to forming terrestrial-type planets. This time can be estimated by counting the numbers of stars with intermediate characteristics. Walter et al. (1988) find that 5 to 10% of their observed sample actually have characteristics intermediate between the NTTS and CTTS. For example, V836 Tau exhibits a small near-infrared excess (Mundt et al. 1983), and a $H\alpha$ equivalent width slightly larger than the other NTTS. If $\sim 10\%$ of the low-mass pre-main-sequence stars are in this transition state, and if the *mean* age of the low-mass population is a few Myr, then the implication is that the disks of the CTTS disappear on a time scale of a few times 10^5 yr (Walter et al. 1988). Observations of NTTS in the II Scorpio OB association (Walter et al., in preparation) generally confirm that the transition time is short. Of 30 NTTS, only 2 show significant near-infrared excesses. For a mean association age of ~ 5 Myr, transition time is again of order 10^5 yr. Skrutskie et al. (1990) arrived at a similar transition time.

It is crucial to understand that the observational evolutionary sequence from CTTS to NTTS as described here says little about the evolution of the star itself. The CTTS-to-NTTS transition is being viewed as a change in

the *circumstellar environment* of the star, and likely has little effect on (and is probably little influenced by) the star's quasi-static contraction, unless a significant fraction of the stellar mass is accumulated from its disk. Recognition of this independence of star and disk evolution could help to explain the curious presence of very young NTTS. From a theoretical viewpoint, dissipation of the disk represents a major challenge. Gravitational instability is unlikely to be effective long after protostellar accretion has ended, while mass transport due to convective processes seems to be far too slow (see, however, the Chapter by Adams and Lin).

The evolution from the NTTS to the ZAMS appears to be undramatic from an observational perspective. Chromospheric and coronal properties of the older pre-main-sequence stars appear very similar to those of their ZAMS counterparts (Walter and Barry 1991). The one identifiable change seems to be in the rotation of the star. As we have already mentioned, the studies of rotational speeds in open clusters indicate that low-mass stars spin up due to the growth of internal radiative cores prior to hydrogen ignition (Stauffer et al. 1984).

THE INITIAL STELLAR POPULATION

HANS ZINNECKER

Universität Würzburg

MARK J. McCAUGHREAN

University of Arizona

and

BRUCE A. WILKING

University of Missouri, St Louis

The collections of young stars with ages of 10 Myr or less found in association with molecular clouds are referred to as the initial stellar population. The majority of this population is comprised of low-mass ($<3 M_{\odot}$) objects with long time scales for thermal contraction to hydrogen burning stars. As a result, they can display a wide variety of evolutionary states ranging from deeply embedded infrared sources to optically visible stars with enhanced magnetic surface activity. Hence, the study of the initial stellar population requires observational techniques spanning the entire electromagnetic spectrum. Two recent advances in infrared astronomy, the Infrared Astronomical Satellite all-sky survey, and the growing availability of infrared array detectors, have dramatically improved our sensitivity to heavily obscured solar- and sub-solar-mass objects, and greatly enhanced our ability to sample completely the young stellar population over an entire cloud. We begin this chapter with a brief discussion of current theories for the origin of stellar masses and the initial mass function, focusing on the formation of stars in clusters, and the possibility that several different formation mechanisms are at work in the Galaxy. Motivated by recent infrared camera observations of obscured clusters, models are presented for the evolution of the $2.2 \mu\text{m}$ pre-main-sequence luminosity function of a young coeval star cluster, with a discussion of the implications the results have for the conversion of an observed luminosity function into the underlying mass function. A description of theories which allow spectral energy distributions of young stellar objects to be used as diagnostics of their evolutionary states is given. The observational section of this chapter begins with a discussion of techniques employed to study the initial stellar population. Observations of young stellar populations over a wide range of distances from the Sun are reviewed, beginning with low-mass aggregates in nearby dark clouds and ending with clusters surrounding massive stars in distant giant molecular clouds. Particular attention is paid to populations within 500 pc of the Sun, including those associated with the ρ Ophiuchi, Taurus-Auriga and Orion molecular clouds, where a significant number of solar- and sub-solar-mass objects are observed. The question of the existence of sub-stellar objects (brown dwarfs) in nearby young clusters and regions of star formation is addressed. Finally, we briefly discuss current problems and future directions for studies of the initial stellar population.

I. DEFINITION, MOTIVATION, AND SCOPE

The term “initial stellar population” has been coined to describe the ensembles of young stellar objects (YSOs) with typical ages of 1 to 10 Myr or younger, found associated with molecular clouds. Because the objects cannot have moved far from their birthplaces, studying the distribution of their masses gives us insight into the origin of the stellar mass function at birth, i.e., the initial mass function (IMF), averaged over a molecular cloud. We may hope to find out whether or not the IMF is different in different types of molecular clouds, or in regions where star formation appears to be spontaneous rather than externally triggered. By studying the youngest observable populations in star-forming molecular clouds, we may ultimately be able to tackle some of the following questions:

1. Are there significant variations in the stellar mass spectrum from cloud to cloud? Is there a difference in the low-mass stellar content between regions that have or have not formed massive stars?
2. Is there mass segregation in a young cluster? Do massive stars tend to form near the cluster center? Are there halos of low-mass stars around the clusters?
3. Is the most massive star that can form related to the depth of the gravitational potential of the protocluster?
4. Is there a cutoff at some characteristic low mass or are there many brown dwarfs forming in clouds?
5. Do all stars in a cluster form at the same time? If not, what governs the age spread in a very young cluster? Do low-mass stars form first? Do stars form sequentially in mass?

If we can answer these questions, we will go a long way towards understanding the details of the star-formation process. We may be able to determine the rules of star formation, if any. By trying to observe collections of young stars as early as possible, we can hope to identify temporal and spatial correlations between stars of different masses (e.g., initial mass segregation and/or hierarchical stellar groupings) before they are erased by averaging over the field.

Studies of the initial stellar populations in molecular clouds face two problems—one is theoretical, the other observational. The theoretical problem is that it is not trivial to relate the luminosity of most YSOs to their mass. Only massive stars are born almost directly as hydrogen-burning main-sequence objects. Lower-mass objects exhibit luminosity evolution along pre-main-sequence (PMS) tracks, taking progressively longer times to reach the main sequence, e.g., a few $\times 10$ Myr for a $1 M_{\odot}$ star. Thus the conversion of an observed luminosity function into a mass function by virtue of a time-independent main-sequence mass-luminosity relation is not possible: this step requires a theory that describes changes in the bolometric luminosity or absolute infrared brightness of PMS objects as a function of age and mass.

The observational problem is that the photospheres of YSOs are partially or totally obscured by dust at optical wavelengths. This dust can absorb much of the YSO luminosity and reprocess it to infrared wavelengths from 1 to 100 μm , depending on the proximity of the dust to the YSO. In addition, in clouds where massive stars have formed, the accompanying H II region nebulosity is often bright and can present a serious contrast problem in the optical. Therefore, in general, the earliest phases in the life of a YSO are best studied in the infrared, where YSOs are most luminous, where dust obscuration is vastly reduced, and where contrast against any nebular background is increased. Until recently, however, only single-element infrared detectors were available, making it impossible to carry out sensitive studies of large ensembles of sources. Instead, most studies concentrated on low-sensitivity, low-resolution surveys, or detailed studies of individual or small groups of objects. In addition, groundbased studies at thermal infrared wavelengths were severely hampered by the enormous background flux from the warm telescope and lower atmosphere.

With the introduction of infrared array detectors in the past five years, it is now possible to obtain high-resolution (~ 1 arcsec), high-sensitivity near-infrared (1–5 μm) images over relatively large areas of the sky. The same period saw detailed analyses of data from the Infrared Astronomical Satellite (IRAS) mid- and far-infrared (12–100 μm) all-sky survey. These two factors have led to a flood of new information about the embedded stellar populations of galactic star-forming regions. In this chapter, we review both the observational and theoretical progress in studying the initial stellar population since the publication of *Protostars and Planets II* in 1985. For a clear picture of our prior state of knowledge regarding fragmentation, star formation (including that in OB associations and young clusters), and the IMF, we refer the reader to reviews from the previous books in this series (e.g., Lada et al. 1978a; Scalo 1978; Silk 1978; Klein et al. 1985; Evans 1985; Scalo 1985; Strom 1985; Wilking and Lada 1985).

II. THEORETICAL CONCEPTS

We begin this section with some basic ideas regarding the origin of stellar masses and the IMF, as one of our prime goals is to understand which types of stars are born in the various kinds of molecular cloud. We continue with a simplified analysis of the time dependence of the mass-luminosity relation for low-mass PMS stars. Combining this relation with a given mass function, we examine the time-dependent behavior of the corresponding luminosity function. The model predictions suggest a new technique that may prove very useful for the interpretation of empirical 2.2 μm luminosity functions of embedded clusters, surely a very topical subject in the next few years. Finally, we discuss some of the more realistic aspects of YSOs, in particular the interpretation of the spectral energy distributions in terms of the evolution of YSOs and their circumstellar material. These considerations lead to a

better delineation of the components of a YSO (star + disk + halo) that must be included in radiative transfer calculations to allow fits in observable parameter space.

A. The Origin of Stellar Masses and the IMF

An increasing body of observational data leads to a picture of star formation in which stars are born in individual dense clumps or protostellar fragments that appear to be more massive than the stars that eventually form from them (see Myers [1991], and references therein). This fact suggests that the origin of stellar masses and the IMF are inextricably linked to the mass distribution of dense clumps and the efficiency with which an individual dense clump forms a star or a group of stars. Through spatially- and velocity-resolved molecular line observations, it has recently become possible to identify dense clumps in molecular clouds and establish their mass distribution over a wide range of spatial and density scales (Blitz 1987*b*; Stutzki and Güsten 1990; Lada et al. 1991*a*; Chapter by Blitz). The mass distribution (dN/dM) appears to be very similar in each cloud studied so far and may be fairly universal: it scales as the clump mass M to roughly the -1.5 power. In order to obtain the IMF of stars born in these clumps, we require an “initial-final mass relation” to translate the (initial) mass distribution of the clumps into a (final) mass distribution of stars (Zinnecker 1989*b*, 1990). If the final stellar mass m scales with the initial clump mass M as $m \propto M^p$ (with $p < 1$; cf. the observations of Stacey et al. [1988]), one can easily show that the stellar mass spectrum is a power law with index $x = -(0.5 + p)/p$. For example, to produce the index of the Salpeter IMF ($dN/dm \propto m^x$, $x = -2.35$; Salpeter 1955) requires $p \sim 0.4$. The observed mass distribution of dense clumps may be a result of collisional fragmentation (see, e.g., Nozakura [1990], and references therein) and/or the hierarchical structure of interstellar clouds (see, e.g., Elmegreen’s [1985*c*] model, and Zinnecker [1985]). The physical justification for the power p in the initial-final mass relation may come from the theory of protostellar winds dispersing the parent clumps (for low-mass stars: see Shu et al. [1991]) and the theory of radiation pressure acting on dust grains in protostellar envelopes to reverse their infall (for high-mass stars: see Yorke [1980] and Wolfire and Cassinelli [1986]). In addition, it would seem that magnetic field tension can help prevent complete accretion of the envelope mass, especially for low-mass stars (Nakano 1984; Lizano and Shu 1989; Mouschovias 1991*b*). All these ideas are still rather crude and the details have yet to be worked out, but the suggestion is that it will be progressively harder for the more massive clumps to accrete a substantial fraction of the original clump mass, while for the lower-mass clumps relatively more dense gas ends up in the star. This theory therefore suggests splitting any understanding of the IMF into two parts, namely the clump mass distribution and an initial-final mass relation. The advantage is that, at least in principle, each part can be tested separately by observations.

The theory as outlined above neglects various details of the star-forming

process. For example, is there a characteristic mass for the clumps (con: Shu et al. 1987a; pro: Mouschovias 1991b)? Does every clump form a star (Larson 1991)? Do larger clumps subfragment into several yet denser clumps (Zinnecker 1990)? Current theory suggests that indeed there *is* a characteristic clump mass ($\sim 1 M_{\odot}$), selected and preserved by self-gravity in a dense, turbulent, and magnetic interstellar medium (Mouschovias 1991b; Larson 1991). It is suspected that every clump above some critical density *does* form a star, and that subfragmentation *does* become increasingly important for progressively larger clump masses (Larson 1978, 1991). Indeed, if the probability of subfragmentation increases with clump mass, this will steepen the slope of the original clump mass spectrum, as required to explain the observed IMF. Furthermore, this process can produce an IMF which does not have a single power-law slope, but a slope whose index changes gradually with mass, much like the Miller-Scalo IMF (Miller and Scalo 1979)—in this case, the variable p would have to be a function of the clump mass.

Implicit in these considerations is the route by which the IMF arises in a system of stars such as a protocluster (cf. Scalo 1986; Zinnecker 1986a). Larson (1990a) and Myers (1991) have discussed the possible evolution of protoclusters, with emphasis on dissipational processes. Larson (1991) further elaborated on the origin of the slope of the upper IMF in a protocluster, suggesting that the power-law extension of the IMF toward higher masses may result from accretional growth of some stars to much larger masses. However, there must be a limit to accretion on each star, and a key question on the way to a full understanding of the origin of the IMF is the process by which accretion is cut off. Does the protostar terminate the mass inflow by switching on a protostellar wind, thereby defining its own mass (self-limited accretion; Shu et al. 1987a)? Is the reservoir for accretion limited by the other stars competing for material (competitive accretion; Zinnecker 1982)? Or is the amount of accretable material mostly dictated by the initial conditions (e.g., angular momentum limited accretion; Larson 1978)? Hopefully, detailed observations will provide us with some clues.

Finally, in any discussion of the IMF, we cannot ignore the fact that most stars are binaries. In particular, with regards the observational determinations of stellar luminosity and mass functions presented later in this chapter, the effect of unresolved binaries may be quite important, and has recently been discussed in some detail (Kroupa et al. 1991; Piskunov and Malkov 1991; Reid 1991). However, these analyses, along with the origin of binary stars and the origin of their mass ratios, are beyond the scope of this chapter, and the reader is referred to the Chapter by Bodenheimer et al. for more information.

1. Isolated vs Collective Star Formation

There are several distinct effects that come into play regarding collective as opposed to isolated star formation, including tidal forces, mass segregation, and radiative implosion. These effects imply qualitatively observable consequences.

First we consider tidal effects. Accretion may be inhibited by the tidal forces generated by a star on the disk or protostellar envelope of a neighboring stellar core, or perhaps more importantly, by a protocluster cloud on smaller extended fragments that are randomly positioned off-center within it. Both effects limit the reservoir for accretion, unlike the single star case considered by Shu et al. (1987a) where only the star itself (i.e., via its wind) can limit the accretion. At the same time that tidal forces limit the reservoir for accretion, they may also increase the *rate* at which the remaining material is accreted, due to the tidal torques that are present. Thus overall, young stars in a protocluster may have less massive but more rapidly evolving circumstellar disks than isolated objects of the same age.

A second important effect in a protocluster is mass segregation. Are the more massive stars born in the denser, more central regions of the cloud? A naïve application of the Jeans criterion for a centrally condensed isothermal cloud would predict the opposite outcome, with low-mass stars in the center and high-mass stars at the periphery. However, in the center, the clump-clump collision time scale is shorter than the collapse time scale of an individual clump. This effect, along with accretion of residual gas sinking towards the center due to dissipational processes, leads to a prediction that the more massive stars will indeed form near the cloud center. More specifically, we predict that the mass of the most massive star should scale with the depth of the gravitational potential well at the cloud center, because the deeper the well, the more difficult it is for gas to escape. Clumps farther from the center will avoid collisions more readily and will remain small, forming lower-mass stars.

A third effect concerns star formation triggered by the radiative implosion of clumps, initiated by ionization shock fronts from newly formed OB stars in the cluster (Klein et al. 1980). Close to the massive stars the clumps should be completely obliterated, creating a zone of avoidance (R. Klein, personal communication), while at greater distances, dense enough clumps will survive to form other high-mass or intermediate-mass stars. Infrared imaging observations might be able to reveal evidence for gaps around the most massive members of a cluster.

In summary, the conditions that arise only in a cluster environment could play a dominant role in producing the wide range of masses observed in the stellar mass spectrum. In particular, perhaps massive stars can only form in a cluster. Furthermore and equally important, the majority of field stars may be former members of clusters and OB associations (see Chapter by Lada et al.), and therefore the form of the *field star* IMF may be determined more by the effects of the cluster environment than by any other factor.

2. Bimodal Star Formation

The concept of a decoupling of low- and high-mass star formation originated with Herbig (1962b). In his picture, low-mass stars form continuously over a long period, only to be interrupted by the relatively rapid formation of

high-mass stars, the violence of which leads to dissipation of the remaining molecular material. This idea of temporal variations in the star-formation process with respect to stellar mass was further codified to refer to separate formation mechanisms for high- and low-mass stars, perhaps leading to distinct formation sites for OB stars and low-mass stars. This is the basis for so-called bimodal star formation (see, e.g., Eggen 1976; Mezger and Smith 1977; Güsten and Mezger 1982). However, as noted by Herbig (1962*b*), OB associations commonly have related associations of low-mass T Tauri stars, whereas the converse is not always true. Therefore, one continuous process could be at work, with an upper mass limit in regions of low-mass star formation set by, say, the initial reservoir of cloud material. The proof for separate mechanisms for high- and low-mass stars would be a region that has formed high-mass stars exclusively, implying a process that either prevented or biased against low-mass star formation.

Perhaps the strongest evidence for bimodal star formation has come from the study of starburst galaxies where low M/L ratios are best explained by the formation of predominantly high-mass stars in the nuclear regions (cf. Larson [1986], and references therein). Whether or not there are individual H II regions in our Galaxy whose exciting stars are *not* accompanied by low-mass stars is a very important question, with many implications for the origin of the IMF, both within a given cloud and throughout the field. However, until recently, finding firm observational evidence for this has been hindered by the difficulties encountered in detecting low-mass stars in regions where more massive stars are known to have formed.

In the spirit of bimodal star formation, Shu et al. (1987*a*) and Lizano and Shu (1989), following ideas by Mestel (1985), proposed a model whereby two distinct star-forming mechanisms can operate depending upon the ratio of magnetic support to cloud self-gravity. A small cloud dominated by magnetic support evolves slowly via ambipolar diffusion to form a low-mass core and subsequently a low-mass star. Conversely, if enough of these smaller clumps can agglomerate into larger clumps, for example in a giant molecular cloud via some external trigger, gravity can overcome the magnetic support, and these clumps will collapse rapidly, forming high-mass stars. In the latter scenario, fragmentation can also take place, perhaps forming low-mass stars. This model also explains the low star-formation efficiency seen in complexes with only low-mass cores and stars. The long time scale for low-mass core evolution leads to an incoherence across the cloud complex, and the collapse of some cores may be disrupted by the stellar winds of nearby newly formed stars.

Mouschovias (1987*a*) took another perspective on the difference between low- and high-mass star formation. In his scenario, low- and intermediate-mass stars form in quiescent clouds collapsing at sub-Alfvénic speeds, while a cloud initially supported by magnetic fields then imploded by an external trigger may collapse rapidly at Alfvénic or super-Alfvénic speeds, forming more massive stars.

It is important to note that neither of these models seems to preclude the formation of low-mass stars alongside the high-mass stars. Indeed, if the high-mass stars form first, they may trigger low-mass star formation in the clumpy medium by radiative implosion (Klein et al. 1980,1983; La Rosa 1983).

As our sensitivity to low-mass stars in the more distant massive star-forming regions improves, our ideas of bimodal star formation will become better developed. A possible example of bimodal star formation in our Galaxy, in the star-forming region S 255/257, is described below in Sec. III.C.2.

B. Evolution of a Model PMS Infrared Luminosity Function

From an observational standpoint, the near-infrared ($1\text{--}2.5\ \mu\text{m}$) is perhaps the best wavelength range over which to find young low-mass stars in clusters. Using array detectors, it is now easy to detect and measure the near-infrared fluxes of large numbers of stars in such clusters, as we shall see in Sec. III. Unfortunately, it remains hard to make immediate astrophysical sense of these raw measurements. Because the stars are heavily reddened and may have large infrared excesses, it is not easy to determine the total stellar luminosity. Because the stars are young, a time-independent main-sequence mass-luminosity relation cannot be used to determine the stellar mass, and a time-dependent PMS relation must be used: for example, an empirical fit to the models presented below shows the near-infrared (K) luminosity for low-mass stars evolving down their Hayashi tracks changing as $L_K \propto M^{1.6} \times t^{-2/3}$.

The classical approach to these problems for PMS stars is to measure the underlying spectral type of each star and thence the reddening towards it. The luminosity is determined by integrating under the spectral energy distribution, and by combining this with the effective temperature, the age and mass of each star can be found by comparison with PMS evolutionary tracks in an HR diagram (Cohen and Kuhn 1979). However, it is difficult to obtain spectral types and reddening for all the members of a dense, heavily obscured PMS cluster, and some assumptions have to be made. For example, in their study of the Trapezium Cluster, Herbig and Terndrup (1986) measured a few stars spectroscopically and then used the mean derived extinction to deredden the rest of the cluster members. As an alternative, Straw et al. (1989) assumed all the stars they measured in NGC 6334 were on the zero-age main sequence (ZAMS), and moved them parallel to the reddening vector in the HR diagram until they intercepted the ZAMS locus. In the former case, it is highly unlikely that all stars in an embedded cluster have the same extinction. In the latter case, assuming the stars to be on the ZAMS when they are more likely to be PMS will overestimate their mass. However, if there was some other way of estimating the age of a PMS star or even a whole cluster, it should be possible to deredden the stars in the HR diagram until they intercept the appropriate PMS isochrone, thus determining their masses. The possibility of infrared excesses will complicate such simple approaches, but to some extent that can be dealt with by looking at a star's location in a near-infrared color-color

diagram. In these diagrams, the reddening vector, isochrones, and isomass tracks all form a roughly parallel locus, whereas stars with infrared excesses fall below this line.

With this problem in mind, and as part of an on-going study of young clusters and how observations may be converted into physically useful parameters, we have performed some simple modeling which allows us to explore the phase space covered by young low-mass stars in near-infrared coordinates. One particular point of interest is the predicted PMS evolution of the near-infrared luminosity function. Some qualitative results relating to this are given here.

1. Modeling

We have taken a homogeneous grid of PMS tracks (0.1 to 10 Myr) for low-mass (0.08 to $2.5 M_{\odot}$) stars, kindly provided to us by I. Mazzitelli, and converted them from T_{eff} , R/R_{\odot} coordinates into near-infrared magnitudes assuming the stars to be blackbodies, and using the Sun as a zero point, also assumed to be a blackbody. As the Sun is *not* accurately represented by a blackbody, and low-mass PMS stars even less so, this work must be repeated using synthetic spectra. However, for illustrative purposes here, the results obtained using blackbodies give a qualitative if not quantitative picture. Normally an observed luminosity function is converted to a mass function via some empirical or model mass-luminosity relation. Here we reverse the procedure. To derive a near-infrared $2.2 \mu\text{m}$ (K) luminosity function (i.e., dN/dK), we begin by assuming a given mass function (i.e., $dN/d \log M$) and then evaluate the following equation:

$$\frac{dN}{dK} = \frac{dN}{d \log M} \times \frac{d \log M}{dK} \quad (1)$$

where $d \log M/dK$ is the slope of mass- K luminosity relation, and $K = -2.5 \log(L_K/L_{\odot K})$. For these models, we used the half-gaussian form of the Miller-Scalo IMF (Miller and Scalo 1979) and the slope of the mass- K luminosity relation as derived from the transformed PMS tracks at each age and mass. It has been pointed out many times (see, e.g., D'Antona 1986; Bahcall 1986; Kroupa et al. 1990) that it is the *slope* of the mass-luminosity relation that is involved here, and that simple inflections in that relation can lead to significant features in the luminosity function, as we shall see below.

2. Results

Figures 1 a,b,c,d show the model mass- K luminosity relations at four different ages (0.3, 0.7, 1 and 2 Myr), while Figs. 2 a,b,c,d show the corresponding model K luminosity functions (KLFs) for a coeval cluster of low-mass stars at the same four ages. Note that the distance to the cluster is assumed to be 10 pc, i.e., in these figures, $K \equiv M_K$. For reference, Fig. 3 shows an empirical

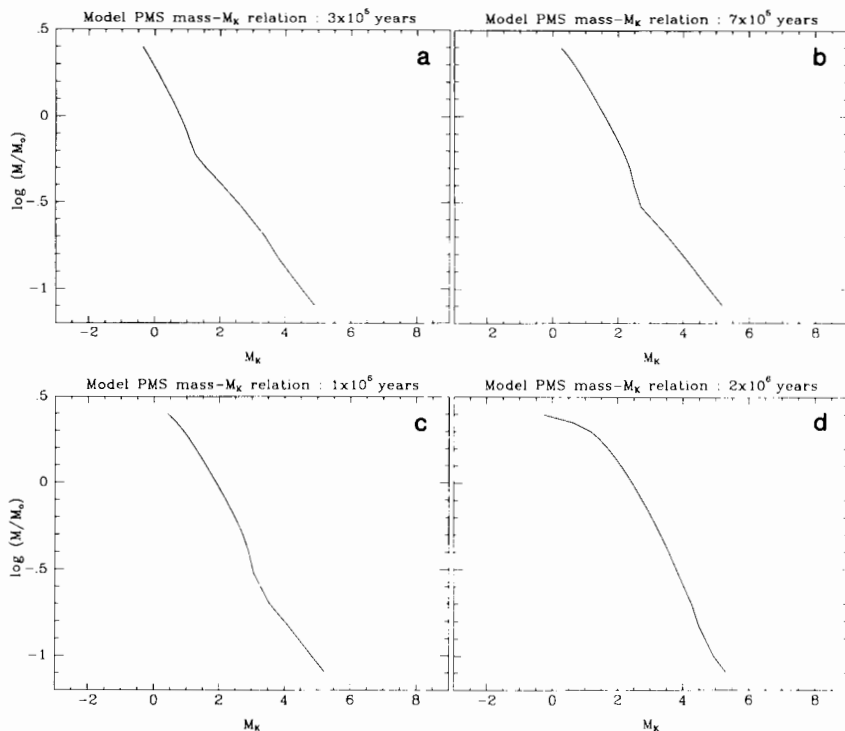

Figure 1 a,b,c,d. Time-dependent mass- M_K luminosity relations, as derived from homogeneous tracks of pre-main-sequence evolution calculated and kindly provided by I. Mazzitelli. Four ages are shown: 0.3, 0.7, 1, and 2 Myr.

mass- M_K relation and corresponding spectral types for main-sequence stars. Also note that $0.3 M_\odot$ corresponds to $\log M = -0.5$ in these diagrams.

At 0.1 Myr (not shown), the shape of the KLF largely reflects the shape of the Miller-Scalo IMF, i.e., turning down and flattening towards the lower masses, corresponding to the almost straight mass- K luminosity relation at this age. Whether or not such a KLF would ever be seen in practice is debatable however, as stars this young would still be deeply embedded in their protostellar cocoons, making it unlikely that the “naked” PMS stars would be seen at this stage. By 0.3 Myr, features become apparent in the KLF, and by 0.7 Myr, there is a sharp peak in the KLF which can be traced to a sharp inflection at the corresponding point in the mass- K luminosity relation. This point of inflection is seen to move towards lower masses with time, and by 2 Myr the peak in the KLF has moved down close to our chosen mass cutoff at $0.08 M_\odot$. By 10 Myr (not shown), the peak is long gone.

The inflection in the mass- K luminosity relation is a feature caused by

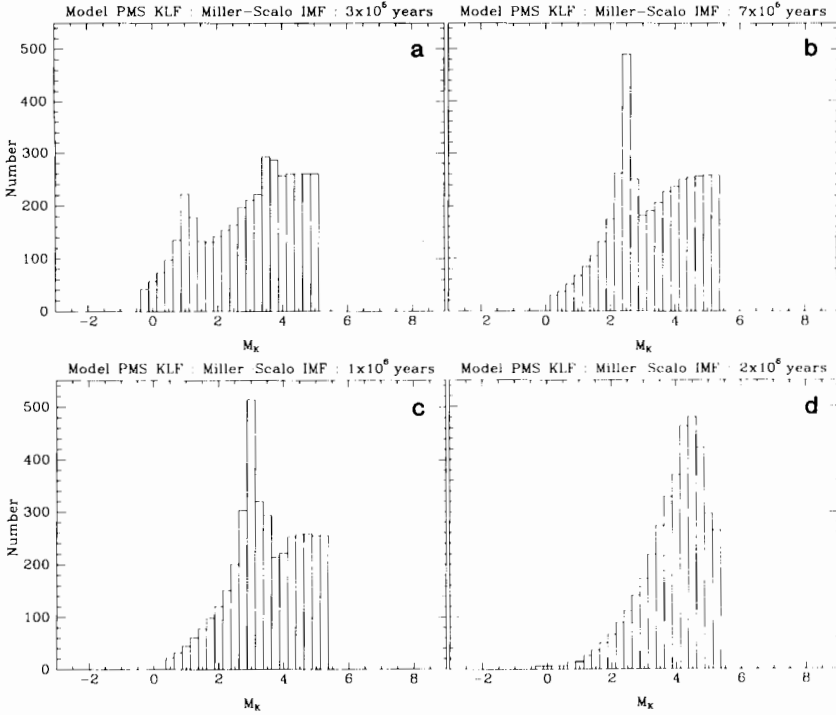

Figure 2 a,b,c,d. Model $2.2 \mu\text{m}$ (M_K) luminosity functions for a coeval cluster of low-mass stars at the same four ages shown in Fig. 1. The luminosity functions were calculated by convolving the mass- M_K relations with a Miller-Scalo IMF. Note the strong peak due to deuterium burning in the last three luminosity functions.

deuterium burning in contracting PMS stars. D-burning occurs when the Kelvin-Helmholtz contraction has proceeded far enough to raise the central temperature to $\sim 10^6$ K. For a $0.3 M_\odot$ PMS star, D-burning occurs at an age of ~ 1 Myr and lasts for ~ 1 Myr, until most of the central deuterium is consumed. These time scales are fairly independent of the precise value of the initial deuterium abundance, although for reference, the Mazzitelli models were calculated using a deuterium abundance of 2×10^{-5} by mass, as derived for the solar neighborhood (York and Rogerson 1976). While deuterium is burning, the corresponding nuclear energy generation provides substantial support against continuing PMS contraction, i.e., for a while the star's radius and luminosity remain almost constant (see Fig. 2 of Mazzitelli and Moretti 1980). While the deuterium is burning strongly in stars of a given mass, D-burning is ending in slightly higher-mass stars, and has yet to begin in lower-mass stars. Thus, at the mass where peak D-burning is occurring (i.e., the mass whose time scale for the onset of strong D-burning is equal to the

Figure 3. An empirical mass- M_K luminosity relation for main-sequence stars, derived from the data of Miller and Scalo (1979), and Koornneef (1983*b*), following Straw et al. (1989). Corresponding spectral types are also marked. It should be noted that there is considerable uncertainty in this relation for spectral types K0 and later, as seen when compared to other empirical determinations (M. Simon, personal communication; Henry 1991).

present age of the coeval cluster in question), there is a kink in the mass-luminosity relation. This leads to an increase in the value of $d \log M / dK$, and a boost in the luminosity function at the corresponding K magnitude, creating a peak and the subsequent turnover. A physical interpretation is that as the cluster members are decreasing in luminosity, evolving down their Hayashi tracks, stars in a certain mass range temporarily decrease less, and pile up in a slightly brighter than expected magnitude bin. It is, however, important to note that at no point in our completely coeval model cluster does a star of mass M appear more luminous than a star of mass $M + \delta M$, as the D-burning never completely halts the PMS contraction.

It is a general feature that the duration of the D-burning phase for a given star is roughly equal to its age at the onset of D-burning (cf. Mazzitelli and Moretti 1980). For example, D-burning starts in a PMS star of $1 M_\odot$ at ~ 0.1 Myr and lasts approximately 0.1 Myr. These time scales are in accordance with the location of Stahler's (1983*a*) "birthline" in the HR diagram, the location below which optical T Tauri stars seem to appear for the first time, thought to be set by the D-burning "quasi-main sequence."

So we can see that for young clusters, features such as peaks and turnovers in the K luminosity function cannot be *assumed* to imply corresponding

features in the IMF; rather, they may often reflect the complex process of PMS evolution. Therefore we caution against overly simplistic analyses of near-infrared luminosity functions and inferences for the IMF. On the other hand, such features might still be used to our advantage, namely as a possible age indicator. This somewhat surprising result might even hold when our simplifying assumptions are replaced in more realistic models, e.g., allowing for age spreads and infrared excesses due to circumstellar disks. We will also have to include intermediate-mass stars in this procedure, which we have omitted here. The PMS evolution of these stars is currently under investigation (Palla and Stahler 1990,1991; see also Chapter by Stahler and Walter).

C. Spectral Energy Distributions

The previous discussion was idealized by considering only naked PMS stars without any circumstellar material. But it is known from observations of infrared excesses and sub-millimeter continuum emission that YSOs can possess substantial amounts of circumstellar dust. The distribution and quantity of this dust determines the shape of the emergent energy distribution from the YSO. Low-mass YSOs gradually dissipate their circumstellar dust as they approach the main sequence and over their extended evolutionary time scales, the shapes of their spectral energy distributions (SEDs) change dramatically. Therefore, by constructing the energy distribution of a YSO over the 1 to 100 μm spectral region, the evolutionary state can be inferred. Empirically, sources can be classified according to the slope of their 2 to 25 μm SED in a $\log \lambda F_\lambda$ vs $\log \lambda$ plot (see, e.g., Lada 1988a). The most heavily obscured and presumably youngest YSOs are optically invisible and have SEDs which rise into the far-infrared with a slope greater than zero: these are Class I sources. Visible but reddened YSOs with strong mid-infrared excesses have SEDs with slopes between 0 and -2 and are classified as Class II sources: these objects are usually associated with classical T Tauri stars. Finally, YSOs which have weak or no infrared excesses have SEDs resembling reddened blackbodies (slope ~ -3). These objects, associated with weak emission T Tauri stars, are the Class III sources.

It has been suggested that the variations of shape in the SEDs observed for YSOs represent a quasi-continuous evolutionary sequence from protostars (Class I) to weak-emission T Tauri stars (Class III) (see, e.g., Adams and Shu 1986; Adams et al. 1987,1988; Myers et al. 1987; Rucinski 1985). As shown schematically in Fig. 4, Class I SEDs can be successfully modeled as accreting protostars comprised of three components (stellar core, circumstellar disk, and a quasi-spherical envelope or halo), with the far-infrared emission arising from the infalling envelope and the mid-infrared emission from the spatially thin disk. A stellar wind soon develops which breaks out at the rotational poles of the envelope, thereby reducing the extinction to the central YSO. Emission from the central object can now be observed at near-infrared wavelengths, producing a double-peaked, or Class IID, SED. As the wind dissipates the residual envelope, the central YSO plus disk are fully revealed resulting in

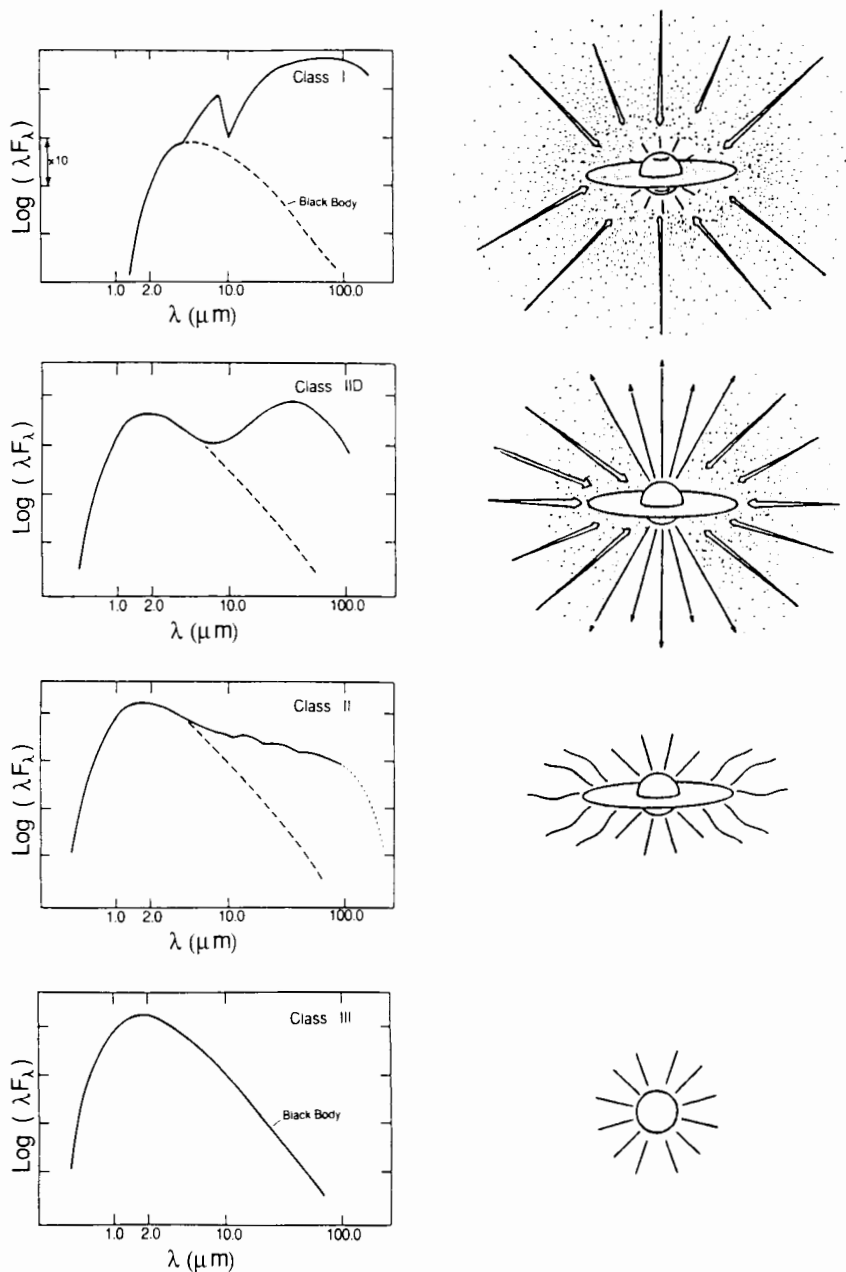

Figure 4. A schematic of the sequence of protostellar evolution, along with the accompanying evolution of the spectral energy distribution (SED). This figure, taken from Wilking (1989), illustrates the ideas described by Lada (1988a) and in the review article by Shu et al. (1987a).

either a flat spectrum SED, indicative of $r^{-1/2}$ disk temperature gradient, or a Class II SED whose slope approaches $-4/3$, characteristic of a disk with an $r^{-3/4}$ temperature gradient. Finally, as the disk is dissipated, a Class III SED is observed. The time a given YSO spends in each of the Class I, II and III phases is believed to be longer for the later stages; e.g., for a $1 M_{\odot}$ star, 1 to 0.2 Myr, 1 Myr, and 10 Myr, respectively. These are only rough estimates, and we should keep in mind that the discrete classes are just an approximation of a continuous evolution.

To further characterize the evolutionary state of a protostellar Class I (or IID) object, it is possible to use its total luminosity L and the visual extinction to the stellar surface, A_V . Evolutionary L - A_V diagrams have recently been calculated from models of rotating low-mass YSOs in an attempt to provide the equivalent of an HR diagram for protostars (Adams 1990; see Chapter by Adams and Lin). As accretion proceeds for a given rotation rate, objects increase in luminosity while the visual extinction through the infalling envelope drops. This work extends that of Yorke and Shustov (1981) who had originally suggested the use of such diagrams for young massive stars embedded in spherical dust cocoons. Observationally, the total luminosity can be determined by integrating the SED; A_V is more difficult to determine but can be estimated from the depth of the $10 \mu\text{m}$ silicate absorption features (Rieke and Lebofsky 1985), from a comparison of the intrinsic and the observed ratio of near-infrared hydrogen recombination lines (see, e.g., Alonso-Costa and Kwan 1989; Evans et al. 1987), or from near-infrared color indices which are free of excess emission (Myers et al. 1987). However, for very high extinctions ($A_V > 100$ mag) none of these methods work, and even for lower extinctions each method suffers from specific problems, e.g., how to separate the intrinsic object extinction from foreground cloud extinction.

While Class I objects cannot be placed on a conventional HR diagram, Class II and III sources usually can. It must be noted however, that only the stellar luminosity should be used in placing the YSO on PMS tracks, not the total luminosity, which often also includes a significant contribution from an active or even a passive disk (Bertout et al. 1988; Kenyon and Hartmann 1987). Strom et al. (1989*d*) and Cohen et al. (1989*b*) have discussed methods for splitting the stellar and circumstellar contributions to the luminosities of T Tauri stars with disks, but the problem is far from trivial. Recently, Kenyon and Hartmann (1990) have investigated how a random distribution of disk inclination angles, coupled with a plausible range of accretion rates, can introduce a significant scatter in apparent luminosities for intrinsically identical stars. Age determinations for many PMS stars may therefore be uncertain by as much as factors of 2 to 3. Ultimately, PMS tracks need to be calculated where the luminosity arises not only from Kelvin-Helmholtz contraction, but also in part from disk accretion (see, e.g., Stringfellow 1989).

In summary, the current theory of YSO SEDs suggests that Class I objects consist of three distinct components, Class II of two, and Class III essentially of only one, i.e., the naked young star. However, this theory may be too sim-

ple. For example, Class I models may *not* require much of a disk (F. Adams, personal communication; Butner et al. 1991), while Class III models could include a disk with a large central hole (Beckwith et al. 1990). Also the time-dependent and possibly episodic nature of disk accretion should be considered in future models. For example, recent observations of YSOs in ρ Oph indicate a poor correlation between the mass of circumstellar material and the strength of the infrared excess (André et al. 1990*b*), suggesting variations in the compactness of disk material within SED classes. The origin of the $r^{-1/2}$ disk temperature gradient in flat-spectrum sources poses a particular problem, and suggests that future YSO evolutionary models should consider active as well as passive disks. Finally, the likelihood of binary and multiple YSOs sharing circumstellar material needs to be accounted for in analyzing SEDs.

III. OBSERVATIONS OF INITIAL STELLAR POPULATIONS

In this section, we will review the various observational techniques, from radio to X rays, employed to study YSOs over the full range of evolutionary states from protostar to weak-emission T Tauri star. The observational picture has changed dramatically since 1984 due to the success of IRAS and the growing availability of infrared array cameras. Examples of studies of the initial stellar population are given for diverse molecular environments ranging from nearby dark clouds, through giant molecular clouds, to regions of star formation in the Magellanic Clouds.

A. Techniques and Their Selection Effects

In order to find and study low-mass YSOs in all phases of PMS evolution, it is necessary to use a wide variety of observational techniques spanning the entire electromagnetic spectrum. At the same time, no single technique is likely to produce a complete sample of YSOs in any given star-formation region. The following are some of the techniques that have been used to reveal the whole range of YSOs, from Class I to Class III:

1. Far-infrared surveys (e.g., the IRAS all-sky 12–100 μ m survey)
2. Near-infrared surveys (e.g., 1–2.5 μ m)
3. 2.6 mm CO line surveys
4. 6 cm radio continuum surveys (e.g., with the VLA)
5. Optical objective prism surveys
6. X-ray surveys (e.g., with the EINSTEIN Observatory)
7. Optical proper motion surveys

Next, we shall discuss these techniques in more detail, paying particular attention to the inevitable selection effects and other shortcomings associated with each of them.

Since 1974, the Kuiper Airborne Observatory (KAO) has carried out studies of both massive and low-mass embedded YSOs at far-infrared wavelengths (see Thronson and Erickson [1984] for a review). Angular resolutions

are typically 50 arcsec at 50 and 100 μm ; for strong sources, diffraction limited resolution is possible, e.g., ~ 23 arcsec at 100 μm (Lester et al. 1986). The KAO is somewhat limited in its spatial coverage and sensitivity, and therefore a major step forward was taken in 1983 when the cryogenically cooled IRAS carried out an all-sky survey at four mid- to far-infrared wavelengths (12, 25, 60, 100 μm) with a resolution of 0.75, 0.75, 1.4, and 3 arcmin, respectively. In addition to finding a number of deeply embedded YSOs (Beichman et al. 1986; Beichman 1987), IRAS was also sensitive to many of the previously known emission-line objects and objects associated with optical nebulousity. Thus IRAS detected several classes of YSOs and would have been superior to optical and near-infrared surveys were it not for a lack of sensitivity to low-luminosity objects (e.g., faint T Tauri stars in nearby dark clouds) and the low spatial resolution. Combined, these shortcomings implied that at the distance of Orion, IRAS was not only sensitivity limited but also confusion limited. In some cases, high-resolution pointed IRAS observations have overcome the source confusion problem in *nearby* dark clouds (e.g., in ρ Oph: Young et al. 1986; in Cha I: Prusti et al. 1991), as have follow-up KAO observations. However, at the distance of even the nearest H II regions, the IRAS and KAO views are blurred.

Groundbased mid-infrared observations with larger telescopes can deliver higher spatial resolution, but at a great expense in sensitivity, due to the enormous thermal background encountered at 10 to 20 μm . In contrast, the thermal background is negligible shortward of 2.5 μm , and near-infrared observations at 1 to 2.5 μm can result in high spatial resolution *and* high sensitivity. The advantages of near-infrared observations are that Class II and III YSOs emit most of their luminosity in that wavelength range; extinction due to foreground dust is greatly reduced compared to optical wavelengths; and competition from the bright ionized nebulousity associated with H II regions is considerably reduced. In general, only the very youngest and coolest, and/or most deeply embedded YSOs will escape detection at near-infrared wavelengths, thus requiring far-infrared and sub-millimeter observations. In the past, near-infrared surveys were limited by the need to scan a single detector over a region of star formation, resulting in a serious compromise between sensitivity, resolution, and areal coverage. Employing sensitive two-dimensional infrared detector arrays (with $\sim 64 \times 64$ to 256×256 pixels), near-infrared cameras are now being used to image large areas of star-forming regions. These observations result in simultaneous high spatial resolution (seeing limited, ~ 1 arcsec FWHM) and sensitivity (point sources as faint as $K \sim 17$ mag are visible in about two minutes on a 2 meter class telescope). It is important to note that for the majority of massive star-forming regions in the Galaxy (1–3 kpc), simultaneous high resolution and sensitivity are required to prevent a bias against detection of the lowest-mass stars, which would otherwise be lost in the “glare” of the ionizing massive stars. As we shall see below, the power of near-infrared cameras to reveal large clusters of low-mass stars associated with H II regions is proving to be a major step forward in YSO

surveys. Perhaps the major complaint against these near-infrared surveys is that they can be *too* effective: in addition to revealing almost the entire YSO population associated with a star-forming region, these surveys can also detect large numbers of stars along the line of sight to and beyond the region, due to the effectiveness with which near-infrared photons can penetrate dust, and the general preponderance of the galactic field-star population towards low-mass, red objects. Surveys of this kind must employ reasonably sophisticated sorting criteria and/or statistical techniques to winnow out the field population, particularly in the more distant regions close to the galactic plane and within the inner Galaxy.

Mid-infrared (10 and 20 μm) cameras are also being built and becoming operational. They will complement observations at near- and far-infrared wavelengths and will serve as a high-resolution probe of deeply embedded YSOs, although again, the extremely high thermal background seen from the ground will limit them to objects that are sufficiently bright, on the order of a few hundred mJy at 10 μm .

Deeply embedded YSOs, as well as some Class II objects, are associated with energetic mass loss revealed as high-velocity molecular gas, Herbig-Haro objects, and/or free-free emission. Unbiased surveys for CO outflows in whole clouds such as NGC 2264 and the L 1641 cloud in Orion have revealed the crude positions of the sources that drive these outflows (Margulis and Lada 1988; Fukui et al. 1989; Fukui 1989). Sensitivity and resolution problems also plague this technique, and primarily higher luminosity sources have been found. If a source is close to the cloud surface, optical Herbig-Haro objects and jets may result, and infrared searches around them can be used to locate their obscured driving sources (Cohen and Schwartz 1983; Reipurth 1989c). There must be many cases, however, where the HH objects and jets are themselves deeply embedded in the molecular clouds, avoiding detection in the optical: few optical HH objects are seen near the ρ Oph cloud for example. Infrared cameras offer the potential for revealing HH objects and jets even in highly obscured regions: a recently discovered highly collimated structure in a dense core near IC 348 (Fig. 5; see also Color Plate 1) is invisible at wavelengths less than 1 μm , and may be a HH-like object, perhaps radiating strongly in the near-infrared lines of shocked molecular hydrogen and [Fe II].

Potentially promising for uncovering deeply embedded low-luminosity YSOs, as well as Class III objects, are large-scale radio continuum surveys carried out at the VLA (20 cm and 6 cm wavelengths). Typical maps can cover a few square degrees with synthesized beams of order 10 to 20 arcsec and source positions better than 5 arcsec. This technique is very sensitive to small amounts of ionized gas arising from stellar winds (Class I sources) or magnetic surface activity (Class III sources). However, it turns out that most low-mass YSOs have only low levels of radio continuum emission. For example, André et al. (1987) and Stine et al. (1988) conducted a VLA survey of 4 square degrees in the ρ Oph cloud. Only a few of the known YSOs were detected and none of the optical T Tauri stars: 90% of the YSOs remained

Figure 5. A K ($2.2\ \mu\text{m}$) image of the IC 348-IR region, covering $\sim 3.2 \times 3.2$ arcmin ($\sim 0.3 \times 0.3$ pc at 300 pc). A previously unknown jet-like feature is revealed, possibly a Herbig-Haro object. The associated driving source, which must be a very young and highly obscured star, has not yet been identified. The data were obtained using a 256×256 pixel HgCdTe array on the University of Hawaii 2.2-m telescope.

undetected down to a limit of 1 mJy. The bulk of the sources detected at 20 cm at the VLA are unrelated to known YSOs, which calls for tedious identification procedures involving the determination of radio continuum spectral indices and thus multi-wavelength data. However, the radio continuum observations did discover a few new, very interesting embedded young sources which would otherwise have been overlooked, e.g., VLA 1 in the HL/XZ Tau region (Brown et al. 1985) and recently VLA 1623 in ρ Oph near GSS 30 (André et al. 1990a).

Objective prism surveys ($H\alpha$) have been very powerful in revealing

classical T Tauri stars characterized by strong emission lines at visible wavelengths (see, e.g., Herbig and Bell 1988). Also, surveys for Ca emission have been undertaken to search for weak-emission T Tauri stars, but have discovered few, adding only about 20 emission-line stars in Taurus, for example, (Herbig et al. 1986). One caveat in using H α surveys is that the line strength could be highly variable. For example, emission-line objects found on prism plates taken at one epoch have shown less than 50% overlap with those found on plates taken just a decade or so later: e.g., compare Dolidze and Arakelyan (1959) with Wilking et al. (1987) who surveyed the same area in the ρ Ophiuchi dark cloud. This variability is worrisome, undermining the usefulness of single-epoch H α surveys to assess the number of young low-mass stars in even lightly obscured star-forming regions.

X-ray surveys pick out young stars with magnetic surface activity and have uncovered a population of YSOs which have no or only weak H α emission and thus were missed in the classical H α surveys (Feigelson and de Campli 1981; Montmerle et al. 1983a; Walter 1986; Walter et al. 1988; Feigelson and Kriss 1989). Apparently, these weak-emission T Tauri stars have dissipated most of their inner circumstellar gas and dust; however, they still may have *outer* dust disks detectable at millimeter continuum wavelengths (cf. Beckwith et al. 1990). Because of the limited nature of X-ray surveys with the EINSTEIN Observatory and the highly variable nature of the emission, we cannot say at present how many of these Class III objects have been missed. With the ROSAT X-ray satellite, launched in June 1990, we should be able to address this problem in the near future. However, even moderately embedded Class III objects can escape detection due to the absorption of soft X rays by small amounts of cloud material; an optical extinction of $A_V \sim 5$ ($\tau_{1.5\text{keV}} \sim 1$) may suffice to lose these young stars.

One of the most unbiased techniques used to identify lightly-obscured YSOs in nearby star-forming regions is an optical proper motion survey. For the Taurus clouds, the pioneering work of Jones and Herbig (1979) was recently extended by Hartmann et al. (1991), who covered ~ 9 square degrees to an estimated completeness limit of $V=15$ mag. Optical spectra were obtained for the subset of stars with proper motions consistent with Taurus membership, leading to an increase of about 20% in the number of PMS objects in the main survey region, essentially the value predicted by Jones and Herbig (1979). The newly discovered PMS stars have ages around 1 Myr, even though much older stars could have been detected. Thus the problem "where are all the post T Tauri stars?" (Herbig et al. 1986; Walter et al. 1988) remains: they do not seem to be there. It is unlikely that a large population of Class III objects has been missed due to selection effects: the only apparent biasing effect is caused by the movement of the photocenter of binaries due to their mutual orbital motion rather than proper motion.

Proper motion surveys for other regions are badly needed, but the effort is huge, and only a few other populations have been examined, e.g., the Orion region centered on the Trapezium Cluster (Parenago 1954; Jones and Walker

1988; van Altena et al. 1988; McNamara et al. 1989). As many members of these populations remain embedded in molecular cloud material, ultimately we will need proper motion surveys in the near-infrared.

B. Young Stars Associated with Dark Clouds

Low-mass star formation is best studied in the nearby (<200 pc) dark cloud complexes. There one can apply the greatest variety of observational techniques with maximum sensitivity to low-luminosity YSOs and with the highest linear spatial resolution. Additionally, most of these dark clouds lie well outside of the plane of the Galaxy, so that confusion from background stars is minimized.

1. Taurus-Auriga and ρ Ophiuchi

Among the most intensively studied star-forming regions are the Taurus-Auriga and ρ Ophiuchi dark cloud complexes (Figs. 6 a,b). These are intermediate-mass molecular complexes ($\sim 10^4 M_{\odot}$) which lie close to the Sun, at distances of about 140 pc and 160 pc respectively. At these distances, their sub-solar mass populations of YSOs are easily accessible to groundbased observers even at mid-infrared wavelengths. Indeed, of the ~ 100 YSOs identified with each cloud, almost all are low-luminosity ($<5 L_{\odot}$) objects. These YSOs cover the full range of expected evolutionary states, from heavily obscured Class I sources to optically visible weak-emission Class III stars. HR diagrams of the T Tauri populations in these clouds coupled with theoretical PMS tracks suggest that star formation has been going on for at least the past few million years (Cohen and Kuhn 1979; Stahler 1983a); yet as we discuss below, current evidence suggests that the mechanism for star formation may have been different in the two clouds.

While these molecular cloud complexes have similar masses and are formation sites for comparable numbers of low-mass stars, there are important differences between their young stellar populations. Some, if not all, of these differences can be traced to the different interstellar and molecular environments in which the stars have formed. First, the interstellar radiation field is less intense in Taurus-Auriga than in ρ Oph. In the Taurus complex, there are only 8 associated B stars within a 12 pc projected radius of the cloud center (Elias 1978c; Walter and Boyd 1991). In contrast, the ρ Oph cloud lies in the Upper Scorpius subgroup of the Sco-Cen OB association, and has about 20 B or A0 stars within a four times smaller area (radius ~ 6 pc), with the B2 V star (HD 147889) and a B3–B5 V star (Source 1) embedded in the western edge of the complex (Elias 1978a; de Geus et al. 1989). As a result, warmer dust and gas temperatures are observed in ρ Oph relative to Taurus-Auriga (see, e.g., Greene and Young 1989; Jarrett et al. 1989; Snell et al. 1989).

A second important difference between these young stellar populations relates to their distributions. Most of the YSOs in the Taurus-Auriga cloud are found in the vicinity of molecular cores with typical masses of $1 M_{\odot}$, densities of 10^4 to 10^5 cm^{-3} , temperatures ~ 10 K, and visual extinctions of 5

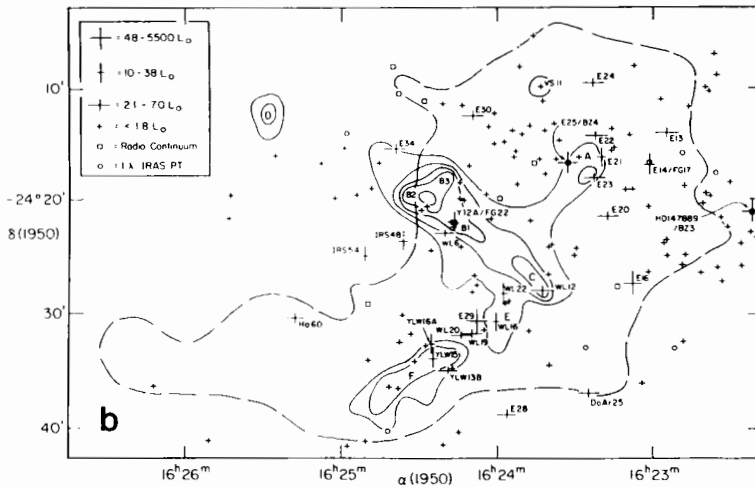

Figure 6a,b. The spatial distribution of YSOs in the Taurus-Auriga dark-cloud complex (covering $\sim 2400 \text{ pc}^2$) from Kenyon et al. (1990), and the spatial distribution of YSOs in the ρ Ophiuchi dark cloud core covering $\sim 4 \text{ pc}^2$ (figure from Loren et al. 1990).

mag to 10 mag (see Myers [1985], and references therein; Myers et al. [1987]). The cores, and hence the YSOs, are distributed throughout a low-extinction, filamentary molecular complex covering about 2400 pc^2 (Ungerechts and Thaddeus 1987). On the other hand, most YSOs in ρ Oph are concentrated toward a $1 \times 2 \text{ pc}$ ridge of high column density gas at the western edge of the complex, containing about $550 M_{\odot}$ of molecular gas (Vrba et al. 1975; Elias 1978*a*; Wilking and Lada 1983; Loren 1989*a,b*). Characteristic visual extinctions in this region are 50 mag to 100 mag. High-density molecular cores are found within the ridge, displaying higher masses and temperatures than their Taurus-Auriga counterparts (Loren et al. 1990). A lower density of YSOs is found in the filamentary streamers of Ophiuchus, forming in the vicinity of molecular cores in the manner observed in Taurus-Auriga.

The stellar density within the high column density ρ Oph cloud core is about $150 \text{ stars pc}^{-3}$, and the star-formation efficiency (SFE) is roughly 22% (Wilking et al. 1989*a*). Thus it has been suggested that given the time-dependent nature of the SFE and the slow release of gas from the cloud, a gravitationally bound stellar cluster of order 100 stars will ultimately emerge from the core (Wilking and Lada 1985). While it is true that the SFE in Taurus-Auriga is high in the vicinity of dense cores, the current distribution of YSOs does not suggest the formation of a large bound stellar group there.

Significant differences between these stellar populations also arise when a detailed comparison of the luminosity functions of their Class I and Class II sources is made (see, e.g., Wilking et al. 1989*a*; Kenyon et al. 1990). Spectral energy distributions for the YSOs and the resulting luminosity functions have been constructed by synthesizing visible-wavelength data with near- to far-infrared data, thus yielding the most reliable estimates for the YSOs' SED classes and bolometric luminosities. In regions of low source density, the completeness limit imposed by the IRAS sensitivity for the luminosity function in the Taurus-Auriga cloud is $>0.3 L_{\odot}$ for Class I sources and $>0.5 L_{\odot}$ for Class II stars. In ρ Oph, these limits are higher due to greater extinction in the cloud: Class I sources are completely sampled throughout the entire depth of the cloud core for $>1 L_{\odot}$, but $1 L_{\odot}$ Class II sources are completely sampled in only the outer $A_V \sim 35$ mag to 40 mag of the cloud. The luminosity functions for these two clouds are shown in Fig. 7, with the number of Class I and Class II sources in each bin indicated. In ρ Oph, the intermediate luminosity range ($5.6\text{--}56 L_{\odot}$) is dominated by Class I objects (80%) and their number drops with decreasing luminosity. This observation can be understood if these Class I sources form a population of heavily obscured 0.1 to $1 M_{\odot}$ objects with an excess of luminosity relative to their Class II counterparts, i.e., they derive part or all of their luminosity from accretion. Alternatively, it is possible that these Class I sources are very young 2 to $3 M_{\odot}$ objects, implying that the cloud is forming stars sequentially in mass. In Taurus-Auriga, there are fewer Class I objects relative to Class II at intermediate luminosities (45%), and their number *increases* with decreasing luminosity. There are several selection effects present in ρ Oph which could give rise to the observed differences

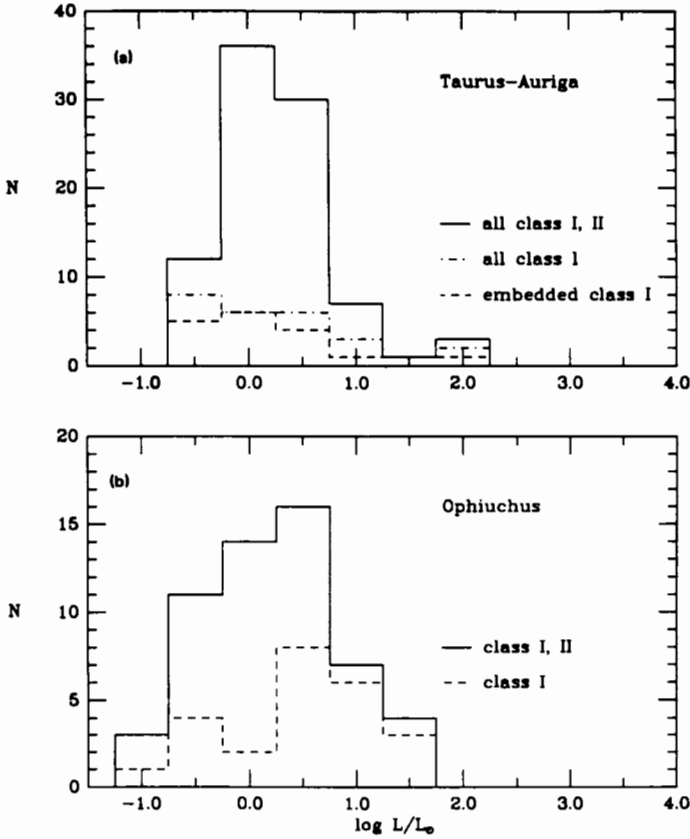

Figure 7. A comparison of the bolometric luminosity functions for young stellar objects in the Taurus-Auriga dark cloud and in the ρ Oph molecular cloud core. The number of Class I and II sources in each bin is indicated. Significant differences are apparent between the two luminosity-limited samples. Figure taken from Kenyon et al. (1990, their Fig. 8).

in these luminosity functions; for example, confusion in the IRAS data and the high visual extinction in ρ Oph could account for the drop in the number of Class I sources with decreasing luminosity. However, the segregation of luminosities by SED class for $L > 5.6 L_{\odot}$ appears to be a real effect in ρ Oph and cannot be accounted for by source confusion in the IRAS data (as determined by deep near-infrared imaging) or by reddening of Class II sources to produce Class I SEDs (as indicated by rising $25\text{--}100\text{ }\mu\text{m}$ SEDs). While the origin of the differences between these luminosity functions is unknown, several explanations are plausible. If intermediate-luminosity Class I sources in ρ Oph are 2 to $3 M_{\odot}$ objects, then perhaps stars in Taurus-Auriga have not formed as recently or are not forming sequentially in mass. On the other hand,

if these Class I sources are 0.1 to $1 M_{\odot}$ objects, then perhaps the accretion rate, and hence luminosity, of protostars is lower in Taurus-Auriga relative to ρ Oph, as predicted by models for spherical accretion in cooler clouds (Adams et al. 1987).

Investigations into the low-mass end of the IMF of the ρ Oph Cluster are now possible using infrared array cameras, with high visual extinctions in the core minimizing confusion with background field stars. A moderately deep $2.2 \mu\text{m}$ survey (to $K \sim 15$ mag) of a 20 square arcmin area of the core by Rieke et al. (1989) revealed no new sources beyond those found by Wilking and Lada (1983), suggesting a deficiency of YSOs with masses below a few tenths of a solar mass. However, a subsequent survey by Barsony et al. (1989a) to $K \sim 14$ mag of a larger area (144 square arcmin) led to the discovery of 35 new sources, and most recently, Greene (1991) surveyed some 650 square arcmin on and off the densest parts of the cloud, finding almost 500 sources to a completeness limit of $K \sim 13$ mag. As such surveys grow in area coverage, it becomes increasingly important to determine what fraction of these new sources are indeed embedded in the cloud by using multi-color infrared photometry (cf. Greene 1991). However, one possible early conclusion is that the IMF of a cloud can vary dramatically over size scales less than 0.5 pc, and that large areas of a cloud must be considered before comparisons are made with other clouds.

The differences noted above between the populations of YSOs in Taurus-Auriga and ρ Oph have led to the idea that different mechanisms of star formation have operated in these clouds, but thus far the observational evidence is sparse. Vrba (1977) and Loren and Wootten (1986) have proposed that compression of the ρ Oph cloud by a shock wave propagating from the southwest has shaped the morphology of the cloud and dense cores, generated small velocity shifts in the molecular gas, and produced the high SFE in the core region. A more recent explanation for the high SFE in the ρ Oph core has been given by Uchida et al. (1990), based upon their discovery of rotational motions about the major axis of the filamentary streamer to the northeast. They suggest that these motions provide an angular momentum drain from the cloud core resulting in enhanced star formation. Consistent with these ideas that the ρ Oph core has lost its internal support, Shu et al. (1987a) suggest that ρ Oph is an example of star formation resulting from cloud contraction where self-gravity dominates magnetic support, thus producing a high SFE. In contrast, magnetic fields may dominate the evolution of molecular cores in Taurus-Auriga, resulting in longer contraction times and lower values for the SFE.

2. Other Dark Clouds and Globules

There are a number of star-forming regions within several hundred parsecs of the Sun whose young stellar populations have yet to be examined as extensively as those in the Taurus-Auriga cloud or ρ Oph core. These regions include the Lupus dark cloud (125 pc), the R Coronae Australis cloud

(130 pc), the filamentary streamers in Ophiuchus, L 1689/L 1709 (160 pc), the Chamaeleon dark clouds (115–220 pc), and globules selected from southern and northern hemisphere photographic surveys (≤ 500 pc). Future studies of these regions will provide important comparisons with Taurus-Auriga and ρ Oph, and give further insight into the process of low-mass star formation in dark clouds. Investigations of the YSO populations in several of these regions are briefly described below.

Like Taurus-Auriga, the Lupus dark cloud complex also has a filamentary appearance. It consists of 4 sub-regions, of which 3 are actively forming low-mass stars (see Krautter [1991] for a review). Preliminary indications are that the YSO population also resembles that in Taurus-Auriga, i.e., there appears to be a low ratio of embedded Class I sources to emission-line Class II stars. However, previous surveys for YSOs have selected against heavily obscured objects, and confirmation of the scarcity of Class I objects awaits a thorough analysis of the IRAS data for the region (see, e.g., Carballo et al. 1991) and near-infrared imaging of the cloud. Since Class I objects are most often found associated with mass loss, one might expect a low incidence of HH objects/optical jets in Lupus. This is in fact observed (Krautter 1986; Heyer and Graham 1989), although high visual extinction in the cloud can produce the same effect (e.g., as seen in the ρ Oph core). The early indications are that Lupus is an older star-forming region where activity has already died down. Consistent with this picture is the fact that the Lupus T Tauri population is dominated by M-type stars (Krautter and Kelemen 1987; see also Appenzeller et al. 1983). It will be interesting to see whether the ROSAT X-ray survey will reveal the large population of weak-emission T Tauri stars, particularly those with K spectral types, expected for a more mature star-forming region.

The R Coronae Australis dark cloud bears many similarities to the ρ Oph complex. The clouds are located about 17° out of the plane of the Galaxy, almost mirror images at galactic longitude $l \sim 355^\circ$. The morphologies of their molecular gas are also similar, with lower-density streamers of gas and dust extending from centrally condensed cores (Loren et al. 1983), although different mechanisms could produce this morphology (Vrba 1977; Vrba et al. 1981; Fleck 1984). Like ρ Oph, the most active star formation is in the core, where 13 YSOs distributed over a 0.08 pc^2 area centered on the star R Cr A comprise the Coronet Cluster (see, e.g., Taylor and Storey 1984; Wilking et al. 1986). In the absence of massive stars, the core could be the site of formation of a small gravitationally bound cluster, and yet overall, the density of YSOs in the R Cr A cloud appears lower than in ρ Oph. H α studies have yielded only ≤ 17 bona-fide emission-line stars (Marraco and Rydgren 1981) while at least 65 have been identified in ρ Oph (Wilking et al. 1987). Preliminary analyses of IRAS coadded survey data of the cloud core and vicinity reveal less than half the number of mid- to far-infrared sources seen in ρ Oph (16 vs 44) and only three of these are invisible, Class I sources (Wilking et al. 1991). The difference between the number of young stars in the two molecular clouds appears to be in rough proportion to their masses, i.e.,

there is a smaller reservoir of molecular gas in the R CrA cloud. Extensive near-infrared imaging of the cloud core is needed to characterize the embedded population in more detail.

The Chamaeleon dark clouds (Cha I and Cha II) have recently been extensively explored through optical, near-infrared, far-infrared, and X-ray observations (Hyland et al. 1982; Jones et al. 1985; Whittet et al. 1987, 1991*a,b*; Assendorp et al. 1990; Prusti et al. 1992; Feigelson and Kriss 1989; Schwartz 1991; Gauvin and Strom 1991). The distance is a particularly controversial parameter, and is somewhere in the range 115 to 220 pc (Whittet et al. 1987; Gauvin and Strom 1991). The streaky, filamentary structure found in the complex is once again reminiscent of the Taurus-Auriga clouds (see, e.g., Mattila et al. 1989), although the star formation in Cha I is much more localized than in Taurus-Auriga: of the 81 YSOs identified over a 50 pc² area of the Cha I cloud, the great majority are concentrated in a ~12 to 15 pc² region near the reflection nebulae Ced 110, 111 and 112 (Schwartz 1991; Prusti et al. 1992). The distribution of spectral types for the optically visible T Tauri stars in Cha I is heavily weighted towards K2–M0.5 stars, suggesting a higher characteristic stellar mass than in the Lupus cloud (Krautter 1991). Prusti et al. (1992) combined near-infrared photometry and IRAS fluxes to determine SEDs and bolometric luminosities for 60 of the YSOs, and thence derived a luminosity function for the association. When compared to the equivalent luminosity functions for ρ Oph and Taurus-Auriga, Cha I has the lowest average luminosity of all three, and fewer Class I objects (six) than either of the others. One possible interpretation is that the Cha I population is older. However, Gauvin and Strom (1991) compared the masses and ages of the optically visible YSOs in Cha I with those in Taurus-Auriga and found no significant differences. They suggest that the dearth of Class I objects in Cha I might indicate an episodic or variable star formation rate, with few stars formed recently. Finally, only ~60% of the previously known T Tauri stars in Cha I were detected by IRAS, in either the main survey or the more sensitive pointed observations. As Whittet et al. (1991*b*) note, this implies that the IRAS data give an incomplete census of low-mass Class II or III YSOs, even in the nearby dark clouds: deep near-infrared surveys such as those carried out by Hyland et al. (1982) and Jones et al. (1985) for Cha I are probably more effective in identifying Class II and III YSOs.

The Cha II cloud contains no reflection nebulae and is less conspicuous than the more extensively studied Cha I. Schwartz (1977) found a small number (~19) of H α emission-line stars along the line of sight towards Cha II, and these objects were recently confirmed as low-luminosity (0.1–1.3 L_⊙) young classical T Tauri stars based on their near- and far-infrared SEDs (Whittet et al. 1991*a*). Apart from one luminous (~40 L_⊙) Class I source with an associated outflow, the Cha II cloud lacks objects with luminosities > 2 L_⊙ compared to Cha I, and the lower-luminosity objects are not obviously clustered.

Recently, infrared studies have been made of more isolated star formation

in small (<10 arcmin diameter), dark clouds within about 500 pc of the Sun, commonly referred to as Bok globules. Persi et al. (1990) have used the IRAS Point Source Catalog to analyze 482 southern hemisphere dark globules from a list compiled by Hartley et al. (1986). They have found only about 10% (53) are associated with point sources displaying a rising 12 to 60 μm flux distribution. Using near-infrared photometry, they have determined that 17 of these IRAS sources are PMS objects, with typical luminosities of 10 to $1000 \times (d/500 \text{ pc})^2 L_{\odot}$. Persi et al. (1990) conclude that star formation in small dark clouds may be very inefficient; however, as discussed earlier, observations over a broad range of wavelengths are necessary to completely sample a YSO population. A similar study of northern hemisphere ($-36^{\circ} < \delta < 90^{\circ}$) globules has been made by Yun and Clemens (1990). They used IRAS co-added images to search for evidence of star formation among the sample of 248 isolated clouds catalogued by Clemens and Barvainis (1988). They find 23% of the sample have associated far-infrared point sources, but argue, on the basis of the limiting sensitivity of their technique to PMS stars with $M > 0.7 M_{\odot}$, that *all* globules in their sample could harbor newly formed stars if the embedded stellar mass distribution follows the Miller-Scalo IMF. Clearly, the Persi et al. (1990) and Yun and Clemens (1990) samples provide useful target lists for follow-up studies with near-infrared cameras, ISO and SIRTf.

C. Young Stars Associated with Giant Molecular Clouds

In order to study the high-mass end of the IMF, we must look to the giant molecular clouds (GMCs) where young OB stars are found. However, GMCs are not only birthplaces of massive stars but also of low-mass stars. In fact, most of the integrated stellar mass in the IMF is in low-mass stars and because most of the molecular mass is in GMCs, it follows that most low-mass stars in the Galaxy should form in GMCs, rather than in smaller, less massive dark-cloud complexes like Taurus-Auriga and ρ Oph.

1. Orion (400–500 pc)

At 160 pc, the Sco-Cen OB association has the distinction of being the nearest to the Sun. However, there is no on-going high-mass star formation in Sco-Cen, although low-mass stars are still forming in the associated ρ Oph dark cloud. Thus it is the Orion OB association and GMC that present us with our closest view of on-going simultaneous low- and high-mass star formation.

We begin by delineating the young populations *near* the Orion cloud complex, namely the stellar content of the adjacent OB association, Ori OB1. This is followed by descriptions of the embedded clusters in the Orion A (L 1641) and Orion B (L 1630) cloud, starting with an in-depth discussion of the Trapezium Cluster, followed by briefer accounts of the clusters associated with OMC-2, NGC 2024, NGC 2023, NGC 2071, and NGC 2068. After discussing the clusters, we also discuss the underlying populations of their host

clouds L 1641 and L 1630. Finally, we discuss the young stars in the nearby λ Ori region.

The Stellar Content of the OB Subgroups The various subgroups (1a, 1b, 1c, 1d) of the Ori OB1 association comprise a so-called “fossil record” (Blaauw 1991) of relatively recent star formation, while new stars are still being formed in the nearby Orion A and B molecular clouds (see Fig. 8). These various components are perhaps all linked via sequential star formation, i.e., the compressive action, via winds and supernovae, of one generation of O stars on adjacent molecular material leading to yet another burst of star formation (cf. Elmegreen and Lada 1977). A speculative sequence of events in Orion may have started with a first phase of star formation leading to the 1a subgroup some 7 to 12 Myr ago, perhaps triggered by the passage of the Orion GMC through the galactic disk (Franco et al. 1988) or by the effects of a runaway O star exploding inside the Orion molecular cloud (Blaauw 1991; A. Blaauw, personal communication). The 1a O stars may then have triggered the younger 1b subgroup (~ 5 Myr), which includes the Orion Belt stars. The 1b subgroup is located between Orion B and Orion A, and it is tempting to speculate that in its turn, the 1b subgroup may have split the two clouds and triggered star formation in both directions at once (a bifurcation), i.e., leading to the NGC 2024 Cluster in Orion B to the north and the subgroups 1c (a few Myr) and 1d (the Trapezium Cluster; ~ 1 Myr) in Orion A to the south.

The stellar content of 1a, 1b, and 1c subgroups was studied by Warren and Hesser (1977, 1978), with the conclusion that only stars earlier than A0 (about $3 M_{\odot}$) are completely known. The number of B stars in 1a, 1b and 1c are 121, 96, and 36 respectively, and the estimated number of supernovae thought to have occurred in 1a and 1b is 9 and 3, respectively (A. Blaauw, personal communication). Clearly, subgroup 1a must have been a very active site of star formation some 10 Myr ago, much more active than the Orion clouds today.

As mentioned above, little is known about the low-mass stellar content of the Ori OB1 association. However, recent Kiso Schmidt $H\alpha$ surveys of the 1a and 1b subgroups have revealed some 250 and 150 new emission-line stars respectively, with magnitudes in the range $V=13$ mag to 17 mag, i.e., most likely low-mass T Tauri stars (Kogure et al. 1989; Wiramihardja et al. 1989). A sizeable fraction (about 30%) of these emission-line stars were found to be variable in $H\alpha$ intensity over a time span of 18 months, again highlighting the limitations of single epoch searches for YSOs via $H\alpha$ surveys. Future work will place the newly revealed Orion association members on the HR diagram and determine their masses, perhaps even their mass function (cf. Cohen and Kuhi 1979).

Proper motion surveys should be less biased, and the 1c subgroup (also known as the Orion Cluster, as distinct from the Trapezium Cluster, subgroup 1d) has long been a target for this technique, beginning with the classic work by Parenago (1954). He listed almost 3000 stars brighter than $B \sim 17$ mag in a 9

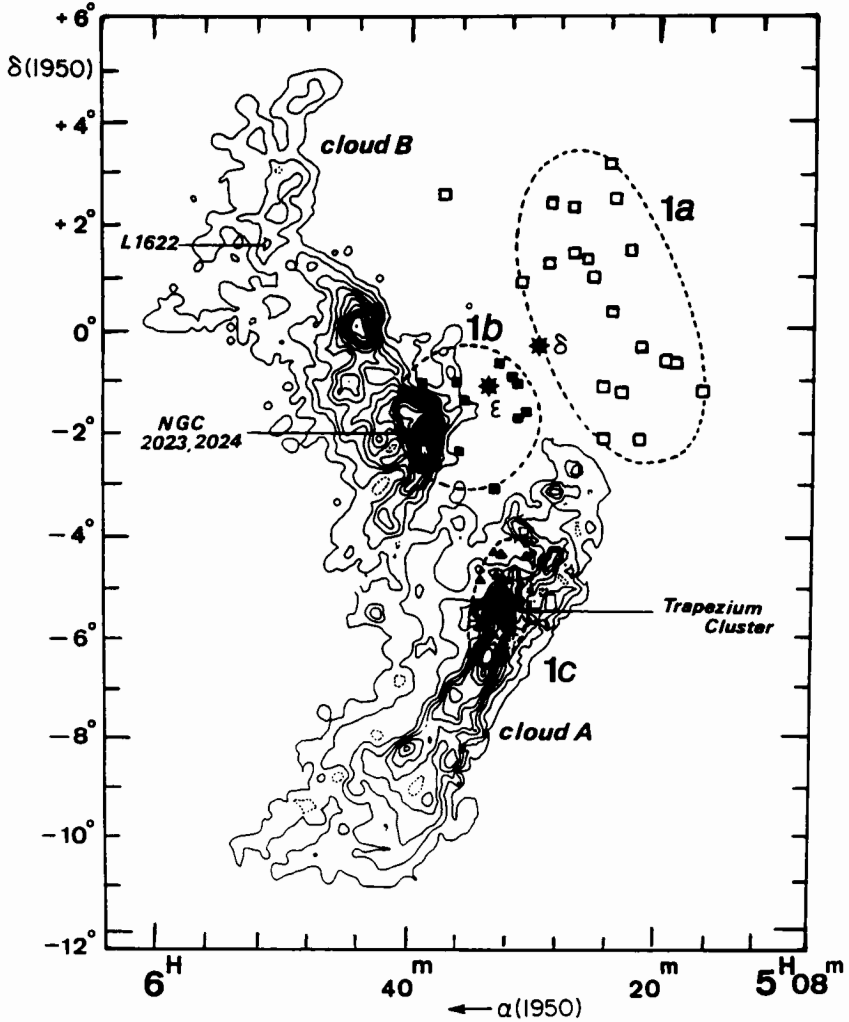

Figure 8. The Ori OB1 association showing the subgroups 1a, 1b and 1c with respect to the molecular clouds Orion A (L 1641) and Orion B (L 1630) (Blaauw 1991). The 1a, 1b and 1c sub-groups cover roughly 45×25 , 25×20 , and 20×10 pc, and are approximately 7–12, 5, and 3 Myr old, respectively. The 1d subgroup (the Trapezium Cluster) lies at the center of the 1c subgroup.

square degree area centered on the Orion Nebula, but due to the relatively crude proper motions, only tentative membership probabilities could be derived. Recent studies have obtained significantly improved results from new and archival material spanning up to 77 years. McNamara et al. (1989) studied a somewhat smaller region (7 square degrees) excluding the central emission

nebulosity, and analyzed 630 stars to a limit of $B \sim 14$ mag, finding that approximately 40% of the stars are probable members. Restricting their study to the 73 stars brighter than $V \sim 12.5$ mag within 30 arcmin of the Trapezium, van Altena et al. (1988) obtained very high precision proper motions, and assigned membership to about 67% of the stars. Lastly, using deep red plates (down to $I \sim 13$ mag in the bright nebulosity, and $I \sim 16$ mag in the outer region) to cover a smaller 15 arcmin radius around the Trapezium, Jones and Walker (1988) detected more than 1000 stars, and found $\sim 90\%$ to be members of the Orion complex. From 693 low error and high membership probability stars, Jones and Walker (1988) derived a one-dimensional velocity dispersion of about 2.3 km s^{-1} , with a distribution that is more or less isotropic and independent of the distance from the Trapezium. Considering only the brighter stars, both Jones and Walker (1988) and van Altena et al. (1988) found a dispersion closer to 1.5 km s^{-1} , and the latter study revealed that the two brightest stars in the Trapezium Cluster ($\theta^1 \text{ Ori C}$ and $\theta^2 \text{ Ori A}$) have very high proper motions, indicating that both are being ejected, and will be more than 5 pc from the cluster within 1 Myr.

Finally, it is worth noting that a special program being carried out with the HIPPARCOS satellite is beginning to provide parallaxes for hundreds of the brighter stars in the Orion region.

The Trapezium Cluster. At the core of the Orion 1c subgroup, near the apex of the L 1641 molecular cloud, is the famous Orion Nebula (M 42, NGC 1976). Much is known about this nearby H II region, the massive stars of the Trapezium OB association (i.e., the 1d subgroup) that ionize it, the background parent molecular cloud OMC-1, and the very young sources of the BN-KL complex embedded within it. Yet there has been remarkably little study of the *low-mass* stellar content of the region, the so-called Trapezium Cluster (Herbig 1982).

Despite the extremely bright H II region nebulosity, it has been known for a long time that the Orion Nebula is host to an unusually large number of faint red stars (Trumpler 1931; Baade and Minkowski 1937). Recently, Herbig and Terndrup (1986) used narrowband optical (at ~ 5500 and 8000 \AA) imaging photometry to reduce the competition from nebular line emission, detecting ~ 150 stars over a region approximately 3×3 arcmin in size. Excluding the OB stars, an extremely high stellar density in excess of 2200 pc^{-3} was derived, although the exact value depends on the volume the cluster is assumed to occupy. Some 68 cluster members were well enough measured to be placed on an HR diagram, allowing estimates of ages and masses by comparison with theoretical PMS tracks. A uniform dereddening, determined from spectroscopy of only 10 stars, was applied to all cluster members. The majority of the stars fell youngward of the 1 Myr isochrone, and including the OB stars, a mean mass density of $3000 M_{\odot} \text{ pc}^{-3}$ was derived, equivalent to $0.6 \times 10^5 \text{ H}_2 \text{ molecules cm}^{-3}$. This latter value is typical of the nearby molecular cloud material, implying that the cluster must have formed with

Figure 9 a,b. A K ($2.2\ \mu\text{m}$) mosaic covering the central 5×5 arcmin ($\sim 0.65\times 0.65$ pc at 450 pc) of the Trapezium Cluster. Some 500 stars are seen to a completeness limit of $K\sim 15.5$ mag. The data were obtained using a 62×58 pixel InSb array on the United Kingdom 3.8-m Infrared Telescope (McCaughrean et al. 1992). For comparison, an optical (I) photograph of the same region is also shown opposite (photograph taken at the Anglo-Australian Telescope, and kindly provided by D. Malin).

a high star-formation efficiency ($>10\%$) from the cloud (Genzel and Stutzki 1989).

However, optical studies tell less than half the story. As we have discussed earlier in this chapter, the near-infrared is a much better wavelength range over which to survey young clusters, and even relatively low resolution and sensitivity raster-scan studies at $2.2\ \mu\text{m}$ demonstrated the existence of a yet higher stellar density than seen in the optical (Hyland et al. 1984). With the introduction of infrared imaging cameras, the Trapezium Cluster was fully revealed, with over 500 members in a 5×5 arcmin region centered on the Trapezium OB stars (McCaughrean 1988; McCaughrean et al. 1992).

Figure 9 a shows a $2.2\ \mu\text{m}$ image of the Trapezium Cluster: by comparison

with an optical image of the same region (Fig. 9b), the cluster appears more symmetric as the optically obscured stars, including those behind the eastern “dark bay,” are revealed. (See Color Plates 2 and 3.) The massive Trapezium OB stars are located right at the center of the cluster, a feature common to many young clusters, as we shall see later (e.g., R 136a in 30 Doradus). The extraordinary stellar density of the Trapezium Cluster can be well illustrated by comparing it to the embedded cluster in the core of ρ Oph. Figure 10a shows the stars in the central 5×5 arcmin of the Trapezium Cluster, while Fig. 10b shows the core of ρ Oph as it would appear if projected to the distance of the Orion Nebula.

In the central 1 arcmin (0.14 pc) diameter core of the Trapezium Cluster, the stellar number density exceeds 10^4 pc^{-3} , although again the exact value depends somewhat on the three-dimensional geometry of the cluster. This density implies a mean separation between the cluster stars of ~ 0.045 pc (1.5×10^{15} m or 10^4 AU). Assuming this length to be equal to the fragmentation scale length in the original molecular cloud, and that fragmentation occurs promptly (e.g., after shock compression) to create protostellar fragments with masses similar to those of the observed low-mass stars (~ 0.2 – $0.6 M_{\odot}$), we

Figure 10 a,b. A comparison between the stellar density of the Trapezium Cluster and that of the embedded ρ Oph Cluster. For this purpose the spatial separations and $2.2\ \mu\text{m}$ luminosities of the ρ Oph Cluster stars have been adjusted to place the cluster at an apparent distance of 450 pc, the distance of the Trapezium Cluster. It is obvious that the Trapezium Cluster is denser and that its members have a greater mean $2.2\ \mu\text{m}$ luminosity. Trapezium Cluster data from McCaughrean et al. (1992); ρ Oph data from Wilking et al. (1989a) and T. Morgan and G. Rieke (personal communication).

Figure 11. The raw (uncorrected for extinction) K ($2.2\mu\text{m}$) luminosity function for ~ 450 stars of the Trapezium Cluster, as derived from the infrared mosaic of the inner 5×5 arcmin of the cluster (McCaughrean et al. 1992). Note the very strong turnover in the luminosity function at $K \sim 12$ mag, well above the completeness limit of 15.5 mag.

can derive a gas density and temperature by requiring the separation and mass to be equal to the Jeans length and mass respectively. In this case, we derive reasonable values of $\sim 10^6 \text{ cm}^{-3}$ for the density and ~ 10 to 20 K for the temperature. This raises the possibility that the original protostars in the Trapezium Cluster may actually have been touching. The protostars probably had a core-envelope structure, with the cores competing gravitationally for material from the weakly bound envelopes, continuing until the stellar mass spectrum was frozen due to lack of accretable material. Such a process can produce a reasonable IMF (Zinnecker 1982). An alternative scenario for the origin and evolution of a protocluster has been discussed by Myers (1991), predicting noncoeval formation of cluster stars in a continually deeper potential well due to gradual accumulation of protocluster gas (cf. Larson 1982).

There is an important point to be made about the Trapezium Cluster: it may be the only nearby star-forming region where we are dealing with a more or less complete and relatively uncontaminated sample. First, the infrared images go deep enough to almost completely sample the entire stellar population, with a strong peak in the K frequency function at 12 mag, well above the detection limit of 15.5 mag (see Fig. 11). The only substantial incompleteness in these data is due to unresolved binaries—very high-resolution imaging will be needed to probe binaries with separations ~ 0.1 arcsec ($\sim 45 \text{ AU}$, the peak

in the distribution of semimajor axes for main-sequence binary stars), and indeed, recent HST imaging has revealed binaries at these separations in the Trapezium Cluster. As the Orion Nebula is nearby, well out of the galactic plane at $b \sim -19^\circ$, and towards the galactic anticenter at $l \sim 209^\circ$, there is minimal foreground or background field star contamination. The only major potential for contamination comes from sources embedded in the background molecular cloud OMC-1 and indeed, there are a relatively small number of very red sources, including the well-known BN-KL complex, which are projected almost exclusively along the ridge of dense gas seen in submillimeter maps of the region (McCaughrean 1988; Mezger et al. 1990). One difficulty does arise however, in determining spatial extent of the Trapezium Cluster: recent larger near-infrared mosaics covering 15×15 arcmin reveal a considerable number of stars over the wider area, albeit at a substantially lower density than in the cluster core. The problem is that many of the stars farther from the core are probably members of the 1c subgroup, rather than the Trapezium Cluster, i.e., the 1d subgroup. The question is, can any real distinction be drawn between the two? Are the Trapezium Cluster stars simply the youngest in a continuous phase of star formation that began with the 1c subgroup, or are the two subgroups well separated in time? Either way, with one projected on the other, care must be taken in drawing conclusions regarding coevality etc., as discussed below.

After applying a small extinction correction of $A_K \sim 0.5$ mag ($A_V \sim 5$ mag), the peak in the Trapezium Cluster K luminosity function at ~ 11.5 mag corresponds to a naked PMS star of $\sim 0.3 M_\odot$, assuming an age of 1 Myr: erroneously assuming a main-sequence mass- K relation would give a much higher mass of $1 M_\odot$. More subtly, it would also be wrong to claim that because the peak in the *luminosity* function corresponds to a $0.3 M_\odot$ star, that there is also a peak in the *mass* function at $0.3 M_\odot$: as we have seen in Sec. II.B, the problem is much more complicated than that, due to the time dependence of the mass-luminosity relation for PMS stars. In light of this, it is worth comparing the Trapezium Cluster KLF with the model KLFs shown in Fig. 2. The precise distance to the Trapezium Cluster still remains somewhat uncertain, but if we assume the widest possible range of 360 to 560 pc (corresponding to distance moduli of 7.8 and 8.7 mag; Genzel et al. 1981; Anthony-Twarog 1982), we can see that the measured peak in the cluster KLF lies in the range $M_K \sim 2.8$ to 3.7 mag. By comparing this to the position of the D-burning peak in the model KLFs, we would estimate an age of 1 to 2 Myr for the Trapezium Cluster, similar to the age determined by other methods (Herbig and Terndrup 1986). Despite the uncertainty in the distance to the Trapezium Cluster, that the observed Trapezium Cluster KLF has not been corrected for extinction, and that neither the observed or modeled KLFs account for infrared excess, this comparison nevertheless shows that the Trapezium Cluster is at least *qualitatively consistent* with a coeval, 1 to 2 Myr old cluster of stars drawn from a fully populated Miller-Scalo IMF.

A more rigorous analysis of the cluster mass function can be attempted us-

ing multi-color infrared data. McCaughrean et al. (1992) have placed the stars on infrared color-magnitude (i.e., K vs $J-K$), and color-color (i.e., $J-H$ vs $H-K$) diagrams, along with suitably transformed PMS tracks and isochrones. As discussed in Sec. II.B, it is almost impossible to make a unique determination of the mass of a PMS star if neither the reddening or age are known. Judging from the spread of stars along the reddening vector in the color-color diagram, there is a wide range of line-of-sight extinctions across the cluster ($A_V \sim 2$ to 20 mag), and therefore the Herbig and Terndrup (1986) assumption of constant reddening is not appropriate. McCaughrean et al. (1992) suggest the more physically realistic assumption of a constant age. Under this assumption, all the stars would be moved parallel to the reddening vector in the color-magnitude diagram until they intercept the chosen PMS isochrone, in this case 1 to 2 Myr. Counting the number of stars falling between any two PMS mass tracks, an approximate IMF would then be derived. As mentioned earlier, this procedure depends on there being little or no infrared excess from circumstellar disks. This question remains open for dense embedded clusters in general, although few of the "normal" Trapezium Cluster stars (i.e., those not associated with dense molecular cloud cores behind the cluster—see below) show much $H-K$ excess in the color-color diagram. Nevertheless, it is worth considering the effect that real excesses would have on this naïve dereddening technique. The foreground dust reddening would be overestimated, but the resulting error in the calculated mass would depend on the nature of the excess: if it was due to the reprocessing of stellar flux (a "passive" disk), the mass would be overestimated, whereas if it was due to heating of the disk by accretion of infalling matter (an "active" disk), the true stellar mass would be underestimated.

It is clear that the Trapezium Cluster warrants considerable future observational attention, as perhaps nowhere else is there a cluster near enough to us and relatively isolated from sources of contamination that we stand a fighting chance of understanding the birth, evolution, and ultimate fate of its members. In this way, it can also serve as an important prototype for other embedded clusters. With this in mind, we now discuss some specific questions about the Trapezium Cluster, questions which may also be applied to other young embedded clusters:

a. Are the Trapezium Cluster stars coeval? In their study of the optically visible population, Herbig and Terndrup (1986) found little evidence for a relationship between mass and age in the cluster, with most of the stars ≤ 1 Myr old. However, more recently, it has been suggested that the shape of the cumulative near-infrared (K) luminosity function indicates a wide spread in ages (Gatley et al. 1991). Based on the fact that the fainter section of their cluster LF parallels the field star LF, while the brighter part is shallower, and more like that expected for a Salpeter IMF, the claim is that the low-mass stars are older than the high-mass stars. However, in making these comparisons, Gatley et al. (1991) used a main-sequence field star LF, and a single power-law conversion from mass to K luminosity derived for massive main-

sequence stars. As the Trapezium Cluster is composed of mostly low-mass pre-main-sequence stars, these comparisons with main-sequence derived LFs are inappropriate. As we saw earlier, the differential KLF for the Trapezium Cluster of McCaughrean et al. (1992) is consistent with model PMS luminosity functions for a completely coeval cluster. Again, while this does not imply that the Trapezium Cluster *is* coeval, any claim of noncoevality based on slope changes in the cumulative luminosity function is probably without basis.

Perhaps a more acceptable hypothesis given the lack of compelling evidence to the contrary, is that the Trapezium Cluster is more or less coeval, in the sense that the formation of the majority of its members was initiated at some "time zero" by the same external event. This is necessarily somewhat vague. It is possible for example that most of the cluster members formed at the same time, but that when the high-mass stars "turned on," they initiated a second burst of low-mass star formation via radiative implosion. Indeed, some stars seen in this region lie in molecular cloud OMC-1 behind the H II region, and *are* probably younger than average. Also, as we discussed above, care must be taken in defining the spatial extent of the Trapezium Cluster: at some radius, confusion with members of the older 1c subgroup will become a problem.

b. Why are the Trapezium OB stars at the center? With star formation initiated in a dense core, more stars would form towards the center where the most material was available, with the most massive stars forming at the core by gradual mass accumulation due to clump-clump collisions in a deep potential well. This would give rise to the high degree of apparent spherical symmetry observed in the Trapezium Cluster, with a higher stellar density towards the center, and the highest-mass (OB) stars right in the middle.

Another possibility is that the OB stars arrived at the center of the cluster by dynamical evolution. The one-dimensional RMS velocity dispersion of the optically visible stars near the cluster center is $\sim 2.5 \text{ km s}^{-1}$ (Jones and Walker 1988), enough for about three crossings of the central parsec, assuming an age of 1 Myr. However, given the apparent independence of the velocity dispersions with respect to mass and distance from the cluster center, it seems as though the mass segregation in the Trapezium Cluster is largely due to initial conditions, i.e., the more massive stars *did* form in the cluster center (Jones and Walker 1988).

At the same time, the Trapezium OB group itself is unlikely to be dynamically stable, with at least four massive components in close proximity: indeed the most massive star, $\theta^1\text{Ori C}$, has a high proper motion and seems to be on the verge of being dynamically ejected (van Altena et al. 1988). Two of the other Trapezium OB stars ($\theta^1\text{Ori B}$ and $\theta^1\text{Ori A}$) are eclipsing binaries (Lohsen 1976; Bossi et al. 1989; Popper and Plavec 1976), which suggests that their angular momentum vectors were closely aligned at the time of formation. One possible theory for the formation of the OB group that would result in such an alignment involves the fragmentation of a rotating ring (e.g., Bodenheimer 1978; Lucy 1981). However, also see Larson (1990)

for alternate possibilities.

c. Is there evidence for substructure? In addition to the “normal” members of the Trapezium Cluster, there are a number ($\sim 10\%$ of the cluster) of very red sources seen almost exclusively to the west of the OB stars, projected against a ridge of dense sub-millimeter peaks (Mezger et al. 1990; McCaughrean et al. 1992). These sources include the BN-KL complex and those associated with a secondary highly collimated molecular outflow, OMC-1S (McCaughrean 1988; Schmid-Burgk et al. 1990). How are these related to the Trapezium Cluster? Are they spatially distinct star-formation sites, or should they all be considered together? The BN-KL and OMC-1S sources are embedded in the molecular cloud OMC-1 behind the H II region M 42, and are probably younger than the normal Trapezium Cluster stars which are mainly in the H II region, in front of the cloud (Herbig and Terndrup 1986). However, it is possible that they will merge at some point, implying that some 1 Myr from now there will be an age spread on the order of several Myr in the Trapezium Cluster. Thus in principle, features in cluster luminosity functions may be due to age spreads of the same order as the cluster age, making interpretation of the luminosity function complicated as it would depend not only on the IMF, but also on the history of star formation in the cluster. However, in the case of the Trapezium Cluster at least, the younger ridge sources constitute only $\sim 10\%$ of the total cluster population, and their effect on the current cluster luminosity function and any derived IMF is probably minimal.

d. Is the low-mass IMF of the Trapezium Cluster different from that in regions like Taurus-Auriga? Historically, the nebulosity of the Orion Nebula and other H II regions has created a bias against the detection of low-mass stars located near the massive stars which cause the nebular emission. Now that near-infrared imaging is revealing the cospatial low-mass clusters, the notion that the Orion 1d subgroup (i.e., the Trapezium OB stars) has fewer associated low-mass stars and therefore a different IMF for low-mass stars when compared to regions like Taurus-Auriga (cf. Larson 1982), becomes difficult to maintain. A more plausible suggestion is that the low-mass end of the IMF is the same for the two and that it is the high-mass end that is different, i.e., there are fewer massive stars in the Taurus-Auriga complex.

e. Do the Trapezium Cluster stars have circumstellar disks? In low-density star-forming regions, young stars are often seen to exhibit infrared and millimeter excesses attributed to dust in circumstellar disks. However, given the very high stellar density in the Trapezium Cluster, disk-disk interactions are very likely, and it is conceivable that the disks are stripped completely at an early stage, or perhaps that outer disks are removed, while inner disks survive. These ideas can be tested in the Trapezium Cluster by combining 3 to 5 μm imaging with the existing 2.2 μm data, to see if cluster members show a significant near-infrared excesses due to hot dust close to the sources. Also, 10 μm and millimeter continuum studies are needed to search for the progressively colder outer parts of disks. An unsuccessful attempt to detect 1.3 mm dust continuum from some cluster members was made by

Chini, McCaughrean and Zinnecker (unpublished data), using IRAM with an 11 arcsec beam. The main problem with this single beam experiment was confusion with extended and structured emission from the background molecular cloud: what is needed is an interferometric study to resolve out the background emission.

f. Could the Sun have formed in a region like the Trapezium Cluster?

Related to the question of disks is the question of the formation of planets from such disks, and in particular, whether or not the Sun and its planetary system could have formed in an environment like the Trapezium Cluster. After all, even *bound* galactic clusters dissolve on a time scale of ~ 100 Myr due to the tidal effects of passing molecular clouds, and thus the fact that the Sun is not *currently* in a cluster does not tell us whether or not it once was. The appeal of the Sun forming in an OB cluster is that supernova pollution of the protoplanetary disk is a natural consequence of the cluster environment (Reeves 1978). Also, the misalignment between the rotation axis of the Sun and the ecliptic might be explained by gravitational perturbations by other cluster members (Mottmann 1977; Herbig 1982; Tremaine 1991). At the very least, it is important not to assume *a priori* that the Sun was born in a low-density region like Taurus-Auriga, as the great majority of low-mass stars appear to be born in clusters, in close proximity to other stars and not in relative isolation.

g. What is the fate of the Trapezium Cluster? Will the Trapezium Cluster remain bound? Based on the cluster velocity dispersion and the mass of the cluster in stars as determined by Herbig and Terndrup (1986), Jones and Walker (1988) concluded that the cluster mass is an order of magnitude less than the mass required to be in virial equilibrium or bound. Although many more stars have been revealed in the near-infrared, they are mainly low-mass stars, and the total cluster mass is probably still too small to keep the cluster bound if the same velocity dispersion applies to those stars. However, combining stars with the ionized and molecular gas, the virial criterion may be satisfied (Genzel and Stutzki 1989). The amount of gas ionized by the OB stars and lost due to over-pressure in the H II region is between 10 to 100 M_{\odot} (F. Yusef-Zadeh, personal communication), less than the cluster mass and therefore not enough to unbind the cluster. Observations of fine structure lines in the far-infrared might help to determine more accurately the amount of ionized gas in and around the Trapezium Cluster.

Clearly, any mass loss loosens the cluster, and it is likely that it has expanded already and will continue to do so. However, if the mass loss is slow enough, a cluster can revitalize with a lower velocity dispersion and remain bound (Lada et al. 1984; Verschueren and David 1989). Therefore, whether or not the Trapezium Cluster will become an unbound OB association with attendant low-mass stars is unknown. It is tempting to speculate that there may still be clumps of dense gas between the cluster stars, not yet evaporated by the ionizing radiation, and perhaps helping to bind the cluster temporarily. Such clumps would be subject to considerable ablation and even radiative

implosion, perhaps leading to another generation of low-mass star formation in the Trapezium Cluster, triggered by the radiation of the OB stars. In this context, it is worth recalling the partially ionized globules seen close to the OB stars (Garay et al. 1987; Churchwell et al. 1987) and the warm (~ 300 K) dust arcs and shells seen in the same region, although the latter are notably *not* coincident with the former (McCaughrean and Gezari 1991). Also there are the small (\sim few M_{\odot}) ammonia cores seen in the BN-KL complex (Migenes et al. 1989).

The OMC-2 Cluster. Some 12 arcmin north of the Trapezium Cluster there is a cluster of compact near-infrared sources associated with a part of the L 1641 molecular cloud known as OMC-2 (Gatley et al. 1974). Recently, Pendleton et al. (1986), Rayner et al. (1989), and Johnson et al. (1990) have studied this cluster using high-resolution infrared mapping, imaging, and polarimetry. Associated with a peak in molecular gas and dust emission and completely obscured in the visible, it is a small cluster with only a dozen sources to $K \sim 17$ mag within a 0.3 pc diameter field. Three of the sources (IRS 1, 2, 4) are deeply embedded ($A_V \sim 30$ to 40 mag), and are probably intermediate-mass YSOs, i.e., Herbig Ae/Be stars. Two sources illuminate bipolar reflection nebulae, implying that circumstellar disks may be present. Direct mapping of the sub-millimeter dust continuum emission could prove the presence of such disks; this group of very young stars might be an ideal place to study the effects of disk-disk interactions, if they have occurred. Most of the remaining sources are low-mass stars with relatively little extinction, possibly members of the wider Orion Cluster (1c subgroup) rather than directly associated with the OMC-2 core. At present it is not known whether a more extended cluster of low-luminosity PMS objects has formed in the same core as the bright embedded sources.

NGC 2024, NGC 2023, NGC 2071, and NGC 2068. The embedded clusters associated with star-forming regions NGC 2024, NGC 2023, NGC 2071, and NGC 2068 in the L 1630 molecular cloud are discussed in detail in the Chapter by Lada et al. We give a brief description here to examine to what degree they may be viewed as analogs to the Trapezium and OMC-2 clusters in the nearby L 1641 cloud. It was known from infrared raster-scan maps that the ionizing star of the H II region NGC 2024 is associated with an embedded cluster of young, lower-mass stars (Barnes et al. 1989). But again, only with infrared cameras was the true extent revealed, with about 300 members brighter than $K \sim 14$ mag within a radius of 1 pc (Fowler et al. 1987; Lada et al. 1991*b*). Like the Trapezium Cluster, the spatial distribution of the young stars is centrally condensed, with the more luminous objects located toward the cluster center. Similarly, the near-infrared luminosity function rises to about $K \sim 12$ to 13 mag before falling again. Lada et al. (1991*b*) noted that up to the turnover at least, the cumulative KLF for NGC 2024 is steeper than the Salpeter initial mass function.

Some 25 arcmin south is the reflection nebula NGC 2023. Sellgren (1983) surveyed the associated cloud to $K \sim 12$ mag, finding a small cluster of 16 infrared sources within a $\sim 0.5 \times 0.5$ pc area, somewhat similar to OMC-2. The brightest source in NGC 2023 is an unreddened B1.5 V main-sequence star that illuminates the nebula, but interestingly is not at the center of the cluster. Surprisingly, a deeper imaging survey to $K \sim 15$ mag by De Poy et al. (1990) found no additional cluster members; the flattening of their cumulative near-infrared luminosity function near $K \sim 12$ mag was interpreted as either a dearth of low-mass stars or as preferential obscuration of the lowest luminosity sources.

Finally, some 2.5 degrees to the north-east of NGC 2024, there are two other embedded clusters associated with NGC 2068 (~ 200 members) and NGC 2071 (~ 100 members). Further details can be found elsewhere (Sellgren 1983; Lada et al. 1991*b*; Lada and Lada 1991), but relevant to the discussion here, it is worth noting that the KLF for NGC 2071 also shows evidence for a turnover at $K \sim 12$ mag (Lada et al. 1991*b*).

The K luminosity functions of the L 1630 clusters were interpreted on the basis of a time-independent main-sequence mass-luminosity relation, instead of accounting for PMS luminosity evolution. In fact, the cumulative KLFs for all the L 1630 clusters are similar in shape to that of the Trapezium Cluster, and as we have seen earlier, the latter is at least qualitatively consistent with a ~ 1 Myr old coeval PMS population with a monotonically rising Miller-Scalo IMF. On this basis, there is probably no real justification for claiming a lack of low-mass stars in any of these regions. Even so, the alternative hypothesis of preferential obscuration of the lowest-mass stars can be tested by $10 \mu\text{m}$ imaging, as suggested by De Poy et al. (1990) in the case of NGC 2023.

The Underlying Stellar Populations in L 1641 and L 1630. It is clear that there is vigorous high- and low-mass star formation in the form of embedded clusters in both L 1641 and L 1630. These clusters occupy only a small fraction of the total mass and volume of the clouds, suggesting that star formation is very localized. However, both L 1641 (Bally et al. 1987; Bally et al. in preparation; see Chapter by Blitz) and L 1630 (Lada 1990; Lada et al. 1991*a*) are clumpy and filamentary like the Taurus-Auriga dark clouds, where isolated star formation is seen throughout the region. Therefore, it is necessary to examine the Orion clouds for evidence of any “pedestal population” in order to assess the relative importance of the cluster and isolated modes of star formation. A wider discussion of the clouds and their stellar content is given in the Chapter by Lada et al.

Nakajima et al. (1986) surveyed some 1.4 square degrees of the L 1641 cloud in the near-infrared to a limiting magnitude of $K \sim 9.5$ mag. Of the ~ 100 sources found, 15 sources were classified as PMS stars based on their near-infrared color excesses, 6 of them newly identified. To the limits probed by Nakajima et al. (1986), the near-infrared luminosity function of L 1641 appears similar to that of L 1630 and the Trapezium Cluster.

Strom et al. (1989*c*) examined the properties of 123 IRAS sources over a ~ 9.5 square degree area in the field of L 1641, finding 93 of them to be young stars associated with the molecular cloud. Based on their SEDs, roughly 60% of the whole sample (123 objects) were classified as Class I sources, most of them without optical or near-infrared counterparts; the majority of the remainder are Class II sources with optical/near-infrared counterparts, and spectra typical of T Tauri stars and young emission-line stars; the rest are Class III sources, all but one of which lie either in front of or behind L 1641. When compared to Taurus-Auriga, L 1641 is found to have a much larger fraction of luminous Class I sources: $\sim 76\%$ of the 93 IRAS sources associated with L 1641 have Class I SEDs, compared to $\sim 25\%$ of the sources in Taurus-Auriga. This difference is attributed to the fact that typical molecular cloud cores in L 1641 have higher optical depths than those in Taurus-Auriga, which leads to greater extinction and reprocessing of optical and near-infrared light out to far-infrared wavelengths. Also, as Orion is farther away than Taurus-Auriga, we must beware of selection effects: the completeness limit for the L 1641 IRAS sources is $\sim 6 L_{\odot}$ (Strom et al. 1989*c*), compared to $\sim 0.5 L_{\odot}$ for Taurus-Auriga (Kenyon et al. 1990).

Thirty objects in the sample of Strom et al. (1989*c*) were detected by IRAS only, having no optical or near-infrared (5σ limit $K \sim 12.8$ mag) counterparts. Nine of these IRAS-only sources were studied further through deeper near-infrared imaging (to $K \sim 16$ mag) by Strom et al. (1989*a*). Most were found to be detected at $K \sim 15$ mag, with all but one as single, isolated sources. This perhaps indicates that only a small number (~ 1) of stars form per core, with the caveat that these sources were only just detected in the deep imaging survey, and that there may be small clusters of lower-luminosity objects around each IRAS source. The obvious exception is IRAS 05338–0624, where Strom et al. (1989*b*) found a cluster of ~ 20 sources within a diameter of 0.16 pc. This is a remarkably dense clustering, although it is probably not fair to interpret all 20 sources as stars, as not all appear point-like (Strom et al. 1989*b*; K.-W. Hodapp, personal communication).

A study of the young stellar population of L 1641 was also made in X-rays using EINSTEIN IPC images (Strom et al. 1990). These images were centered near V 380 Ori (NGC 1999) and cover an area approximately half that of the IRAS study. Some 65 X-ray sources were found, 61 with stellar counterparts: HH 1 and HH 2 are two of the non-stellar X-ray sources. Five of the X-ray sources appear to coincide with optically identified IRAS sources: however, most of the IRAS sources suffer too much extinction to be seen in X-rays. Roughly two-thirds of the X-ray sources show no optical H α emission, indicating once again that X-ray surveys can uncover substantial numbers of PMS stars, apparently somewhat older than classical T Tauris. Conversely, of the 25 H α stars found in the objective prism survey of Parsamian and Chavira (1982), 15 were not detected in X-rays. Thus the ratio of the number of *all* PMS stars (i.e., X-ray stars plus H α stars *not* detected in X-rays) to H α stars in L 1641 is roughly 2. Although this number is somewhat dependent on

limiting magnitude and completeness, it is nevertheless in marked contrast to the predicted ratio of ~ 10 , based on an extrapolation of Taurus-Auriga sources (Walter et al. 1988; Strom et al. 1990, Appendix A).

Therefore, there is a pedestal population of YSOs in L 1641, although the cluster mode of star formation appears to dominate in this region. A rough comparison of the number of sources in the known clusters (Trapezium Cluster, OMC-2, IRAS 05338–0624) to the total number of sources in the cloud (i.e., the cluster sources plus the isolated IRAS, X-ray, near-infrared, and H α sources), shows that about 80% of the stars in L 1641 are in clusters. However, most of the surveys of the pedestal population are likely to be quite incomplete, making this ratio an upper estimate: the X-ray and H α surveys suffer from extinction, and the IRAS survey is complete only to $\sim 6 L_{\odot}$ (Strom et al. 1989c). A more comprehensive near-infrared imaging survey is required to make a better assessment of the L 1641 pedestal population.

Such a survey has been made for the L 1630 cloud (Lada 1990; Lada et al. 1991b). From a survey of the cloud for dense CS $J = 2 \rightarrow 1$ gas (Lada et al. 1991a), regions with and without dense gas totalling ~ 0.7 square degrees were then surveyed to $K \sim 13$ mag. Some 900 sources were detected, of which almost 60% are associated with the previously discussed clusters (NGC 2024, NGC 2023, NGC 2068, NGC 2071). Indeed, after correcting for background and foreground field-star contamination of their survey, Lada et al. (1991b) estimated that the cluster members make up as much as $\sim 96\%$ of the total number of stars actually associated with L 1630. This indicates an overwhelming predominance of the cluster mode of star formation in L 1630, although considerably more work is needed to distinguish genuine cloud members from field stars between the clusters, and even deeper surveys may be needed to fully probe the pedestal population.

The dominance of the cluster mode in L 1630 may be at least in part due to the effects of external triggering. The L 1630 clusters tend to lie on the western edge of the cloud, close to the young Ori 1a and 1b subgroups. Also, there is a strikingly high concentration of H α stars on the western edge of the L 1630 molecular ridge (Wiramihardja et al. 1989), and nearby, in the bright-rimmed globule Ori-I-2, the YSO IRAS 05335–0146 may have been triggered by an O star (Sugitani et al. 1989). Thus triggering by the Ori 1a,b stars may have played an important part in the formation of the L 1630 clusters. When discussing this sort of triggering effect however, it is unclear whether the “pressure” of the OB association actually produces protocluster condensations, or just pushes on pre-existing condensations: it may be both. Indeed, some form of two-step process does appear to be in operation in L 1630. While four of the five most massive ($> 200 M_{\odot}$) cores in L 1630 are host to the four dense stellar clusters, the fifth core (LBS 23) does not appear to be forming stars at present (Lada 1990; Lada et al. 1991a,b).

In summary, the current star formation in both L 1630 and L 1641 appears to be dominated by the cluster mode, although more work is needed to obtain a more accurate census of the pedestal populations. One point to bear in mind

when determining the relative importance of the cluster and isolated modes in a GMC, is that a part of a molecular cloud currently forming only a very low space density of stars may also become the site of a dense cluster in the future, perhaps due to material being piled up and/or triggered by massive stars of an earlier generation.

The λ Orionis Region. The λ Orionis region of star formation lies some 15 degrees north of the Orion Nebula (see Shevchenko [1979] for a POSS mosaic). The OB association consists of an O 8 III star (λ Ori itself) and 12 B stars at the center of a large spherical H II region, at the edge of which lies an H I shell coincident with a ring of dark molecular clouds, the latter seen to glow spectacularly in IRAS 100 μ m images (Maddalena and Morris 1987). The whole complex has a diameter of ~ 10 degrees, ~ 70 pc at a distance of 400 pc. Some 83 H α emission objects, i.e., low-mass PMS stars, have been found in the region. Most are concentrated on the bright-rimmed inside edges of the dark clouds B 30 and B 35, i.e., on the side of the clouds facing the OB association, with most of the remainder scattered in a more or less linear fashion between the two clouds (Duerr et al. 1982). Duerr et al. (1982) noted that the amount of material in the H I shell ($\sim 10^5 M_{\odot}$) is comparable to the amount of molecular gas found in a GMC. Thus they proposed that the region around λ Ori is essentially a well-preserved fossil GMC, recently exposed by the action of the star. They find a star-formation efficiency in the region of only 0.2 to 0.3%.

Mathieu and Latham (unpublished data, as described by Mathieu [1986]) have made a radial velocity study of about 30 of the H α stars in the λ Ori region, and found that the one-dimensional stellar velocity distribution is small, $\sim 2 \text{ km s}^{-1}$, similar to the dispersions found for stars in other GMCs (e.g., the Ori OB1c subgroup: van Altena et al. 1988; Jones and Walker 1988). Locally, near B 30 and B 35, the stellar velocity dispersions are lower, at about 1 km s^{-1} , similar to the CO line widths in the clouds themselves (Maddalena et al. 1986; Maddalena and Morris 1987), and therefore these stars are probably bound to these clouds, much as the stars were bound to the original GMC. However, most of the original molecular material in the region has been swept into an expanding shell (Maddalena and Morris 1987), and the escape velocity for the global system is much lower than the current stellar velocities: with the removal of the gas, the stellar system has become unbound and will ultimately disperse.

2. Other Galactic H II Regions

The bulk of the Galaxy's giant molecular clouds and massive star-forming regions lie at distances greater than that of the Orion complex. Nevertheless, even low-mass stars can now be detected in many of these regions, and in the past few years, many dense embedded clusters have been revealed. Some of these are summarized here, roughly in order of increasing heliocentric distance.

Figure 12. A K ($2.2\ \mu\text{m}$) mosaic of the H II region S 106, covering $\sim 10 \times 10$ arcmin ($\sim 1.75 \times 1.75$ pc at 600 pc). The data were obtained using a 256×256 pixel HgCdTe infrared array at the University of Hawaii 2.2-m (Rayner 1992). Some 200 stars are probable members of a cluster centered near S 106 IRS 4.

S 106 (600 pc). In studies of S 106, the focus has been an embedded O9–B0 V star (IRS 4) and the biconical H II region which it excites (see, e.g., Staude et al. 1982; Bally et al. 1983; Hayashi et al. 1990). In particular, there is some controversy over whether or not a dense molecular disk or ring structure exists around IRS 4, constraining the ionization to form the biconical nebula (Mezger et al. 1988; Barsony et al. 1989*b*; Loushin et al. 1990). Figure 12 shows a recent $2.2\ \mu\text{m}$ image, revealing both a large number of embedded point sources, and highly structured loops and arcs in the nebula (Rayner 1992; see also Color Plate 4). Analysis of an earlier $2.2\ \mu\text{m}$ image has shown that IRS 4 is near the center of a cluster of over 200 point sources, with

about 90% of them within a radius of 1.5 arcmin of the OB star (Rayner et al. 1991a; Hodapp and Rayner 1991). With a completeness limit of $K \sim 14$ mag, the faintest objects detected by Hodapp and Rayner (1991) are probably low-mass PMS stars between 0.2 and 0.5 M_{\odot} , based on a distance of 600 pc, a derived average extinction of $A_V \sim 13.5$ mag, and an assumed cluster age of 1 Myr. A direct age estimate was made by Hodapp and Rayner (1991), who found that only 4 out of 80 cluster members with masses above 1 M_{\odot} show evidence for local nebulosity and high intrinsic polarization, and therefore ongoing mass loss. This, combined with a typical duration of 5×10^4 yr for the mass-outflow phase in YSOs (Fukui 1989), suggests to them that star formation has been going on in S 106 for 1 to 2 Myr, i.e., they infer an age spread of this order, if the star-formation rate has been constant. The latter is an implicit assumption: there is no obvious evidence to counter the possibility that most of the cluster formed in a single short burst, and that there is some secondary star formation occurring now, perhaps including IRS 4 itself.

The S 106 K luminosity function does not exhibit any hint of a turnover down to the completeness limit of 14 mag. In contrast, if the Trapezium Cluster were moved to a distance of 600 pc and an extra $A_K \sim 1$ mag of extinction added, its luminosity function turnover would still be detectable to that limit. Therefore at first sight, it seems as though the two clusters may be different. On one hand, if the S 106 cluster is *older* than the Trapezium Cluster, then any peak in the luminosity function due to deuterium burning (Sec. II.B) would have moved to lower masses and be undetected at the current completeness limit. On the other hand however, the angular spacing between the S 106 stars seems smaller than that for the Trapezium Cluster stars, which could indicate an even higher stellar density and perhaps a *younger* age for the S 106 cluster. Perhaps a simpler explanation that would fully reconcile these contradictory pieces of evidence is that S 106 is farther away than the nominal 600 pc. Indeed, uncertainty in the spectral classification of IRS 4 and the number of stars foreground to the nebula imply that it could be as far away as 2 kpc (Th. Neckel, personal communication; Rayner 1992).

NGC 2264 (900 pc). The young (~ 10 Myr) open cluster NGC 2264 lies at a distance of 900 pc, in the Mon OB1 association between the O star S Mon and the famous Cone Nebula. From their optical color-magnitude diagram, Adams et al. (1983) found that, contrary to previous claims, the cluster does have low-mass stars, and also that there is an age spread in its members of ~ 10 Myr. Stahler's (1985) analysis confirmed this age spread, but did not confirm the sequential build-up in mass space nor the exponential increase in star-formation rate in the cluster claimed by Adams et al. (1983). In addition, selection effects prevent us from trusting that the optical surveys have revealed the complete stellar population. IRAS data on the embedded cluster have been analysed by Margulis et al. (1989), who identified 18 Class I and 8 Class II sources, with the caveat that two-thirds of these sources are probably associated with two or more YSOs. All seven of the far-infrared sources with

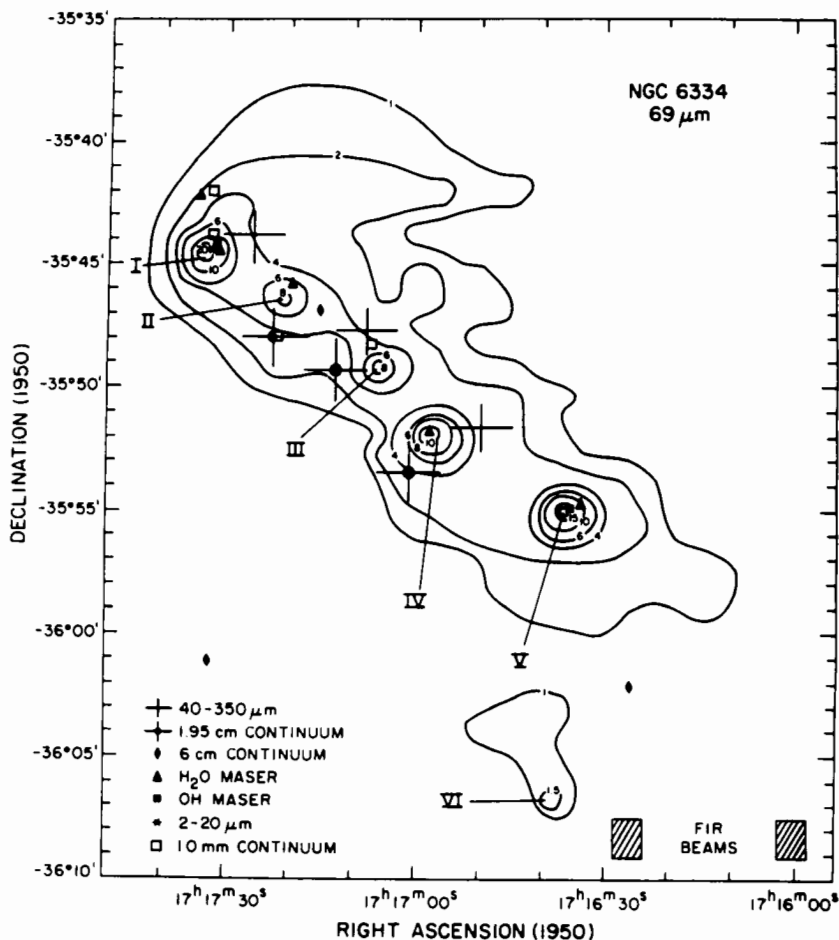

Figure 13. A KAO map ($40-250 \mu\text{m}$ filter, effective wavelength $69 \mu\text{m}$) of the NGC 6334 molecular cloud and star formation region, from McBreen et al. (1979). Note the characteristic spacing of the luminous far-infrared sources, indicated by the Roman numerals. The beam size is of order 1 to 2 arcmin.

$>100 L_{\odot}$ were found to be Class I objects. Near-infrared imaging is required to reveal the embedded population in this region, because part of the “optical” cluster is obscured by a molecular cloud (Crutcher et al. 1978), and may in fact be cut in two by it (Mathieu 1986).

NGC 6334 (1.7 kpc). Figure 13 shows a far-infrared map of the NGC 6334 molecular cloud in which several separate condensations are discerned, with a projected spacing of around 10 pc at a distance of 1.7 kpc . This region has recently been studied in detail by Straw and Hyland (1989) and Straw et al.

(1989). Straw et al. (1989) made a near-infrared raster-scan survey of the embedded populations in 11 regions of NGC 6334 that show indications of ongoing star formation, and found several hundred sources to a completeness limit of $K \sim 14$ mag, corresponding to a main-sequence stellar mass of $\sim 1 M_{\odot}$ if unobscured, or $\sim 4 M_{\odot}$ if embedded in the molecular cloud cores typically with $A_V \sim 30$ to 40 mag. In several of the regions, a large fraction of the sources were seen to have $H-K$ excesses, indicating PMS objects. In order to determine masses, the majority of the sources were plotted in an infrared color-magnitude diagram ($J-K$ vs K), and then projected back along a standard reddening vector until they intercepted the main sequence. A main-sequence absolute M_K magnitude versus mass relation (similar to that shown in Fig. 3) was then used to determine the individual masses, and thence the IMF. Sources showing some evidence (e.g., spectroscopic) for being PMS objects were dereddened back to suitably transformed PMS tracks, although as noted elsewhere in this chapter, masses derived by this procedure depend strongly on the chosen isochrone. The general conclusion from the work of Straw et al. (1989) is that the stellar mass distribution in the NGC 6334 complex is similar to that found in other young visible clusters and embedded clusters, i.e., roughly equal to the Salpeter IMF.

There are a number of problems with the general approach of Straw et al. (1989) which illustrate some of the difficulties encountered when converting measured fluxes into masses for embedded stars. First, many of the objects were red enough that they were only detected at K but not at J , leading to a complicated dereddening scheme in which the J magnitude was calculated via a number of *ad hoc* assumptions. Second, some of the objects may be background giants, which must be discriminated against spectroscopically and removed from the IMF determinations, although Straw et al. (1989) calculated that in most of their regions, contamination by background field sources was not that important. Third, Straw et al. (1989) did not discuss the effects of infrared excess emission at all. Finally, some of the sources assumed to be on the main sequence may actually be young, and Straw et al. (1989) assessed the error that can be made by assuming the stars to be main rather than pre-main sequence: it can be huge. For example, an object at $K = 11.0$ mag and $J-K = 3.0$ mag in the color-magnitude diagram could either be a $5 M_{\odot}$ ZAMS object obscured by $A_V \sim 4$ mag, or an unobscured young (10^5 yr) T Tauri star of mass $1 M_{\odot}$ at the top of its Hayashi track. Deep optical CCD imaging in the I -band (cf. Hunter and Massey 1990) may help separate heavily extincted sources ($A_V > 15$ mag) from less heavily extincted ones, which in turn will help to discriminate ZAMS from PMS stars.

M 17 (2.2 kpc). The M 17 H II region and the adjacent molecular cloud is a well-studied site of massive star formation and has a very high ratio of far-infrared luminosity to molecular gas mass (Mooney and Solomon 1988). A cluster of OB stars within an obscured portion of the H II region is responsible for most of the observed radio continuum and far-infrared emission (Beetz

Figure 14. A near-infrared ($1\text{--}2.5\,\mu\text{m}$) mosaic of M17 covering $\sim 9\times 9$ arcmin ($\sim 5.8\times 5.8$ pc). Approximately 100 stars (B9 or earlier) towards the center of the image have been identified as cluster members. The data were obtained using a 256×256 pixel PtSi array on the KPNO 2.1-m telescope (Lada et al. 1991).

et al. 1976; Gatley et al. 1979; Chini et al. 1980). Recent near-infrared imaging at J , H , and K of a 9×9 arcmin area of the complex (Fig. 14) clearly defines the true size and extent of the cluster, revealing about 100 stars of spectral type B9 and earlier within a 2.8 arcmin (1.8 pc at 2.2 kpc) radius (Lada et al. 1991; see also Color Plate 5). In addition, these observations indicate that most of the cluster members possess infrared excesses, suggesting that circumstellar disks may play a more important rôle in the early evolution of OB stars than previously suspected. The cumulative K luminosity function for the cluster stars, after subtraction of an unobscured background field, displays a slope which is significantly shallower than that observed for field stars, but which

is consistent with that of the Salpeter IMF. Despite the fact that the detected massive cluster members are believed to be on the main sequence, Lada et al. (1991) point out that comparisons with the IMF may be complicated by the apparent ubiquity of excess emission at $2.2\ \mu\text{m}$.

Deeper infrared images should reveal the extent of the low-mass population of the cluster. However, it is worth noting that for regions such as M 17, within the inner Galaxy and close to the line of sight towards the galactic center, confusion will be extreme due to the very high density of field stars, particularly those behind the star-forming region which are revealed as the extinction in the molecular cloud is penetrated in the near-infrared. Separating cluster and field stars will be very difficult in such regions.

In a larger scale study, Elmegreen et al. (1988) searched for IRAS sources coincident with bright photographic near-infrared stars over a 25 square degree region of M 17 SW, the GMC to the south-west of M 17. Of the almost 2000 IRAS point sources in this region, some 360 were classified as embedded based on their positions in either the $12\text{--}25\text{--}60\ \mu\text{m}$ or $25\text{--}60\text{--}100\ \mu\text{m}$ IRAS color-color diagrams, with 22 sources classified as embedded in both. Some of these 360 sources were identified with previously known compact H II regions, three of them beyond M 17, while many of the remainder are consistent with embedded late O to late B type stars. By blinking *B* and *I* photographs, just over 2000 bright near-infrared stars were identified in the same region, of which 20 were found to lie within 1 arcmin of an embedded IRAS source. Elmegreen et al. (1988) suggest that at least 60% of these coincidences are likely to be physical associations. Some 13 of these stars were seen on both the *B* and *I* plates, and assuming these sources to be at the distance of M 17, their colors and magnitudes are also consistent with embedded ($A_V \sim 7$ mag) B stars. Thus these results lend support to the idea that there may be 20 to 50 B stars in the M 17 SW cloud (Stutzki et al. 1988), and therefore also suggest a large population of lower-mass PMS stars.

S 255/S 257 (2.5 kpc). S 255 and S 257 are diffuse, low-excitation H II regions associated with two early B stars, part of a small complex of H II regions (S 254–S 258) in the Gem OB1 association. They have diameters of ~ 2.5 pc and their centroids have a projected separation of 3.8 pc, assuming a distance of 2.5 kpc to the complex. Between them is a dense molecular cloud (Evans et al. 1977; Mezger et al. 1988; Heyer et al. 1989) with a double, embedded near/mid-infrared source (S 255-IR) which radiates about $8 \times 10^4 L_\odot$ in the far-infrared (Beichman et al. 1979). Near-infrared images of the region show the bright embedded source S 255-IR surrounded by a dense cluster of ~ 175 lower-luminosity objects within a ~ 1 pc radius (McCaughrean et al. 1991; Tamura et al. 1991; see Fig. 15 and Color Plate 6), most of them probably cluster members judging from the local field-star density. The cluster appears to be sandwiched between two peaks of molecular emission (Snell and Bally 1986; Heyer et al. 1989), apparently at the position where two clouds are colliding, and it is possible that the cluster formation was triggered by the

Figure 15. A K ($2.2\ \mu\text{m}$) mosaic of the S 255/S 257/S 255-IR region covering 8×5.2 arcmin ($\sim 5.8 \times 3.8$ pc at 2.5 kpc). At left center and right center are the two B0 stars which excite the H II regions S 255 and S 257; note that they have no spatial clusters. Between the two H II regions, the infrared cluster associated with the source S 255-IR is seen. The data were obtained using a 128×128 HgCdTe infrared array at the Steward Observatory 2.3-m telescope (McCaughrean et al. 1991).

compression due to that collision. Perhaps the most remarkable feature of this region is that in contrast to the dense cluster between them, the two B stars exciting the H II regions S 255 and S 257 appear to be more or less isolated: they do not seem to have cospatial low-mass clusters, at least to a 5σ point-source sensitivity limit of $K \sim 16.5$ mag, corresponding to a ~ 1 Myr $0.2 M_{\odot}$ star behind $A_V \sim 10$ mag. There are several possible explanations here. Firstly, the B stars may have been dynamically ejected from the embedded cluster, a possibility that can be tested by radial velocity measurements. Secondly, perhaps the high-mass stars formed first in S 255 and S 257, and low-mass stars have yet to form; this seems unlikely in light of the nearby dense cluster of high- and low-mass stars that shows every sign of being younger than the S 255 and S 257 H II regions. Lastly, perhaps a cloud *can* form high-mass stars without also forming low-mass stars: this would support the theory of separate modes of high-mass and low-mass star formation, i.e., bimodal star formation (cf. Güsten and Mezger 1982), in which case this complex appears to be our only concrete example of such so far.

W 3(OH) (3 kpc). The ultracompact H II region W 3(OH) coincides with a cold, luminous source of infrared, millimeter continuum, and OH maser emission, which points to the existence of an embedded massive star or group of stars (Wynn-Williams et al. 1972; Reid et al. 1980; Dreher and Welch 1981; Turner and Welch 1984). A $2.2 \mu\text{m}$ image of W 3(OH) (Fig. 16) reveals an associated cluster of lower-luminosity embedded sources (Rayner et al. 1991a): more than 150 objects are found within a 1 pc radius, assuming a distance of 3 kpc. However, the most important feature of this image may be that which is unseen. High-resolution far-infrared observations by Campbell et al. (1989) have resolved the compact source (FWHM ~ 13 arcsec at $100 \mu\text{m}$), and their models allow us to estimate the dust column density in the volume over which the stars are distributed (see also Richardson et al. [1989]). With the assumption of a central cavity of radius 3.3×10^{14} m (the radius of the ultracompact H II region) and an $r^{-1.5}$ density profile outside this radius, they derive a visual extinction towards the central compact source of ~ 1000 mag, which implies an $A_V > 30$ mag even at a radius of 10 arcsec (0.15 pc) from the cluster center. Thus somewhat surprisingly, even near-infrared images of this region may give an incomplete picture of the young stellar population near the core, showing only the stars embedded in the outer skin or shell of the protocluster condensation.

Other Galactic Clusters. In the last few years, near-infrared cameras have revealed many other young embedded clusters in the Galaxy, many of which have so far only been discussed in conference proceedings, preprints, and refereed journals. There are too many to discuss in detail, but some are listed here for completeness. These include clusters associated with the Serpens dark cloud (Eiroa and Casali 1989), NGC 3603 (Moneti and Zinnecker in preparation, as shown by Melnick 1989), W 75 N (Moore et al. 1991), S 228

Figure 16. A K ($2.2\,\mu\text{m}$) image of the infrared cluster associated with the W 3 (OH) ultracompact H II region, covering $\sim 3.5 \times 3.5$ arcmin ($\sim 3 \times 3$ pc at 3 kpc). There is so much extinction towards the core of the cluster that the innermost stars are probably not detected in this image. The data were obtained using a 256×256 pixel HgCdTe infrared array at the University of Hawaii 2.2-m telescope (Rayner et al. 1991a).

(Carpenter et al. 1991), LkH α 101 (Barsony et al. 1991), Mon R2 (Aspin and Walther 1991), GM 24 (Tapia et al. 1991), S 235, S 269, GL 437 (Rayner et al. 1991a), W 51 (Goldader and Wynn-Williams 1991), and NGC 7538 (Rayner et al. 1991b).

3. Clusters in the Magellanic Clouds (55 kpc)

Studies of the upper IMF in Large and Small Magellanic Cloud clusters are tractable using sensitive CCD detectors and sophisticated software for

crowded-field photometry. The advantage of these studies is that Magellanic Cloud young clusters both extend to higher stellar masses (hence the name “blue populous clusters”) and have a larger number of stars of all masses than open clusters in our Galaxy (Elson et al. 1989). Thus they can provide more meaningful statistics overall, and in particular at the high-mass end. Furthermore, as the clusters are all at the same distance, an intercomparison of their individual mass functions is easier.

30 Doradus. The core of the 30 Doradus or Tarantula Nebula in the Large Magellanic Cloud (LMC) has long been a focus of attention. Weigelt and Baier (1985) resolved the luminous central object R 136 into at least eight individual stars using two-dimensional optical speckle interferometry, a result recently confirmed by direct ultraviolet imaging using the FOC of the Hubble Space Telescope (Weigelt et al. 1991). On a slightly larger scale, a deconvolved direct image taken with the ESO 2.2-m revealed some 30 stars in a $\sim 4 \times 4$ arcsec ($\sim 1 \times 1$ pc at 55 kpc) region surrounding R 136 (Maaswinkel et al. 1988). More recently this region was imaged with the Planetary Camera of the WF/PC on the HST. In the raw image (i.e., not deconvolved to remove the spherical aberration of the HST primary), at least 300 stars are seen within a 2 arcsec radius at the R 136 core. For the 22+ visible B and earlier type stars within a 1 arcsec diameter circle centered on R 136, a conservative minimum stellar density of $5 \times 10^4 \text{ M}_\odot \text{ pc}^{-3}$ has been estimated (B. Campbell, personal communication). See Fig. 17 a for the HST WF/PC image and Fig. 17 b for a recent groundbased speckle image of a slightly smaller region (Pehlemann et al. 1992).

While the 30 Dor cluster has many more high-mass stars and extends to much higher individual stellar masses (up to 250 M_\odot), there are nevertheless many similarities with the prototypical galactic young cluster, the Trapezium Cluster: the most luminous stars in 30 Dor are at the center of the cluster, surrounded by lower-mass stars; the cluster age is ~ 1 Myr (Melnick 1985); and in addition to the optical cluster, there is evidence for recent and ongoing star formation in this region, in the form of four highly luminous (1 to $5 \times 10^4 L_\odot$) infrared sources found in a $\sim 80 \times 110$ pc survey centered on R 136 (Hyland and Jones 1991), and a number of red reflection nebulae interpreted as clumps of gas with embedded young massive stars (Walborn and Blades 1987; Walborn 1990).

Based on the cospatial presence of red supergiants and OB stars, McGregor and Hyland (1981) suggested that there had been at least two distinct bursts of star formation in the 30 Dor region. They advanced the idea that a wave of star formation had moved from the periphery to the center (R 136) of the 30 Dor cluster and that new stars had formed at the intersection of the prominent wind-blown bubbles or shells in the region, powered by older massive stars in the outer parts of the cluster. However, Melnick (1985) pointed out that the red supergiants seem to be uniformly distributed in the region, suggesting that relatively quiescent star formation may have been occurring

Figure 17 a,b. Optical image ($\sim 5740 \text{ \AA}$) of the central $\sim 11.5 \times 10 \text{ arcsec}$ ($\sim 3.1 \times 2.7 \text{ pc}$ at 55 kpc) region of the 30 Dor cluster, taken with the WF/PC of the HST (B. Campbell, personal communication). The apparent ring in the nebulosity surrounding the cluster center is an artifact of the photographic technique used to compress the dynamic range across the print, and is not present in the original data. Note that the massive stars are located near the cluster center. For comparison, a groundbased optical image of the inner $\sim 4.8 \times 4.8 \text{ arcsec}$ ($\sim 1.3 \times 1.3 \text{ pc}$) region obtained using speckle techniques is also shown (Pehlemann et al. 1992).

throughout the region for 10 to 20 Myr, with a single violent burst of star formation leading to the nebula and massive OB cluster more recently, only some 2 Myr ago.

Another scenario for the triggering of the most recent phase of star formation is suggested by the impression that star clusters seem to form at the apex of a cloud exposed to external compression, combined with the striking fact that 30 Dor, the most luminous star-forming region in the LMC, is located on the leading edge of the motion of the LMC through the halo gas of our Galaxy. X-ray observations with ROSAT should reveal the hot gas associated with any bow shock preceding the LMC, and hydrodynamical calculations should then demonstrate whether or not this particular form of external compression could have triggered the formation of the 30 Dor cluster.

Finally, 30 Dor is near the end of the LMC bar, i.e., the bulk of the old stars, suggesting yet another possible source of triggering: in many irregular galaxies, vigorous star formation is seen to occur near the end of an underlying stellar bar, perhaps due to increased gas compression there (Elmegreen and Elmegreen 1980; Gallagher and Hunter 1984).

An all-important question is whether or not 30 Dor is home to any low-mass (i.e., subsolar) stars. As it is the nearest prototype of a starburst system, the current paradigm for starbursts would predict the suppression of low-mass star formation in 30 Dor. There is currently no direct proof for a lack of low-mass stars in 30 Dor, and even though their detection would be extremely difficult, this very important experiment may be possible in the near future, by coupling adaptive optics, infrared arrays, and an 8-m class telescope. If the 30 Dor cluster is found to contain low-mass stars, there would be important implications for the notion of bimodal star formation in more distant starburst galaxies. Also, any such discovery would reinforce the hypothesis that the 30 Dor cluster may actually be a young globular cluster, i.e., similar to those that formed 10 to 15 Gyr ago in the haloes of most galaxies, including our own. Its mass of $\sim 10^5 M_{\odot}$ (Melnick 1985) is indeed similar to that of the old globular clusters.

Finally, because the 30 Dor cluster is so massive, the whole range of stellar masses should be populated in significant numbers according to any reasonable IMF. Current population synthesis models do not contain good templates for young metal-poor populations (cf. Bica and Alloin 1986*a,b*), and therefore the stellar content of 30 Dor might be considered a unique "template initial stellar population," useful for models of protogalactic evolution at times when the metallicity was far below solar.

Other LMC/SMC Clusters. In addition to the young 30 Dor cluster, the Magellanic Clouds are home to a number of somewhat older (10 to 100 Myr) clusters, the luminosity and mass functions of several of which have recently been studied in detail by Mateo (1988) and Sagar and Richtler (1991) using CCDs, and by Elson et al. (1989) using photographic plates.

As part of his study of LMC and SMC clusters across a wide age range,

Mateo (1988) determined the IMFs for the young clusters NGC 330 in the SMC (~ 10 Myr) and NGC 1711 in the LMC (~ 50 Myr), finding both to be characterized by a power law with slope $y = -2.4 \pm 0.6$ (cf. $y = -1.35$ for the $dN/d \log m \propto m^y$ form of the Salpeter IMF) for stars in the mass ranges ~ 2 to $12 M_{\odot}$ and ~ 2 to $7 M_{\odot}$ respectively. In contrast, Sagar and Richtler (1991) found a slope of $y = -1.5 \pm 0.3$ for NGC 1711: it is likely that this significant disagreement is due to the different incompleteness corrections applied, the technique of Mateo (1988) tending to overcorrect, resulting in a steeper IMF, and that of Sagar and Richtler (1991) tending to undercorrect, leading to a shallower IMF. It may well be that the correct IMF slope for NGC 1711 is somewhere between the two results, $y \sim -1.9$ (Mateo 1990; M. Mateo, personal communication).

For two other clusters in their sample, NGC 2164 and NGC 2214, Sagar and Richtler (1991) derived roughly the same slope of $y \sim -1.1$, close to the Salpeter and Miller-Scalo values for stars in the corresponding mass range of 2 to $14 M_{\odot}$. From their photographic photometry of these clusters however, Elson et al. (1989) derived almost flat IMFs, with slopes $y = -0.8$ and $y = +0.2$ across the mass range ~ 1.5 to $6 M_{\odot}$, a result at least partially accounted for by their not using PSF fitting techniques: crowding tends to discriminate preferentially against fainter stars, thus flattening the derived IMF slope. Following this tack even further, Sagar and Richtler (1991) discussed the effect of unresolved optical and physical binaries. If plentiful ($> 50\%$), these can also flatten the slope of the *derived* IMF significantly, particularly if the slope of the *intrinsic* IMF is already rather flat. For example, in the extreme case of all observed stars actually being paired with another star of random mass, an intrinsic Salpeter slope of $y = -1.35$ would be flattened to a measured value of $y \sim -1.0$. Finally, looking at their study of five LMC/SMC clusters (NGC 1711, NGC 2004, NGC 2100, NGC 2614, NGC 2214) as a whole, Sagar and Richtler (1991) found no strong evidence for mass segregation (cf. Sagar et al. [1988], and references therein), although they did not study the crowded inner cores (< 5 pc radius) of the clusters.

There remain significant uncertainties in IMF slope determinations for LMC/SMC clusters due to their relatively large distance, corresponding technique questions (e.g., PSF fitting, incompleteness corrections), and choice of comparison stellar models. However, there does seem to be some consensus emerging, with IMF slopes slightly steeper than Salpeter slopes, and evidence for cluster-to-cluster slope variations (M. Mateo, personal communication). Higher spatial resolution data may begin to settle some of these issues in the near future.

IV. THE QUESTION OF THE EXISTENCE OF BROWN DWARFS

Since publication of *Protostars and Planets II* (Black and Matthews, eds. 1984), there has been an increasing interest in finding observational evidence for the existence of brown dwarfs, i.e., substellar objects ($< 0.08 M_{\odot}$) that

Figure 18. Log-normal model IMF for low-mass stars according to Zinnecker (1984*b*). The IMF shown here is the relative number of newly born stars as a function of mass (in units of solar mass) per unit log mass interval. This curve is very similar to the well-known Miller-Scalo IMF, except for the (log-normally continued) extrapolation to substellar masses.

are not massive enough to ignite hydrogen burning (D'Antona and Mazzitelli 1985). There are many low-mass stars just above this critical mass, and it seems reasonable to expect many objects below it, as the minimum Jeans mass in a collapsing cloud is $<0.01 M_{\odot}$ (Low and Lynden-Bell 1976; Rees 1976). Also, in a more general sense, it seems unlikely that the physical processes of nuclear fusion that determine whether or not a star is massive enough to burn hydrogen have much to do with the processes that governed the fragmentation and initial phases of collapse that resulted in that star. If the empirically determined Miller-Scalo IMF for stars (a half-gaussian in log-mass, peaking at $0.1 M_{\odot}$) extrapolates as a descending gaussian below the peak, as some hierarchical fragmentation models would suggest (Zinnecker et al. 1980; Zinnecker 1984*b*; see Fig. 18), one would expect as many substellar objects in the range 0.01 to $0.1 M_{\odot}$ as PMS stars in the range 0.1 to $1.0 M_{\odot}$. Liebert and Probst (1987) and Stevenson (1991) have presented extensive, thorough reviews of the theory and observations of these objects, but in the present context of young stellar populations, we shall give a brief account of searches for *young* brown dwarfs in regions such as Taurus-Auriga and the Pleiades, where low-mass stars are known to have recently formed or are still forming.

There are major observational advantages in searching for young brown dwarfs. First, the search area is much better defined, because regions with young stars, i.e., clusters, are more coherent in space and time than the galactic disk in general. Second, young brown dwarfs are easier to detect than old brown dwarfs because they are still rather bright due to very slow quasi-static contraction. For example, at a distance of 125 pc, probable Pleiades brown dwarfs (age ~ 100 Myr) are expected to be at $I \sim 17.5$ mag and $K \sim 14.5$ mag (Simons and Becklin [1991*b*], derived from Burrows et al. [1989]). In

Taurus-Auriga at 140 pc, probable brown dwarfs should be at $I \sim 14.0$ mag and $K \sim 11.0$ mag assuming an age of ~ 1 Myr, or $I \sim 15.7$ mag and $K \sim 12.7$ mag at ~ 10 Myr (derived from the PMS tracks discussed in Sec. II.B, provided by I. Mazzitelli). These magnitudes are for objects on the star : brown dwarf dividing line at $0.08 M_{\odot}$, and therefore genuine brown dwarfs ($< 0.08 M_{\odot}$) would be somewhat fainter. Even so, such objects should still be well within the capabilities of current optical and infrared imaging systems: it is their unambiguous identification that poses significant problems. This is mainly due to contamination by background field stars, but also partly due to a lack of knowledge about exactly where to draw the line between very low-mass stars and brown dwarfs in a young cluster. On the latter point however, recent theoretical models suggest that in the HR diagram of a young (≤ 100 Myr) cluster, brown dwarfs should be well segregated from very low mass stars, primarily in T_{eff} rather than L (Stringfellow 1991).

If the putative brown dwarf population *can* be kinematically and spectroscopically identified for a given star-forming region of known distance and age, we should then be able to determine whether the luminosity function is rising or falling with decreasing luminosity. This question has obvious implications for the IMF and for the “missing mass” problem. In order to address these wider issues however, it is not enough to search for brown dwarfs occurring as binary companions (see, e.g., Zuckerman and Becklin 1987; Becklin and Zuckerman 1988; Henry and McCarthy 1990): it is also necessary to assess the existence of a possible “free-floating” population. In that context, we will discuss searches for this population in Taurus-Auriga, ρ Oph, the Pleiades, and the Hyades.

Forrest et al. (1989) carried out a $2.2 \mu\text{m}$ (K) imaging survey in the immediate vicinity (within a few tens of arcsec) of 26 known PMS members of the Taurus-Auriga association. Of the 20 new objects detected, four were classified as Taurus-Auriga members based on their proper motions. These four have K magnitudes ranging from 14.2 to 15.8 mag, leading to estimated masses $\sim 0.01 M_{\odot}$, and all are far enough separated from the nearby PMS star that they would more likely be free-floating than part of a bound multiple system. However, these candidate Taurus-Auriga brown dwarfs seem strangely scattered in the near-infrared color-color diagram, and follow-up optical spectroscopy seemed to rule out the possibility that they are very cool objects (Stauffer et al. 1991). So at least for the time being, there appears to be no strong case for a large brown dwarf population in Taurus-Auriga.

The same seems to be true for ρ Oph, the subject of several recent near-infrared surveys. While Rieke et al. (1989) surveyed the ρ Oph dark cloud core to a limiting magnitude of $K \sim 14$ mag and found no new sources over and above those found in a previous shallower survey to $K \sim 12$ mag (Wiling and Lada 1983), another survey to $K \sim 14$ mag over a larger area did reveal some 35 new sources (Barsony et al. 1989*b*). However, there is no indication that these sources are necessarily substellar, and although an even deeper survey (to $K \sim 15.5$ mag) finally uncovered three, as yet unconfirmed, brown dwarf

candidates (Rieke and Rieke 1990), the present conclusion is that there is no evidence for a *substantial* brown dwarf population in ρ Oph.

A limited start at the search for brown dwarfs in the Pleiades was made by Skrutskie et al. (1986), who looked at eight known cluster members and found no faint near-infrared companions. Searching for a free-floating population of brown dwarfs, CCD surveys in the central region of the Pleiades were made by Jameson and Skillen (1989) and Stauffer et al. (1989), covering 125 square arcmin at R and I , and 900 square arcmin at V and I , respectively. Although in both cases a small number (~ 5) of very faint, very red sources were found to fall in the part of the color-magnitude diagram expected for brown dwarfs, Stauffer et al. (1989) concluded that the mass distribution peaks near $0.2 M_{\odot}$, and falls rapidly thereafter, so that brown dwarfs are not a major component of the Pleiades.

In contrast, Hambly and Jameson (1991) used R and I Schmidt photographic data to study the faint stellar and substellar content of a 3 degree diameter region centered on the Pleiades. After a statistical subtraction of field-star contamination as determined from the outer regions of their plates, they placed a lower limit of 30 on the potential number of brown dwarfs in the whole cluster, and concluded from their I luminosity function that the mass function is flat at the lowest masses. Finally, looking in the wavelength region where low-mass stars and brown dwarfs are most luminous, Simons and Becklin (1991*a,b*) surveyed some 200 square arcmin over several regions of the Pleiades in the near-infrared using the UKIRT infrared camera to $K \sim 17$ mag, and in the optical using a CCD camera. Control fields 5 degrees away at the same galactic latitude were also surveyed to assess the field population. Plotting an I vs $I-K$ color-magnitude diagram overlaid by theoretical brown dwarf curves at the appropriate age, they isolated sources that lay close to the lower main sequence. After correcting for the background population, they were left with some 22 ± 10 free-floating objects with nominal masses in the range ~ 0.04 to $0.1 M_{\odot}$, and a mass function that continues to rise steeply through the star: brown dwarf dividing line. When extrapolated to the whole cluster, these results imply a much larger population of substellar objects than that of Hambly and Jameson (1991), with objects in the 0.04 to $0.1 M_{\odot}$ range contributing some $200 M_{\odot}$ to the total Pleiades cluster mass of $\sim 1000 M_{\odot}$, as determined from velocity dispersion measurements (van Leeuwen 1980, 1983).

The results of Hambly and Jameson (1991) and Simons and Becklin (1991*b*) indicate that if most stars in the galactic disk are formed in clusters, and if the Pleiades is a typical cluster, then it is reasonable to suppose that brown dwarfs in the field are common. However, it must be noted that all these large-area surveys of the Pleiades used the temperature calibration for low-mass stars derived by Berriman and Reid (1987), which Stringfellow (1991) has recently found to be erroneous. This discovery places the results of Jameson and Skillen (1989) and Hambly and Jameson (1991) in serious doubt, and those of Stauffer et al. (1989) and Simons and Becklin (1991*b*)

somewhat less so. This finding, along with the present degree of uncertainty in evolutionary models of very low-mass stars and brown dwarfs against which the observations are tested, suggest caution in interpreting the observational data. Also, as all the various authors point out, definite confirmation of any of these brown dwarf candidates as Pleiades members awaits accurate proper motion studies.

The older (600 Myr) but closer (~ 40 pc) Hyades cluster has also been surveyed for faint members (Leggett and Hawkins 1988, 1989). Using Schmidt plates, they selected objects with large $R-I$ colors for follow-up near-infrared (J, H, K) photometry, in order to derive near-infrared luminosity functions. It is worth noting here that it probably makes more sense to talk in terms of the near-infrared LF for low-mass stars and brown dwarfs than the usual optical LF, since the former is much closer to the bolometric LF than the latter, due to the relatively cool temperature of these objects. Leggett and Hawkins (1988, 1989) found a near-infrared LF for the Hyades which peaks at absolute magnitudes $M_J = 7.6$ mag, $M_H = 7.0$ mag, and $M_K = 6.7$ mag, corresponding to $\sim 0.2 M_\odot$. Henry and McCarthy (1990) dispute the significance of this peak, suggesting that unresolved binaries may be boosting the bright end of the luminosity function, while depressing the faint end. Hubbard et al. (1990a) calculated bolometric luminosity functions for stars and substellar objects spanning the range 0.03 to $0.2 M_\odot$, and compared their model luminosity functions for the age of the Hyades with the observations of Leggett and Hawkins (1988, 1989). They inferred that the mass distribution does not rise with decreasing mass over the mass interval studied. This is consistent with the negative result of a high-sensitivity 1 to $2 \mu\text{m}$ photometric search for cool, low-mass companions to 8 white dwarfs in the Hyades (Zuckerman and Becklin 1987).

It is interesting to note (cf. Hubbard et al. 1990a) that it is at a cluster age about equal to that of the Hyades that the luminosity function begins to separate into two components: that of the brown dwarfs and that of the lower main sequence. Therefore, deeper surveys of the Hyades may be able to differentiate between these two components. In older clusters, the brown dwarfs become harder to detect, because they will have evolved to even lower luminosity. On the other hand, Stringfellow (1991) presents isochrones spanning a mass range of 0.01 to $0.2 M_\odot$ and an age range of 1 to 300 Myr. As mentioned above, he emphasizes that the best opportunity to discover brown dwarfs may be in even younger clusters (≤ 100 Myr), where the brown dwarfs should also be well segregated from the very low-mass stars in the HR diagram.

Finally, it is worth reporting the observational results on the low-mass stellar content of much older systems, globular clusters, as some of these may yet contain their low-mass initial stellar population. Drukier et al. (1988) and Richer et al. (1990) have both investigated the luminosity function of M 13 (metallicity $[\text{Fe}/\text{H}] = -1.4$) and concluded that the derived mass function rises steeply below $0.4 M_\odot$ with no sign of flattening at the lowest observable

masses (0.2 to $0.4 M_{\odot}$). The more metal-rich M 71 and more metal-poor NGC 6397 exhibit flatter (but still rising) mass functions in the same mass range (Richer et al. 1990; Fahlman et al. 1989). Thus, contrary to earlier data (McClure et al. 1986), the most recent CCD photometry does not indicate a correlation between the slope of the mass distribution at the lowest masses and the metallicity of a cluster, but instead suggests that the steepest mass functions are found in the dynamically least-evolved clusters, such as M 13. Dynamically older systems, such as M 71 and NGC 6397, may have lost a much greater fraction of their low-mass stars due to evaporation, thus making for a shallower slope at the low end of their mass functions (Richer et al. 1990). This is now further confirmed for a larger sample of globular clusters, implying a very large initial population of low-mass stars and perhaps even brown dwarfs in globular clusters, and possibly in the galactic halo in general (Richer et al. 1991). Thus it seems that the conditions for forming very low-mass stars and brown dwarfs may be more favorable in Population II than in Population I regions (cf. Zinnecker 1986*b*).

V. SUMMARY AND OUTLOOK

In conclusion, we return to the questions posed in the introduction, summarize our present knowledge and ignorance about young stellar populations, and take a speculative look forward to some of the problems that may be addressed between now and the time of the *Protostars and Planets IV* book.

In most H II regions, massive stars do not appear alone but are usually accompanied by a cluster of low-mass PMS stars; i.e., low-mass stars and high-mass stars form in the same molecular cloud cores. Evidence for high-mass stars without accompanying low-mass stars (bimodal star formation) is very rare, while there are many examples of the converse, namely low-mass stars without high-mass stars. Taking the Galaxy as a whole however, it remains an open question whether the majority of low-mass stars form as cluster members near OB stars, or as a more widely dispersed background population in giant molecular clouds unrelated to OB stars. Recent results discussed in this and other chapters of this book seem to indicate a move toward the former hypothesis.

Clusters of PMS stars associated with OB stars form from dense gas concentrations in molecular clouds. It appears that some clusters owe their origin to the triggering push of adjacent active regions which compress pre-existing overdense clumps (obstacles); e.g., the ρ Oph cluster and those in L 1630. Thus there is evidence for sequential star formation (cf. Elmegreen 1989*b*). In some cases, two daughter sites of star formation may spring from one mother site: as discussed earlier, the Trapezium Cluster and the NGC 2024 cluster may both be offspring of the Orion 1b association, and a similar form of bifurcation may also have operated in the Sco-Cen association (de Geus et al. 1989). Other clusters may form as self-initiated independent condensations in molecular clouds, e.g., as in NGC 6334. If star formation in

clusters is triggered, the age spread of the cluster stars should be small, while in self-initiated protocluster condensations, the individual clumps should have a larger age spread, probably governed by the time scale of the loss of magnetic support in the individual protostellar clumps.

The evolution of the IMF, star-formation rate, and star-formation efficiency in a protocluster are not yet well known. The IMF is thought to evolve from the clump mass spectrum, which in turn must be regulated by a balance of clump collision and fragmentation processes. The clump mass spectrum is relatively flat ($dN/dM \propto M^{-1.5}$), with most mass in the massive clumps, while the final stellar mass spectrum is steeper ($dN/dm \propto m^{-2.35}$), with most mass in the low-mass stars. Preferential fragmentation of the massive clumps and mass-dependent feedback processes could steepen the flat clump spectrum by the required amount to result in the final stellar mass spectrum. Clump collisions should be more prevalent near the protocluster center, in which case we would expect more massive clumps near the center, implying that the more massive stars are born predominantly near the cluster core. The more massive a protocluster cloud, the deeper its central potential well, which should lead to a correlation between total cluster mass and the most massive stars formed in the cluster, as seems to be observed.

At the time that *Protostars and Planets II* (Black and Matthews, eds. 1984) was written, it was generally felt that low-mass stars form first and over a long time scale (a few times 10 Myr) throughout a GMC. If and when high-mass stars form, they dissipate the reservoir of material, preventing further star formation (Strom 1985). This paradigm was based on observational evidence including the age spread of T Tauri stars (Cohen and Kuhi 1979) and of the low-mass members of the Pleiades (Herbig 1962a). The same “low-mass first, high-mass later” buildup in the IMF was found for the young clusters NGC 2264 and NGC 6530 (see, e.g., Iben and Talbot 1966; Adams et al. 1983), although Strom (1985) cautioned that these conclusions rested heavily on comparisons of the observational data with theoretical PMS tracks. Indeed, subsequent re-analyses have shown the same data to be more consistent with simultaneous formation of stars of all masses and a roughly constant star-formation rate in young clusters (Stahler 1985; Schroeder and Comins 1988).

There probably is a low level of low-mass star formation throughout a GMC to begin with, but when massive stars finally form, they are generally accompanied by vigorous low-mass star formation in the same molecular core, as indicated by the extensive clusters of low-mass stars seen surrounding OB stars in their H II regions. It is unknown to what degree these events are truly simultaneous: for example, the low-mass star formation may actually be triggered by radiative implosion or the powerful winds from the massive stars. In any case, the notion of “coevality” in a cluster may be hard to define both theoretically and observationally on time scales of <1 Myr. Even if the collapse of a dense molecular core is triggered at some “time zero” by an external event, the collapse and accretion phases for stars over a range of masses may be quite different. Low-mass stars may acquire their final mass

first, but will then take a long time to reach the ZAMS; high-mass stars may take longer to accumulate their mass, but then evolve rapidly onto the ZAMS. By the time the cluster becomes visible, there may well be an *apparent* spread in stellar ages. Observationally, any test of coevality depends on comparing the positions of stars in an HR diagram with theoretical isochrones. The isochrones are difficult to model for both high- and low-mass stars (e.g., are the accretion rates constant?), and it is difficult to place photospheres in an HR diagram accurately when they are partially or totally obscured by dust. At this time, only the rather general conclusion can be made that in all clouds, stars have formed coevally to within 10 Myr, while in the cases of ρ Oph and the Trapezium Cluster, it appears that most stars have formed coevally to within a few Myr.

In more detail, complex star-formation histories in star clusters may be the rule rather than the exception. We cannot trust present PMS tracks enough to unravel the complex time sequences of star formation with confidence. It can be speculated that the time evolution of the total star-formation rate in a cluster may be described by $1/f$ noise (cf. Bak et al. 1988). This implies self-organized weak chaos, characterized by "memory effects": rare short periods of vigorous star formation alternate with more frequent periods of low-level activity.

Similarly, the star-formation efficiency in a protocluster is a highly time-dependent quantity, namely the integral of the star-formation rate up to a given time, if star-formation is still occurring. The asymptotic, overall star-formation efficiency with which a cluster will form probably depends on the initial conditions, most importantly on the mean gas density but probably also on the total mass of the protocluster (cf. Pandey et al. 1990). High protocluster densities apparently lead to high star-formation efficiencies: for example, in the Trapezium Cluster, the protostellar envelopes must have been touching each other at the time of formation. We speculate that triggered clusters will form with a higher star-formation efficiency, will be more compact, and also more coeval, than self-initiated clusters. Conversely, it is clear observationally that outside of massive cores of molecular clouds, the star-formation efficiency is always low: for example, the total stellar mass to total gas mass ratio is at most a few percent in the Taurus-Auriga complex (which lacks a massive core), as it is outside the core of the ρ Oph region.

The study of star formation in clusters as opposed to isolated star formation raises many interesting new problems: for example, it may be that a full distribution of stellar masses with a large spread in mass only comes about because the primary sites of star formation are protoclusters in which a rich variety of competing processes takes place. If so, future studies of the initial stellar population should focus even more on young star clusters.

Observationally at least, this task will be made easier by likely technological innovations and evolutions during the next decade. Infrared array detectors have emerged as perhaps the key component for studies of young stellar populations. These detectors have increased in size from 32×32 to

256×256 pixels since the production of *Protostars and Planets II* in 1984, and arrays with more than 10^6 pixels are anticipated within the next few years, allowing us to survey all galactic massive star-forming regions for all but the very youngest and most deeply embedded stars. By using these detectors at high spatial resolution, even the remotest galactic clusters will be disentangled, and binarity in the nearer regions probed. Active and adaptive optics techniques will be used on the new generation of large groundbased telescopes (~ 8 to 16-m effective aperture) to achieve extraordinary resolutions (between ~ 0.02 and 0.2 arcsec) in the near-infrared, while a near-infrared camera under development for the Hubble Space Telescope will yield a unique combination of high spatial resolution and very low background at 1 to 2 μm . Near-infrared spectroscopy will also gain enormously from advanced arrays: the first generation of array spectrometers are now available, and promise much in the understanding of the physical nature of sources revealed by camera surveys.

Mid- and far-infrared array detectors may be somewhat behind the near-infrared arrays in terms of size, but major technological breakthroughs have been made in preparation for the next generation of cryogenic infrared space observatories, ISO and SIRTf. While IRAS used a small number of individual detectors for an all-sky survey, both ISO and SIRTf will use large array detectors for pointed observations, and the great increase in sensitivity should result in fundamental changes in our knowledge of the youngest, coolest, and most deeply embedded sources in star-formation regions. At far-infrared and sub-millimeter wavelengths, high sensitivity and spatial resolution will be made possible with SOFIA, an airborne 2.5-m telescope.

Complementary progress is being made at other wavelengths. The ROSAT X-ray observatory, already in operation, will detect many new weak-emission T Tauri stars in the nearer regions such as Taurus-Auriga; the larger AXAF will provide the spatial resolution and sensitivity needed to probe the X-ray emission from young stars in the clusters associated with GMCs. Studies of molecular clouds—the raw material of star formation—are benefitting from the new large millimeter and sub-millimeter telescopes already in operation or under construction, including the IRAM 30-m, the 15-m SEST, the 15-m JCMT, the 10-m CSO, the Nobeyama 30-m, and the 10-m SMT. Linking arrays of telescopes, millimeter interferometry will allow studies of the smallest scales of molecular cloud cores and clumps, in an effort to relate the cloud mass spectrum to the stellar mass spectrum. In addition, sub-millimeter interferometers should allow us to resolve cold disks around young stars where planets and/or binary stars are believed to form.

With the ever larger fields of view, higher spatial and spectral resolution, and greater sensitivity afforded by new instrumentation and techniques, we will be able to take a more global view of star formation within a cluster, a molecular cloud complex, or our whole Galaxy, rather than concentrating intently on the detailed physics of single objects. For the interpretation of these larger-scale observations, we require theoretical advances, such as improved PMS evolutionary tracks, including the effects of disk accretion. At the same

time, the new observations can be expected to stimulate new theories.

An understanding of the problems of star formation and early stellar evolution is clearly an important part of our understanding of the origin of the solar system and planet formation. Also, as stars are the basic building blocks of galaxies, these very same problems bear heavily on our comprehension of galaxy formation and evolution, and many of the large-scale cosmological questions related to the early Universe. Therefore, if most stars form in dense clusters, then it is clear that the formation and early evolution of clusters and the stars that comprise them must be better understood.

Acknowledgments. Many people have contributed to making this work as inclusive and up to date as possible, a particularly difficult problem considering the rate at which new data are becoming available, especially from infrared arrays and space-based instruments. We would like to thank A. Blaauw, M. Haas, T. Henry, G. Herbig, K.-W. Hodapp, C. Lada, C. Leinert, M. Mateo, H. Richer, G. Rieke, R. Sagar, D. Simons, J. Stauffer, G. Stringfellow and F. Walter. We would particularly like to thank J. Rayner for allowing us to make extensive use of as yet unpublished images and information from the collaboration between him and two of us (HZ and MJM). We would also like to thank I. Mazzitelli for providing the homogeneous PMS tracks used in Sec. II.B; S. Kenyon for providing Fig. 7; the WF/PC Investigation Definition Team, B. Campbell, and T. Lauer for the HST image of 30 Doradus; and G. Weigelt for the speckle image of R 136. Thanks are also due to R. Genzel for challenging us to make some sense of the near-infrared images of star-forming regions and the modeling of $2.2\ \mu\text{m}$ luminosity functions. This work was begun while HZ enjoyed a visiting astronomer position at the Institute for Astronomy at the University of Hawaii, and was later supported by the Deutsche Forschungsgemeinschaft. BW would like to thank C. Lada and J. Moran for their hospitality and generosity during his tenure as a Visiting Scientist at the Harvard-Smithsonian Center for Astrophysics. Part of this work was funded by a NASA ADP grant to BW. Finally, numerous U.S. and foreign government agencies are acknowledged for their continued funding of the national and international computer networks: without e-mail, this task would have been impossible.

YOUNG STARS: EPISODIC PHENOMENA, ACTIVITY AND VARIABILITY

LEE HARTMANN, SCOTT KENYON

Harvard-Smithsonian Center for Astrophysics

and

PATRICK HARTIGAN

University of Massachusetts

Much of the variability of pre-main-sequence stars is now attributed to changes in the mass accretion rates of circumstellar disks. The largest variations are observed in the FU Orionis outbursts, in which disk accretion rates increase by 2 orders of magnitude or more. At outburst maximum, accretion rates onto the central T Tauri star are $\gtrsim 10^{-4} M_{\odot} \text{ yr}^{-1}$. Event statistics indicate that many, if not most, low-mass stars undergo multiple FU Orionis events, ultimately accreting at least 5% to 10% of the total stellar mass from the disk during these brief episodes. As much as $0.01 M_{\odot}$ can be accreted in an individual event, demonstrating that FU Orionis disks are fairly massive. The rapid accretion causes the disk to become very hot during outbursts, which may have implications for solar nebula evolution. FU Orionis disk accretion produces very energetic winds, capable of driving bipolar molecular flows and Herbig-Haro objects. Studies of the interaction of pre-main-sequence winds with the interstellar medium suggest that these flows are not steady, but are composed of separate ejection events. The link between ejection and accretion may permit the inference of the accretion histories of individual objects from analyses of pre-main-sequence jets.

I. INTRODUCTION

Over the last few years several lines of research have suggested that disk accretion is an important phenomenon in early stellar evolution. Recent observational estimates suggest that at least 5% to 10% of the mass of an average low-mass star is accreted from its surrounding disk during optically visible stages of evolution (Hartmann and Kenyon 1990). The total amount of disk matter actually accreted onto a young star could be considerably larger than this estimate, because disk accretion probably also occurs during the earliest evolutionary phases, when young stars are completely shrouded from our view by their dusty envelopes.

Disk accretion appears to be highly time variable. The low-mass, pre-main-sequence T Tauri stars can vary in brightness by a factor of 10 or more on time scales of months to years (see, e.g., the review by Appenzeller and

Mundt [1989]), and fluctuations of the optical and ultraviolet excess emission within a 24-hr time interval seem quite common (Hartigan et al. 1991; Basri and Batalha 1990; Chapter by Basri and Bertout). Much of this variability is probably caused by changes in disk accretion rates (though not all; see Gahm et al. 1989; Herbig 1990). The most spectacular variations in T Tauri disk accretion are found in the classical FU Orionis (Fuor) outbursts (Herbig 1977, 1989*a*), in which the mass accretion rate increases by up to 3 orders of magnitude on a time scale of a year or so (Hartmann and Kenyon 1985). Accretion rates of $10^{-4} M_{\odot} \text{ yr}^{-1}$ or more appear to be characteristic of Fuor disks, and 10^{-3} to $10^{-2} M_{\odot}$ can be accumulated by the central T Tauri star during a single outburst lasting for decades or more. Such high accretion rates imply that the disk and central star evolve much more rapidly than previously thought, at least for short periods of time.

Fuor accretion disks are especially interesting for several reasons. First of all, Fuor outbursts tell us that protostellar disks can be quite massive—the masses typically are larger than the minimum mass solar nebula and perhaps are large enough for gravitational instabilities to be important. The high disk surface temperatures produce a wealth of atomic and molecular lines ideal for detailed optical and near-infrared spectroscopic studies. The time-variability of Fuor accretion yields important insights into the properties and physics of protostellar disks which are difficult or impossible to determine from first principles. The extreme variability of Fuors also implies a rapid cycling of disk temperatures and mass infall rates, which may be of some significance for certain aspects of planetary formation. Finally, Fuors are often associated with bipolar flows and jets, and they appear to be capable of rapidly ejecting material (roughly 10% of the mass accretion rate) from the surfaces of their inner disks. Their brightness makes it possible to study the wind acceleration region in some detail and constrain the mechanisms of mass loss.

In the following sections, we concentrate on the behavior of Fuors as the extreme example of pre-main-sequence accretion disk variability. We begin by outlining the standard picture of disk accretion for the typical solar-type, young (T Tauri) star in Sec. II. Trusting souls can skip Secs. III, IV and V, where we summarize the astronomical arguments supporting the standard picture, and proceed to Sec. VI, where we consider the implications of the observations for the physics of protostellar disks. Finally, in Sec. VII we describe observations of mass loss from Fuors, and consider the implications for the physics of disk winds and effects on the neighboring interstellar medium.

II. OVERVIEW

The early phases of low-mass star formation are thought to involve the collapse of a compact, dusty, opaque gas cloud into a star plus disk system (see Shu et al. 1987, and references therein). The best observational constraints suggest that this infall phase typically lasts $\gtrsim 2 \times 10^5$ yr (Myers et al. 1987; Kenyon et al. 1990), which is reasonably consistent with theoretical predictions (Adams

et al. 1987). Mass loss from the central object eventually clears away some of the dusty circumstellar material to reveal a newly formed T Tauri star (Shu et al. 1987a; Chapter by Basri and Bertout).

Our picture of the accretion events following the onset of protostellar collapse is illustrated schematically in Fig. 1. Once the infalling envelope has been exhausted and/or expelled, material from the disk generally accretes onto the central star at a modest rate, $\sim 10^{-7} M_{\odot} \text{ yr}^{-1}$ (Chapter by Basri and Bertout). This "background" disk accretion is punctuated by Fuor eruptions in which the mass flow rate through the disk reaches $\sim 10^{-4} M_{\odot} \text{ yr}^{-1}$ for an uncertain length of time (~ 10 to 1000 yr). The large increase in the accretion rate causes the disk surface temperature to increase substantially (see Fig. 2a). The increase in the disk *midplane* temperature could be considerably larger than the surface temperature jump, because disks in the "T Tauri" state may be nearly isothermal (Kenyon and Hartmann 1987), while Fuor disks are likely to have relatively warm interiors (Clarke et al. 1990; Sec. IV).

Figure 1. Schematic illustration of the variation of accretion rate (\dot{M} in $M_{\odot} \text{ yr}^{-1}$) with time for a young star. Mass from the circumstellar envelope initially falls onto the star quite rapidly, but material primarily lands on the disk at later times. Accretion from the disk onto the star increases from zero to some significant background rate and then slowly decreases with time during the T Tauri phase of evolution. The background accretion is supplemented by recurrent periods of very high \dot{M} (Fuors) and moderately high \dot{M} (Exors). Accretion from the disk ceases eventually, and the young star is then called a weak-emission T Tauri star.

The number of Fuor outbursts observed within 1 kpc of the Sun in the last 50 yr is approximately ten times larger than the estimated star-formation rate within this same region (Hartmann and Kenyon 1985; Herbig 1989a), so the "average" young star must undergo ~ 10 Fuor events during its lifetime. Fuor eruptions may be more common at earlier times, because all known Fuors are

Figure 2. Properties of protostellar accretion disks. (a) The variation of disk surface temperature with radius in a Fuvor disk (dotted line), determined from observations of the emergent spectrum. The inferred range of disk temperatures for typical T Tauri stars is indicated by the dotted area. (b) The right panel shows the observed spectral energy distribution of FU Ori (filled circles) from Kenyon et al. (1988). The FU Ori temperature distribution shown in (a) produces the broad energy distribution denoted by the solid line. The energy distribution of a normal G-type star (essentially a one-temperature blackbody distribution) is plotted as a lighter line.

associated with reflection nebulae (Goodrich 1987; see Table I), whereas only a fraction of T Tauri stars are associated with such nebulae.

Aside from Fuvor outbursts, a T Tauri star may undergo more modest bursts of accretion which can be associated with the “Exor” events identified by Herbig (1977, 1989a). Figure 1 places Exor eruptions near the end of the lifetime of a classical T Tauri star when the background accretion rate is small, but it is possible that Exor events are interspersed among the much larger Fuvor events. The Exors may also be more frequent than Fuvors; the recurrence rate is not known.

Present estimates suggest that the typical T Tauri star accretes roughly the same amount of disk material in Fuvor events as in relatively steady accretion: $\gtrsim 0.05 M_\odot$ in Fuvor episodes (Hartmann and Kenyon 1987a) and $\sim 0.1 M_\odot$ in T Tauri disk accretion (Hartmann and Kenyon 1990). The classical T Tauri phase ends when the disk becomes less efficient at transporting material radially inwards. Pre-main-sequence stars which no longer accrete from their disks have a much smaller range of activity than classical T Tauri stars and have become known as “weak-emission T Tauri stars” (see Chapter by Montmerle et al.).

We emphasize that the evolution outlined in Fig. 1 is highly schematic and that all stars may not follow the same evolutionary path. In particular, there is no guarantee that the solar system experienced Fuor events. Even so, Fuor eruptions must represent a fairly common phenomenon in the earliest phases of star formation, because they appear to be more frequent than individual star-forming events.

We adopt a spectroscopic definition for Fuors in this chapter and consider objects with similar spectra (similar surface temperature distributions). This choice groups together systems with qualitatively different outburst behavior and includes several objects with no recorded outburst. It is possible that some objects listed in Table I are extremely young and have continuously rapid disk accretion instead of recurrent eruptions. Others may be starting to run out of accretable disk material, so their “engine” starts to “cough” (outburst) as the “fuel” runs out.

III. WHY DISKS?

Fuors are relatively luminous objects found in regions of star formation (Herbig 1977,1989a). Attention was drawn to the first members of this class because of large increases in optical brightness (factors $\sim 10^2$) on time scales of about 1 yr. A single pre-outburst spectrum of one object, V1057 Cygni,

indicated that the Fuor outburst was associated with a faint T Tauri star. This result is very important, because it demonstrates that the outburst of V1057 Cyg was not simply the result of disruption or dispersal of a dust cloud, but involved a change in the intrinsic spectrum (Herbig 1977).

The accretion disk model for Fuors (Hartmann and Kenyon 1985; Lin and Papaloizou 1985) initially was motivated by analogy to other astrophysical objects with similar outburst behavior and by the need to explain the observed broad spectral energy distributions (Fig. 2). Assuming optically thick emission, the ~ 2000 K gas responsible for the $2\text{ }\mu\text{m}$ continuum of FU Ori must have an area ~ 10 to 20 times larger than the ~ 5000 K gas producing the optical continuum at a wavelength of $\sim 0.5\text{ }\mu\text{m}$. Similarly, the ~ 300 K material responsible for the $10\text{ }\mu\text{m}$ excess must have ~ 100 times the emitting area of the optical continuum region, etc. The variation of temperature with radius expected from a disk naturally explains these observations (Lynden-Bell and Pringle 1974), and a simple steady accretion disk model explains the observed infrared excess emission of FU Ori (Fig. 2), V1057 Cyg, and V1515 Cyg reasonably well. Unfortunately, at the large distances of known Fuors, direct spatial resolution of the optical and near-infrared emitting disk regions (sizes $\lesssim 1$ AU observed at distances of $\gtrsim 500$ pc) is presently impossible.

The observed variation of spectral type with wavelength provides additional evidence that a Fuor possesses a significant range of emitting temperatures (Herbig 1977). Strong water vapor absorption features detected in FU Ori and V1057 Cyg at $1.6\text{ }\mu\text{m}$ are only seen in stars with surface temperatures $\lesssim 4000$ K (Mould et al. 1978), while the optical and ultraviolet spectra of these objects imply surface temperatures closer to 6000 to 7000 K (cf. Kenyon et al. 1988, 1989).

A fundamental, testable prediction of the disk model follows from the apparent variation of surface temperature with the wavelength of observation. Because the spectrum at progressively longer wavelengths is dominated by the cooler, outer disk regions, the observed velocity broadening of spectral features observed at long wavelengths is smaller than the broadening of lines at short wavelengths (assuming Keplerian rotation). This fundamental prediction of the disk model, pointed out by Hartmann and Kenyon (1985), was later verified for FU Ori and V1057 Cyg by Hartmann and Kenyon (1987b, 1988), who showed that the rotational broadening observed at $2.2\text{ }\mu\text{m}$ was $\sim 2/3$ of the rotational broadening observed at $0.6\text{ }\mu\text{m}$ (Fig. 3). Welty et al. (1991) later presented evidence for a modest, continuous variation of rotational velocity over the range of wavelengths between $0.5\text{ }\mu\text{m}$ and $0.9\text{ }\mu\text{m}$ in V1057 Cyg.

The disk hypothesis can be tested in quantitative detail by constructing a model disk spectrum and comparing it with observations. For simplicity, the disk is assumed to be in a steady state, which may be reasonable for objects on the slowly varying portions of their lightcurves. If this optically thick disk emits roughly as a blackbody, and if the gravitational energy released by the infalling material is dissipated and radiated locally, then the energy balance

equation for a disk annulus at radius R with width ΔR is

$$\frac{GM_*\dot{M}}{R} \frac{\Delta R}{R} = 2 \times 2\pi R \Delta R \sigma T^4 \quad (1)$$

where G is the gravitational constant, σ is the Stefan-Boltzmann constant, M_* is the mass of the central star, and T is the temperature of the annulus. This equation can be rearranged to yield

$$\sigma T^4 \sim \frac{GM_*\dot{M}}{4\pi R^3} \quad (2)$$

(see Pringle [1981] for details and minor modifications which depend upon the inner boundary condition). The scaling of the temperature distribution is set by the maximum disk temperature, which occurs in the innermost disk regions, and this maximum temperature can be estimated from the observed spectra of Fuors at short (optical) wavelengths.

For the purposes of calculating the total disk spectrum, each annulus is assumed to radiate as a star of the appropriate effective temperature; we used supergiant stars, which have surface gravities similar to those expected at the disk surface (Kenyon et al. 1988). This assumption implies that essentially all of the accretion energy is released well below the disk photosphere, which may not be strictly correct. The spectrum of each annulus is convolved with the velocity broadening of Keplerian rotation, and the final synthesized model disk spectrum is the sum of the individual annular spectra.

A simple way to analyze the rotational broadening of the absorption lines is through cross-correlation analysis. Cross correlation of an object spectrum with a spectrum of a much more slowly rotating template star produces a correlation peak whose width is a measure of the rotational broadening, and whose shape indicates the line profile, averaged over many lines in the spectral bandpass adopted. We cross correlated both observed and synthesized spectra with the same template spectrum. The central stellar mass and the disk inclination are free parameters in the model; we scaled the rotational velocity to match the optical line broadening. The disk model then predicts the rotation that should be observed in the near infrared (and other spectral regions).

Figure 3 shows the comparison between theory and observation for FU Ori and V1057 Cyg. The agreement between the velocity broadening predicted for a Keplerian disk and the observed velocity broadening is reasonably good. The discrepancy between theory and observations, at the $\sim 20\%$ level, can easily be attributed to uncertainties in the spectral modeling (Kenyon et al. 1988). In particular, the lack of adequate stellar spectral models for regions with surface temperatures $T < 2000$ K, which contribute 20% of the light at $2.2 \mu\text{m}$, makes it difficult to model this portion of the spectrum with great accuracy.

The predicted cross-correlation peaks are “dimpled” or “doubled,” and the observed cross-correlation peaks, which indicate the average line profile,

Figure 3. Comparison of observed (solid lines) and predicted (dotted lines) cross-correlation peaks for V1057 Cyg and FU Ori (Kenyon and Hartmann 1990). The velocity scales of the models have been adjusted to reproduce the observed optical correlation-peak widths. The model cross-correlation peak for V1057 Cyg at $2.2 \mu\text{m}$ is not doubled because the rotational velocity is not very large in comparison with the instrumental resolution.

show similar structure. High-quality spectra of the Fuors show double peaked behavior in individual line profiles in the red spectral region (Fig. 4). A spherical, rotating star of uniform surface brightness produces parabolic line profiles, unlike these observed profiles, but a disk model can account for this behavior quite naturally. A rotating, flat, narrow ring exhibits a line profile, ϕ , as a function of velocity shift from line center ΔV of the form

$$\phi(\Delta V) = \left(1 - \left(\frac{\Delta V}{V_{\max}}\right)^2\right)^{-1/2}, \quad -V_{\max} < \Delta V < V_{\max} \quad (3)$$

where V_{\max} is the rotational velocity of the ring corrected for its inclination to our line of sight (e.g., $v \sin i$; cf. Kenyon et al. 1988). For a disk model, the net profile at a given wavelength of observation is the sum of profiles from several neighboring annuli with different rotational velocities, and this differential rotation somewhat rounds or blurs the profile indicated by Eq. (3). The cross-correlation peak profiles in Fig. 3 indicate that the average line profile is reasonably well matched by the disk double-peaked profile. Direct modeling of the observed spectra also shows (Fig. 5) that the disk profiles work very well in explaining the peculiarities of the observed line profiles for several Fuors in many (but not all) spectral regions (see Sec. V).

Figure 4. Comparison of optical line profiles in three Fuors. Note the double-peaked structure characteristic of a rotating disk.

Figure 5. A portion of the observed optical spectrum of Z CMa, compared with a disk model spectrum. The model spectrum (middle plot) has been subtracted from the observed spectrum (upper plot) to yield a difference spectrum (lower plot) which is essentially featureless except for a strong Fe II λ 5018 "P Cygni" line profile, formed in the strong wind of Z CMa (figure from Welty 1991).

In summary, the disk model is favored for Fuors because it naturally explains the observed broad spectral energy distribution and variation of spectral type with wavelength; it *quantitatively* accounts for the variation of rotation with wavelength; and it simply explains much of the peculiar line profile structure ("doubled" lines).

IV. WHY DISK ACCRETION?

The case for disk accretion is indirect, because it is not possible to observe the low-velocity drift of material from the outer disk to the inner disk and onto the central star. But given the spectroscopic and photometric evidence for disks reviewed in the previous section, disk accretion provides a plausible mechanism for the energy ($\sim 10^{45}$ to 10^{46} erg) released in a typical Fuor event. Accretion disks are known in other astrophysical contexts which exhibit qualitatively similar outburst behavior, and attempts have been made to scale physical parameters to Fuor disks (Lin and Papaloizou 1985; Clarke et al. 1989, 1990).

Other mechanisms seem incapable of producing such a large amount of energy. Nuclear reactions probably are inadequate, because the only nuclear fuels which can be ignited in pre-main-sequence stars, deuterium and lithium (Stahler 1983, 1988), are unlikely to supply enough energy. Furthermore, it is not obvious why nuclear events should be repetitive, as required by source statistics, or how energy produced by nuclear reactions deep in the stellar interior can account for the short rise times observed in most Fuors.

Stahler (1989a) has noted that spherically symmetric accretion produces an entropy distribution that is inconsistent with the structure of stars on radiative evolutionary tracks. He predicts that high-mass ($M > 1 M_{\odot}$) stars may undergo a large increase in their brightness over a short time scale when accretion ends and the internal structure of the star evolves to its proper radiative structure. This mechanism does not appear to apply to most Fuors, because the event statistics require that most stars, not just the massive ones, must undergo at least several eruptions.

The disk accretion model also explains why Fuors generally show strong CO absorption bands at $2.3 \mu\text{m}$, while most T Tauri stars have featureless continua or comparatively weak CO emission or absorption bands even though their $2 \mu\text{m}$ continua also must be produced in disks (Kenyon and Hartmann 1987; Carr 1989). Simple accretion disk models for Fuors predict a temperature that decreases away from the midplane (cf. Clarke et al. 1990), which is exactly what is needed to produce strong absorption lines. However, the accretion rates in T Tauri disks are much lower than in Fuor disks, so disk heating by light from the central star is much more important. Absorption of stellar radiation tends to produce a more isothermal, or even inverted, disk temperature distribution, which results in weak CO absorption, or even CO emission, in T Tauri disks (Calvet et al. 1991a; see also Carr 1989).

In principle, the broad spectral energy distributions of Fuors can also be modeled by a nonaccreting or “passive” disk surrounding a central star, a model which can be applied to many T Tauri stars (Adams et al. 1987). The optical radiation in this picture comes from the central star, while the infrared excess emission is produced by stellar light absorbed by the disk and re-radiated at longer wavelengths. The passive disk model can account for the observed broad energy distributions, but it does not explain the source of outburst energy and also encounters difficulties with other aspects of the observations. For instance, it is difficult to interpret the differences between the CO spectra of Fuors and T Tauri stars, as described above, if both types of disks are purely passive. Welty et al. (1990) suggested that V1057 Cyg exhibits a *continuous* variation of rotation with wavelength in the optical region, difficult to explain with a stellar model but in quantitative agreement with disk model predictions. Finally, the star plus passive disk model also requires the central object to be rotating near breakup velocity, both to explain the ratio of infrared to optical rotational broadening (Kenyon et al. 1988), as well as to explain the doubled line profiles. It is far more straightforward simply to associate the optical spectrum with the inner disk.

IV. DISK MODEL PROBLEMS AND ALTERNATIVES

The case for Fuors as accretion disks becomes clearer when we consider criticisms of the disk model and alternative proposals. In particular, Herbig (1989) has urged caution in adopting the disk model for Fuors. Herbig argues that the profiles of many lines in FU Ori are more complex than those predicted by the simple disk model. While this is true, to the writers’ knowledge no high-quality ($S/N \gtrsim 50$ – 100) spectra of FU Ori at wavelengths exceeding $0.62 \mu\text{m}$ have failed to show the line doubling, at least since 1985. Lines at shorter wavelengths in FU Ori do not appear doubled but are more parabolic in shape (at the *same* time that the longer wavelength lines show doubling). These short-wavelength lines also exhibit a systematic *blueshift* relative to the center-of-mass velocity of the system (Hartmann and Kenyon 1985, 1987*a*, *c*; Kenyon et al. 1988). Our explanation for this behavior, developed in more detail in Sec. VII, is that a powerful wind emanates from FU Ori, which blueshifts the profiles of strong lines and obscures the double-peaked structure. The weakest lines, found preferentially at longer wavelengths, are formed deep in the disk photosphere and thus show only the disk rotation.

Double-peaked profiles are a ubiquitous feature of Fuors; they have been observed in FU Ori and V1057 Cyg (Kenyon et al. 1988), in Z CMa (Hartmann et al. 1989), in BBW 76 (Eisloffel et al. 1990), and in RNO 1B (Stade and Neckel 1991). In fact, every Fuor where adequate spectral resolution and signal to noise can be obtained shows double-peaked absorption profiles (cf. Fig. 4). The disk model naturally explains this general observational result.

Herbig has also pointed out that V1057 Cyg was observed to be rotating faster at maximum light (1971) than at present epochs, whereas an approx-

imation of the outburst by a sequence of steady disk models with differing accretion rates would predict the opposite effect. The ~ 5000 K regions of the disk dominate the optical spectrum, and since $T \propto \dot{M}^{1/4} R^{-3/4}$ (Eq. 2), the optically emitting region is slightly larger at maximum light, and thus should exhibit a smaller rotational velocity. Recent observations indicate that Z CMa also may rotate somewhat more rapidly during its brighter states (Hessman et al. 1991), but the result is marginally significant. Although steady disk models cannot explain such behavior, the observations may simply mean that the disk does not maintain a steady-state temperature distribution when the accretion rate varies by factors of up to 100.

Herbig (1989a) has suggested that the spectral energy distributions of Fuors might arise from an extended, differentially rotating stellar atmosphere. This idea runs into practical difficulties because of the very large spatial extension needed to produce the infrared excess, based on blackbody arguments (Sec. III). For example, the $2\ \mu\text{m}$ continuum must come from a region at least 3 to 4 times the optical radius. This region cannot be supported by thermal pressure. It is very difficult to construct an appropriate wind model to explain this atmospheric extension. Wind models naturally tend to accelerate to something comparable to the escape velocity over several stellar radii, but the CO lines show no evidence for high-velocity blueshifted absorption or profile asymmetries, limiting expansion velocities to ≤ 0.2 of the escape velocity (see Fig. 3). Rapid rotation is the simplest and most obvious mechanism to keep the infrared photosphere suspended at such a large distance from the star; however, a rapidly rotating star would produce differential rotation in the *opposite* sense of that observed, because infrared lines produced in the cool equatorial regions should have a much larger rotational velocity than the polar regions responsible for the optical emission. Binary models can also be ruled out for Fuors, because the large radial velocity variations expected from a close binary have not been observed (see Hartmann and Kenyon 1985).

Simon and Joyce (1988) also raised concerns that during the decline of V1057 Cyg, the spectral energy distribution was somewhat flatter, i.e., had more infrared excess, than is predicted by steady disk models. In a recent detailed study of V1057 Cyg (Kenyon and Hartmann 1991), it is shown that the evolution of the spectral energy distribution can be explained by a two-component model: an accretion disk, with slowly decreasing mass flow rate; and a dusty circumstellar envelope, which absorbs a fixed amount of light from the disk and re-radiates the energy at longer wavelengths. In our model, the distant dust envelope is responsible for the large infrared excesses at wavelengths $\gtrsim 10\ \mu\text{m}$ which cannot be explained with a simple disk model.

It is important to remember the approximation of a time-varying accretion disk by a series of steady disk models with differing accretion rates cannot be strictly correct. The characteristic time scales of accretion must vary as a function of radius, so it is not possible for all regions of a varying disk to have exactly the same \dot{M} . It makes sense to use steady-state models well after outburst, when the Fuors generally exhibit a slow decay in light, but such

models are likely to be inappropriate close to outburst.

We conclude that the accretion disk model currently provides a satisfactory explanation of Fuor properties. This model naturally explains the broad spectral energy distribution and variation of spectral type with wavelength; it quantitatively accounts for the variation of rotation with wavelength and much of the peculiar line profile structure ("doubled" lines) observed, and it provides a convenient explanation of outbursts, consistent with the behavior of other astrophysical disks.

VI. DISK PHYSICS AND PROPERTIES

Observations of Fuors yield several important physical parameters for proto-stellar disks. By matching an accretion disk model to the observed spectral energy distribution, the disk surface temperatures as a function of radius can be inferred fairly straightforwardly if the distance is known (Fig. 2). The mass-accretion rate through the disk can be determined if the mass and the radius of the central star are known. However, the central star is not observed directly, and so observations of the inner regions of the disk must be used to estimate these quantities.

The disk luminosity L_{disk} is related to the maximum disk surface temperature T_{max} and the inner disk radius R_{in} by

$$L_{\text{disk}} = \frac{GM_*\dot{M}}{2R_{\text{in}}} = \text{constant} \times \sigma T_{\text{max}}^4 R_{\text{in}}^2. \quad (4)$$

The short-wavelength optical and ultraviolet spectra provide estimates for T_{max} (Kenyon et al. 1988, 1989). After making the necessary extinction corrections, the observed spectral energy distribution yields $L_{\text{disk}} \cos i$, where i is the inclination of the disk axis to the line of sight; this quantity and the estimated T_{max} determine $R_{\text{in}}^2 \cos i$ using Eq. (4). The projected rotational velocity $v \sin i$ constrains the quantity $(M_*/R_{\text{in}})^{1/2} \sin i$.

The inclinations of the Fuors are not really known. Adopting values of $i \sim 45^\circ$ – 60° , the resulting stellar parameters for most Fuors are $M_* \sim 0.1$ – $0.5 M_\odot$ and $R_{\text{in}} \sim 4$ – $6 R_\odot$, typical values for low-mass T Tauri stars. The derived parameters of Z CMa are $M_* \sim 1.0$ – $2.0 M_\odot$ and $R_{\text{in}} \sim 10$ – $20 R_\odot$, but these values are quite uncertain due to the difficulty in interpreting the spectral energy distribution of this object (Hartmann et al. 1989).

Once M_* and R_{in} are known, \dot{M} is estimated from L_{disk} (Eq. 4). The total amount of mass accreted during an eruption ΔM then follows from \dot{M} and the length of an eruption. Estimates made in this way indicate that Fuor disks are more massive than the minimum-mass solar nebula. The central star in FU Ori is estimated to have accreted $\Delta M \sim 10^{-2} M_\odot$ since the outburst began in 1939. Parameters are more uncertain for Z CMa because we do not know how long this object has remained bright. The estimated accretion rate $\dot{M} \sim 10^{-3} M_\odot \text{ yr}^{-1}$ suggests that roughly $0.1 M_\odot$ has been added to the central

central star since the middle 1800s. Presumably, the disk was initially more massive than the amount accreted.

A more general estimate for the amount of accreted material can be made from the local star formation rate ($\sim 10^{-2} \text{ kpc}^{-2} \text{ yr}^{-1}$; Miller and Scalo 1979), assuming all stars go through Fuor episodes. The observed Fuor rate since 1939 suggests that each low-mass star accretes on average $\sim 0.05 M_{\odot}$. The total accreted mass per star increases to $\sim 0.15 M_{\odot}$ if Z CMa is included, demonstrating that large uncertainties are present due to small-number statistics.

Other (more model-dependent) constraints on disk properties can be made from an analysis of Fuor variability, in much the same way as in studies of dwarf nova accretion disks. As suggested by D. Lin, suppose that the rapid evolution from a T Tauri disk into a Fuor disk is caused by a sharp transition front which propagates inwards from outer disk regions. The optical emission arises from an area having a radius of roughly $10 R_{\odot}$, so the radial infall velocity must be $\sim 0.2 \text{ km s}^{-1}$ to achieve the observed rise time of $\sim 1 \text{ yr}$. The surface density of the disk follows from \dot{M} and is roughly $\Sigma \sim 10^5 \text{ g cm}^{-2}$. This estimate for Σ is at the high end of the range employed in standard models for the solar system disk (see, e.g., Ruden and Lin 1986).

The effective viscosity of the disk ν is related to the drift velocity, v_r , and the disk radius by

$$\nu \Sigma = \frac{\dot{M}}{3\pi} [1 - (R_*/R)^{1/2}] = \frac{2\pi R \Sigma v_r}{3\pi} [1 - (R_*/R)^{1/2}]. \quad (5)$$

If we adopt the standard “ α -model” for the viscosity, then $\nu = \alpha c_s H$, where c_s is the sound speed and H is the local vertical scale height. The properties of Fuor disks suggest $\alpha \sim 10^{-2}$ to 10^{-3} (Clarke et al. 1990).

If we assume that v_r is roughly constant in the disk, then the $\Delta M \sim 10^{-2} M_{\odot}$ accreted by the central star in FU Ori in the past 50 yr originated in a region with outer radius $\sim 2 \text{ AU}$. The actual outer radius for the accreted material is probably somewhat smaller than this estimate, because v_r is more likely to decrease with increasing radius than to remain constant with radius. Nevertheless, this simple calculation suggests that the FU Ori disk contains a mass comparable to the minimum mass solar nebula inside the orbits of the terrestrial planets.

Crude estimates for disk midplane temperatures also can be obtained from the surface density. If the disk behaves as a simple plane-parallel atmosphere, then the temperature should scale with optical depth τ as $T^4 = T_o^4(\tau + 2/3)$ (Mihalas 1978). Using the above estimates for Σ , models for the interior temperature distribution suggest $\tau \sim 10^4$ (Clarke et al. 1990), which would imply that the midplane temperature should be ~ 10 times larger than the surface temperature, at least in the inner disk ($R < 2 \text{ AU}$; see Fig. 2).

The high midplane temperatures predicted by these disk models suggest a possible explanation for the apparent absence of boundary-layer emission

in Fuors. The boundary layer is the region where inner disk material rotating in nearly Keplerian orbits comes to rest onto the (presumed slowly rotating) central star (Lynden-Bell and Pringle 1974). Simple boundary-layer theory predicts high-temperature emission, because the boundary-layer is assumed to have a small surface area and must radiate a total energy comparable to the rest of the accretion disk. FU Ori and Z CMa show no evidence for the hot (3×10^4 K) boundary-layer emission predicted by the simple theory (Kenyon et al. 1989). However, the boundary-layer theory also assumes that the disk is spatially thin ($H/R \sim 0.02$), whereas the models calculated by Clarke et al. (1989,1990) suggest that the disk may be much thicker, $H/R \sim 0.2$ (see also Lin and Papaloizou 1985). If the boundary layer has a scale height comparable to that of the inner disk, then any boundary-layer radiation might well be “swallowed” or absorbed by the thick disk.

Put another way, the 3×10^4 K boundary-layer temperature implied by the simple theory is *less* than the predicted inner disk midplane temperatures (at least 4×10^4 K, for $\alpha = 1$; Clarke et al. 1989). Thus it is not surprising that some modification to the simple boundary-layer picture is required. The basic boundary-layer theory should be much more applicable to the low-accretion T Tauri state, when the disk is much colder and thus much thinner. Indeed, simple boundary layer models appear to work quite well for T Tauri stars (Chapter by Basri and Bertout).

The nature of the mechanism(s) producing the accretion outbursts is (are) not clear, and will probably remain uncertain for some time to come, in view of our poor understanding of viscosity. One point of importance is that the relatively large masses inferred for Fuor disks

$$M(\text{disk}) > \text{total mass accreted} \sim 0.05 M_{\odot} \quad (6)$$

suggest that gravitational instabilities might play an important role in driving Fuor accretion (see also Lin and Pringle 1987; Adams et al. 1989; Shu et al. 1990; Chapter by Adams and Lin). Rapid Fuor accretion might occur only when the disk is gravitationally unstable, which requires a minimum disk mass. If infalling material is currently landing on the outer disk, as suggested by Kenyon and Hartmann (1991), outbursts could be produced as long as the accretion rate though the inner disk is not closely tied to the rate at which mass is added from the infalling envelope. If the inner disk accretion rate is small enough, then the disk surface density could increase slowly until a critical mass is reached, at which point accretion becomes very rapid and the disk drains onto the central star. This process could repeat as long as material continues to fall onto the outer disk.

If the disks are gravitationally unstable, the instability almost certainly occurs in the outer disk, outside the region responsible for the optical emission. Many Fuor lightcurves show an initially rapid rise followed by a slow decay (Fig. 6).

By analogy with dwarf nova systems, this behavior suggests an “outside-in” transition wave, in which an instability in the outer portions of the disk

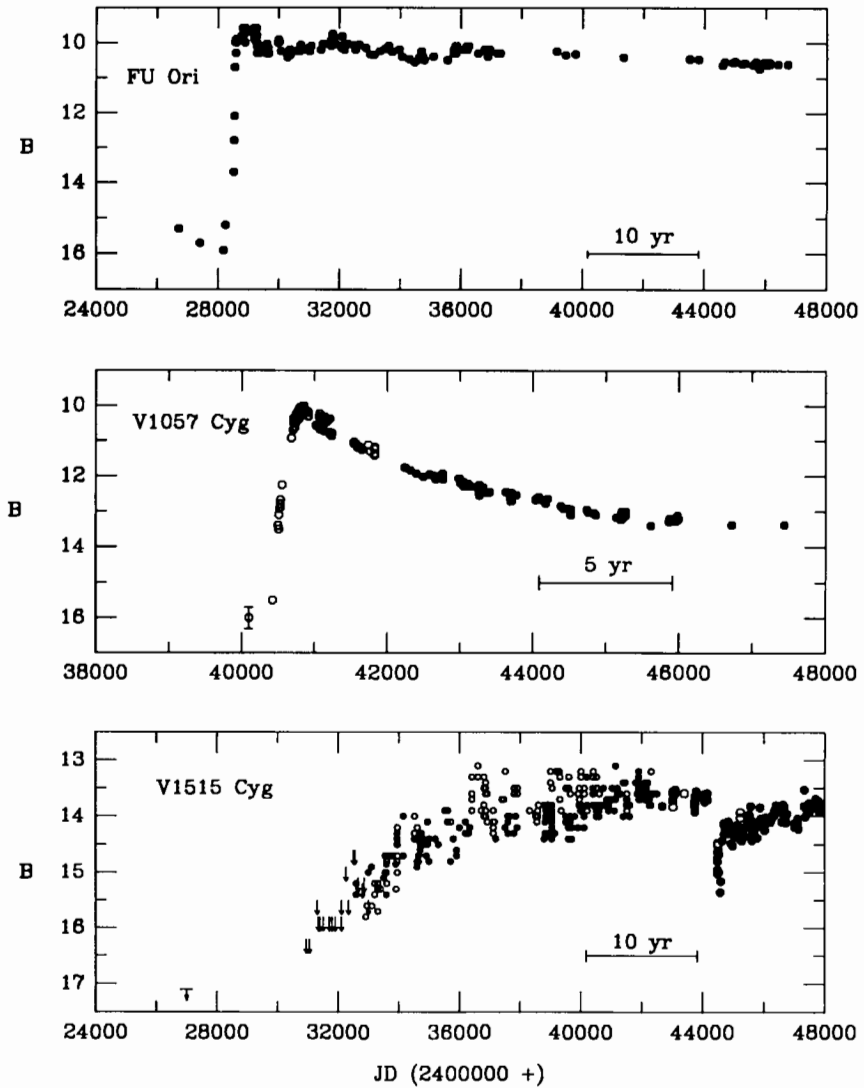

Figure 6. Optical lightcurves for FU Ori (upper panel), V1057 Cyg (middle panel), and V1515 Cyg (lower panel). The data have been compiled from various sources: V1057 Cyg (Kenyon et al. 1988; Simon and Joyce 1988 and references therein); V1515 Cyg (Herbig 1977; Landolt 1977; Tsvetkova 1982; Kolotilov and Petrov 1983); FU Ori (Herbig 1977; Kolotilov and Petrov 1985; Kenyon et al. 1988). Five magnitudes corresponds to a factor of 100 in brightness.

moves inward. The rapid rise in optical light in this picture is produced by the propagation of a transition wave to the inner disk at (roughly) the local sound speed, while the slow decay follows from the length of time required

for material to fall in from the outer disk. A gravitational instability could trigger such behavior (see, e.g., Adams et al. 1989). Alternatively, a close passage of a companion star might similarly perturb the outer disk (A. Toomre, personal communication). An important observational feature of an outside-in eruption is that the mid-infrared lightcurve should begin to rise prior to the optical lightcurve, as illustrated very schematically in Fig. 11 of Kenyon and Hartmann (1988). Perhaps some future Fuor outburst will be identified initially at infrared wavelengths.

Not all Fuors show the same type of light-curve. In particular, V1515 Cyg has exhibited a slow rise lasting many decades (Fig. 6). This evolution is similar to that expected from an "inside-out" eruption which begins near the inner edge of the disk and propagates to the outer disk. Aside from a slow rise in optical brightness, V1515 Cyg has also exhibited a pronounced minimum near JD 2444000 (1979–1981; see Fig. 6). The factor of 6 decrease in B light occurred in ≤ 300 days, and the system returned to its maximum brightness after several years. The observed variation in the overall brightness, $\delta B \sim 1.75$ mag, and the color index, $\delta(B - V) \sim 0.4$ mag, are consistent with a simple increase in the reddening along the line of sight. Thus, this event may have resulted from an occultation of the source by an external dust cloud, rather than an intrinsic change in the structure of the disk.

Thermal disk instabilities, which result when the local heating rate is more temperature sensitive than the local cooling rate, also are a possible outburst mechanism (Lin and Papaloizou 1985; Clarke et al. 1989, 1990). Unfortunately, thermal instabilities tend to occur in a narrow range of disk radii and result in relatively short-lived eruptions. These "standard" models break down if the disk scale height becomes large, because radial transport of energy then becomes an important feature of the calculation. Clarke et al. (1989) showed that radial transport can act to stabilize the disk against transitions to cooler (lower luminosity) states and produce eruptions which remain luminous for many decades.

Much theoretical work remains to be done before Fuor outbursts are understood. On the observational side, improved technology should yield simultaneous optical and infrared photometry of outbursts, which will enable us to study accretion variability over a much wider range of disk radii than before, providing additional clues to the mechanisms of outbursts.

VII. FUOR WINDS AND BIPOLAR FLOWS

A. Disk Winds

In addition to the phenomena we have directly associated with disk accretion, Fuors have very powerful winds (Herbig 1977; Bastian and Mundt 1985). The mass-loss rate in the best studied case, FU Ori, is $\dot{M}_{\text{wind}} \sim 10^{-5} M_{\odot} \text{ yr}^{-1}$ (Croswell et al. 1987). This mass-loss rate is very much higher than that observed from T Tauri stars (see Chapter by Edwards et al.), suggesting that the enhanced outflow of Fuors is related to the accretion outburst. Currently,

it is thought that the winds of T Tauri stars derive their energy from accretion (Cabrit et al. 1990; Hartigan et al. 1990*b*), and the Fuors may represent the extreme limit of mass loss generated by rapid disk accretion.

The amount of energy involved in Fuor winds is substantial. As the mass-loss rate of FU Ori is roughly 10% of the mass accretion rate, and the observed terminal velocity of the wind, V_{wind} , is comparable to the escape velocity at the stellar surface, the kinetic energy in the outflow is $\gtrsim 10\%$ of the accretion luminosity. Thus, the mass loss mechanism must be able to convert accretion energy into outflow kinetic energy very efficiently.

Radiation pressure cannot be responsible for Fuor mass loss, because the surface temperature of the disk is only ~ 6000 K. The low temperature inferred for material in the wind (also roughly 6000 K) implies that thermal pressure gradients are not important in driving the flow (Croswell et al. 1987). Thus, the most likely wind acceleration mechanism is some type of action by magnetic fields.

Rapid rotation is an obvious consequence of disk accretion and may have a crucial effect in driving mass loss. If the magnetic fields are sufficiently strong, gas tied to rotating field lines can be flung outward with high efficiency (Blandford and Payne 1982; Pudritz and Norman 1983; Chapter by Königl and Ruden), even if the wind is very cold (Hartmann and MacGregor 1982). Two variations of this basic picture can be envisaged, as illustrated in Fig. 7.

Figure 7. Two alternative wind models for Fuors. In (a), the wind comes from the near-equatorial regions of the rapidly rotating central star. In (b), the wind originates directly from the surface of the (rapidly rotating) accretion disk. Only the meridional velocity vectors are indicated.

In the first picture, the central star rotates nearly at breakup velocity as a result of the accretion of high-angular momentum material from the disk (Shu et al. 1988). Material is then flung outward from regions near the stellar equator. In the second picture, material is accelerated directly from the surface of the disk along magnetic field lines (Blandford and Payne 1982; Pudritz and Norman 1983; Königl 1989; Lovelace et al. 1991). Note that Fig. 7 denotes

only the poloidal or meridional velocity component; a large azimuthal velocity component also is present which is not shown.

Blueshifted absorption lines are formed in the outwardly accelerating wind material seen in projection against the inner disk, where the optical continuum emission originates. Although the very strong H α line in FU Ori exhibits large blueshifted absorption, indicating wind velocities of up to 300 km s⁻¹, lines of moderate strength show much smaller velocity shifts, ~ 5 to 10 km s⁻¹ (Hartmann and Kenyon 1985; Welty 1990). These small blueshifts are difficult to explain by a stellar wind seen against a disk (Fig. 7a). In most wind models, acceleration to a velocity of order the escape velocity generally occurs within a few stellar radii. Thus, low outflow velocities $\lesssim 0.1$ of the escape velocity should occur only near the star, which is seen in projection against a very small fraction of the optical disk photosphere. Any low-velocity absorption should therefore be quite faint, greatly diluted by light from the extended optical disk. On the other hand, a disk wind model (Fig. 7b) can easily explain the small blueshifts, because the low-velocity wind regions near the disk surface can extend over the entire optical photosphere of the disk. In this model, the high-velocity absorption arises in strong lines formed many scale heights above the disk surface.

Observations of Fuor winds have several other important implications for understanding the mass-loss mechanisms:

1. The outflows are at least partly collimated *as they are accelerated*. This tentative conclusion is based on the lack of high-velocity, redshifted emission in any Fuor. An isotropic wind would produce much more redshifted emission than is observed, unless all Fuors are observed nearly pole-on (see the discussion in Croswell et al. 1987).
2. The mass-loss rate from disk regions at $r \sim 10 R_*$ appears to be smaller than the mass-loss rate deduced from optical absorption lines, which are formed at $r \sim 2 R_*$ (Kenyon and Hartmann 1990). (The outer disk mass-loss rate computed by Kenyon and Hartmann from the $2 \mu\text{m}$ CO lines is probably too small because the distribution over rotational states was neglected in the optical depth calculation.) The estimates of mass-loss rates from infrared studies should improve dramatically in the next few years as high-resolution infrared spectrometers with array detectors become available.
3. The wind probably must be mechanically heated to keep temperatures sufficiently high to produce H α absorption (Croswell et al. 1987). Mechanical heating is also suggested by the presence of strong Mg II emission lines in FU Ori and Z CMa (Ewald et al. 1986; Kenyon et al. 1989). MHD waves are an attractive possibility for producing this heating, and the momentum deposited by such waves near the disk might also assist in initiating the mass loss (cf. Blandford and Payne 1982).

B. Bipolar Flows and Jets

Many young stars are observed to have bipolar outflows and/or jets (see Chapter by Edwards et al.). Accretion-powered winds provide a natural energy source to power such bipolar outflows (see, e.g., Pudritz and Norman 1983; Chapter by Königl and Ruden). We suggest that Fuor disk accretion-driven winds are responsible for many energetic bipolar flows, for the following reasons:

1. The energetics of some Herbig-Haro (HH) objects and jets seem to require very dense outflows, and Fuor winds are the most massive directly observed outflows among pre-main-sequence objects. A causal connection between Fuor winds and HH objects depends upon the (unknown) duty cycle, but even a single “short” burst of mass loss at $\sim 10^{-5} M_{\odot} \text{ yr}^{-1}$ for 10^2 yr, as in FU Ori, can still produce a mass-loss rate of $10^{-7} M_{\odot} \text{ yr}^{-1}$ averaged over a typical flow dynamical time of 10^4 yr.
2. Fuors are commonly associated with jets and HH objects (Reipurth 1989*b*). The most famous bipolar flow source, L1551 IRS5, is spectroscopically similar to other Fuors (Mundt et al. 1985; Carr et al. 1987; Stocke et al. 1988), although it may be a relatively low-luminosity member of the class (Table I). The HH57 emission nebula was known before the associated Fuor erupted (Graham and Frogel 1985), and a jet has recently been discovered in Z CMa (Poetzel et al. 1989).

Mass outflows from young stars should be episodic if accretion is highly variable, and is related to mass loss (Reipurth 1989*c*). The identification of time-dependent outflows can be complicated. Multiple emission knots (shocks) in an outflow do not necessarily require a time-dependent wind, because continuous jets can produce a variety of shocks within the jet and along its surface (see, e.g., Norman et al. 1985; Lind et al. 1989; Blondin et al. 1989; Cantó et al. 1989). However, continuous jet models have several difficulties. The spacing of knots along the HH 34 jet is too small to be explained with simple crossing shocks along a continuous jet (Cantó et al. 1990), and may arise from nonsteady flow (Cantó et al. 1990). Multiple ejections have been proposed to explain the large linewidths observed in HH 32 (Solf et al. 1986; Raga 1986; Hartigan et al. 1986) and in L1551 (Stocke et al. 1988).

Perhaps the clearest argument for multiple ejections arises from cases of multiple bow shocks (cf. Reipurth 1989*b*). In a simple jet, the bow shock is the strong, rounded outer shock, which compresses and heats the ambient medium. Bow shocks are relatively simple to identify both because of their distinctive shape and their well-known kinematic properties. A later ejection plowing into the wake of an earlier bow shock will have similar characteristics to the first, but its emission will be displaced from rest velocity of the ambient cloud by an amount equal to the radial velocity of the wake of the initial ejection.

Reipurth (1989*a*) found two bow-shaped structures in HH 111 and suggested that multiple ejections provide the best explanation for the flow. The HH 47 jet provides particularly strong evidence for the multiple ejection picture because detailed kinematic information is available. The outflow in HH 47 arises from a single, isolated globule and can be studied with excellent spatial resolution without confusion from overlapping material ejected from other sources (Fig. 8; Hartigan et al. 1990*b*).

Figure 8. An image of the HH 46/47 region in [O II] 3727 Å emission. Both HH 47 A and D have shapes and velocity shifts consistent with bow shocks, suggesting multiple ejection events from the embedded young stellar object (see text).

Spatially resolved H α and [Sec. II] emission-line profiles of HH 47D show a hook-shaped position-velocity diagram which shows a striking similarity to the predictions of bow shock models. HH 47A has the shape and velocity characteristics of a second ejection; in particular, its line profiles are shifted from zero radial velocity by the amount expected for a bow-shock moving into the wake of HH 47D (Hartigan et al. 1990*b*); see also Meaburn and Dyson 1987; Reipurth 1989*c*). The elapsed time between the two ejections is roughly 2000 yr.

A combination of a disk wind and a stellar wind is another viable model for HH 147. In this model the region bounded by the outer bow shock (HH 47D) is filled with a poorly collimated disk wind, and a highly collimated jet from a stellar wind produces the bow shock HH 47A. Although this model

differs conceptually from a multiple ejection model, the two scenarios are similar kinematically in that both have a high-velocity collimated flow moving through a less collimated, slower flow. A similar model has been used by Stocke et al. (1988) to explain the Herbig-Haro objects in the L1 551 outflow.

Simple, continuous jet models are hard pressed to explain the kinematic data for HH 47 and are likely to fail in other regions as well (see the discussion in Hartigan et al. 1990*b*). As more examples of multiple ejections are identified, it should become feasible to determine the frequency of multiple ejections in the collimated outflows of pre-main-sequence stars. To the degree that accretion and outflows are connected, it may then be possible to trace the accretion history of a young star by studying shocks in the outflowing wind. Such analyses offer the opportunity for enhancing our understanding of the mechanisms responsible for episodic accretion in young stellar objects.

PART III

Disks and Outflows

THE OCCURRENCE AND PROPERTIES OF DISKS AROUND YOUNG STARS

STEVEN V. W. BECKWITH

Cornell University

and

ANNEILA I. SARGENT

California Institute of Technology

Between 25 and 50% of pre-main-sequence stars in nearby dark clouds have detectable circumstellar disks. Characteristics such as radial temperature distribution and total mass are accurately defined by their spectral energy distributions. The outer disks extend as far as several hundred AU from the stars; some exhibit nearly Keplerian rotation curves at these large radii. The global properties of such disks often resemble those attributed to the primitive solar nebula, suggesting that conditions appropriate for planet formation commonly accompany the birth of low-mass stars. Disk masses, between 0.001 and $1 M_{\odot}$, are generally lower than those of the stars, and may represent only a fraction ($\lesssim 10\%$) of the total system mass. The paucity of near-infrared radiation from some disks implies that in the inner regions there are gaps where the opacity from small particles becomes vanishingly small. Coagulation into large particles may have reduced the opacity coefficient without reducing the total amount of material. The temperatures in the outer parts of the disks (tens of AU from the stars) are too high to result from accretion and stellar radiation alone, although it is energetically possible for these processes to produce the observed luminosities. The total disk luminosity—dominated by far-infrared radiation—is, in fact, correlated with optically detectable inner disk activity, presumably the result of accretion and mass loss. For stars younger than 10 Myr, there is little indication of evolution of disk mass or luminosity. There is evidence that gaps in the inner disks develop preferentially in the oldest objects, suggesting that, with time, matter is lost or accumulates into large particles such as planetesimals, which cannot yet be detected. Studies encompassing a wider range of ages and environments are still required to establish unambiguously the time scales for planet formation around other stars.

I. INTRODUCTION

The title of this book presumes a link between protostars and planets. All plausible theories of the origins of the solar system require the existence of an extended disk of gas and dust around the young Sun before planets formed. Circumstellar disks are also expected as a natural byproduct of stellar birth in molecular clouds. Our planetary system most likely evolved from such a disk, the primitive solar nebula, with almost all the residual gas disappearing before

the proto-Sun reached the main sequence over 4 Gyr ago. Disks, then, are the thread connecting protostars and planets; the detection and study of disks around very young stars is a necessary step to ascertaining if other planetary systems are born in the same manner as our own.

Insight into the potential number of planetary systems in the Galaxy can be obtained from the rate of occurrence of disks around other stars. More importantly, a knowledge of the properties of these disks may well provide details about the very early evolution of the solar system. Such details are essential to a complete understanding of planetary formation and are unlikely to be uncovered from the ancient record in meteors, comets, the planets themselves or their moons. For example, the rate at which the early solar nebula evolved depended on the density, distribution, temperature and viscosity of the gas. These properties can be observed directly only in disks around other stars. The origin of the outermost giant planets remains a mystery, and the role of magnetic fields, turbulence, convection and gravitational waves in planet formation is perhaps open to observational tests through an examination of nearby disks. Quite apart from the potential impact on planetary formation theory, the identification and study of disks around young stars should lead to significant advances in the field of early stellar evolution.

With modern observational techniques, it is possible to detect even tenuous circumstellar disks and characterize their gross properties—mass, luminosity, temperature structure and size. Comparing these properties in large samples allows insights into factors that affect the disk evolution. Since most of the techniques have become available only within the last ten years, this is a propitious time to review the observations. Here, we discuss the occurrence and properties of disks, emphasizing in particular how these may relate to planet formation and the evolution of the solar system.

II. IDENTIFICATION OF DISKS

While there was general enthusiasm for the *concept* of protostellar, possibly pre-planetary, disks at the time of the *Protostars and Planets II* book, there had been no direct identifications of such objects, let alone an understanding of their properties (Harvey 1985). Circumstantial evidence for their existence was, however, considerable. The presence of optical jets (Mundt 1985) and bipolar outflows of molecular gas (Snell et al. 1980) emanating from the vicinity of young stellar objects (YSO's) implied axially (*not* spherically) symmetric distributions of the circumstellar material. Polarization measurements showing that these jets and outflows were generally aligned with the magnetic field direction (Bastien 1982; Hodapp 1984) were also interpreted in terms of a flattened circumstellar particle distribution (Elsässer and Staude 1978). The lack of correlation between interstellar reddening and infrared excess suggested that even visible pre-main-sequence objects, such as T Tauri stars, still have associated circumstellar material (Rydgren and Cohen 1985).

For these, the emission line profiles show preferentially blue-shifted wings, suggesting the presence of disks which occlude the red-shifted emission (Appenzeller 1983). Since T Tauri stars are of approximately solar mass, with pre-main sequence ages between 10^5 and 10^8 yr, they are ideal candidates to search for examples of the primitive solar nebula in its early evolution.

Such studies as those described above have been improved upon and extended over the last six years. Other chapters in this volume (see Strom et al.; Backman and Paresce; Edwards et al; and Basri and Bertout) affirm that the indirect evidence for disk-like structure around pre-main-sequence stars is now overwhelming. As we describe below, observational characteristics which *imply* the existence of disks can be exploited to provide statistical samples of possible pre-planetary nebulae, and to ascertain their gross properties. At the same time, more detailed information on a smaller number of individual disks can be obtained through *direct* observations.

A. Direct Images

To date, only a few disks have been detected directly in images which trace the density distributions of the gas or dust. These represent merely the tip of the iceberg; the next years should see an abundance of images of potential proto-planetary disks.

The most dramatic evidence for circumstellar disks orbiting pre-main-sequence stars comes from aperture synthesis mapping of mm-wave continuum and molecular line emission. The advent of mm-wave interferometers capable of imaging molecular species such as CO on seconds-of-arc scales has opened a new era for the direct study of disks. At these long wavelengths, the cold gas at distances of a few hundred AU or more from a star radiates strongly enough to be detected in the low-order rotation lines of a number of molecules. At shorter wavelengths accessible from the ground ($\lambda \lesssim 20$ μ m), the transition energies require rather hot gas for significant excitation. Sufficiently hot gas exists only within a few AU of the stars, subtending angles of a few millisecond of arc in the nearest star-forming regions, far too small to be resolved by the largest instruments currently available.

Figure 1 shows a particularly clear example of a circumstellar disk seen in ^{13}CO images of HL Tauri made with the Owens Valley Radio Observatory (OVRO) mm-wave interferometer (Sargent and Beckwith 1987, 1991). The highly flattened structure beautifully illustrates the emission from a nearly edge-on disk. The velocities of the gas as a function of distance from the star fit a simple Keplerian rotation curve surprisingly well (Fig. 2), implying that the gravitational potential is dominated by the star. With a radius of ~ 2000 AU and mass $\approx 0.1 M_{\odot}$, there is no doubt that HL Tau is surrounded by a disk similar in its gross characteristics to the primitive solar nebula.

Several other low-mass stars show varying degrees of disk morphology (cf. Sargent 1989, and references therein), probably reflecting different inclinations to the line of sight. Among the more impressive is IRAS 16293-24, shown in Fig. 3, an embedded object in the nearby (160 pc) Ophiuchus dark

Figure 1. The emission from the $J = 1 - 0$ rotational transition of ^{13}CO in a single 2.6 km s^{-1} channel at 2.7 mm from the disk around the T Tauri star HL Tauri. At the 160 pc distance to this star, the $\sim 15''$ extent of the disk corresponds to $\sim 2000 \text{ AU}$. The highly flattened distribution is perpendicular to the axis of mass outflow from HL Tau and defines an edge-on disk.

cloud. OVRO and VLA aperture synthesis maps of IRAS 16293–24, in C^{18}O and NH_3 , suggest a moderately massive disk bound by stellar gravity (Mundy et al. 1986*b*, 1990). Higher-resolution images of the 2.7 mm continuum emission show that this structure is comprised of two separate components and is possibly a young binary system (Mundy et al. 1992). The stars L1551 IRS5, DG Tau, and T Tau also exhibit resolved, disk-like structures in OVRO molecular line maps (Sargent et al. 1988; Padin et al. 1989; Sargent and Beckwith 1989; Weintraub et al. 1989*a*). Owing to the large investments of time required for even one map, the number of stars observed with this technique is small. Nevertheless, these interferometric images make a strong case for the presence of disk-like structures extending several hundred AU or more around young stars of solar mass.

As the stars age, the disks become optically thin, first at infrared wavelengths and finally at visual wavelengths. Short wavelength observations are essential to detect these tenuous disks whose low optical depths may result either from an actual decrease in the amount of material or, more probably, from coagulation of the grains into large particles and planetesimals. The dramatic image of β Pictoris (Smith and Terrile 1984) demonstrates the power of optical images to uncover very small amounts of solid particles in orbit around older ($\sim 0.1 \text{ Gyr}$) stars. In addition, analyses of the optical spectra can provide much-needed information about the velocity fields of material around

HL Tau Rotation Curve

Figure 2. The measured velocities of the ^{13}CO emission as a function of distance from the star along a NW-SE line in the plane of the disk shown in Fig. 1. The solid lines are Keplerian orbital velocities expected at the projected distances around a $0.5 M_{\odot}$ star.

such main-sequence objects (see, e.g., Chapter by Backman and Paresce). It is hoped that, even with degraded optical performance, the Hubble Space Telescope can observe the scattered optical light from the entrained particles around many young stars with resolution better than 10 AU.

B. Indirect Identification

Most disks around young stars are identified indirectly. Fortunately, these identifications are usually unambiguous, making it possible to carry out surveys. The essential points to bear in mind are (cf. Beckwith et al. 1990):

Figure 3. Integrated SO $J = 2,3-2,1$ line emission (left) and 2.7 mm continuum emission (right) from IRAS 16293-2422 from Mundy et al. 1992. The beam for both maps was 4.5×2.5 seconds of arc at a position angle of $13^\circ 6'$. The crosses mark the position of the cm wavelength emission sources.

1. In the mixture of gas and dust prevalent in the interstellar medium (gas:dust = 100:1 by mass), the dust provides all the continuous opacity at temperatures below ~ 1000 K.
2. As cited below, many T Tauri stars emit strongly at far-infrared and mm wavelengths; the opacities imply total masses of order $0.01 M_{\odot}$ (gas and dust) or more.
3. A quantity of $0.01 M_{\odot}$ of gas and dust uniformly distributed in a sphere 50 AU in radius will have a visual optical depth of ~ 500 .
4. The visual optical depth of obscuration in front of T Tauri stars is almost always < 3 .

The first two points suggest that disks will emit at infrared wavelengths if they are heated; radiation from the central stars is sufficient to heat the disks in almost all cases. The last three statements are reconciled only if the stars are surrounded by substantial quantities of matter which is distributed in such a manner as to fill very little of the solid angle around a star. This is most easily realized if the matter orbits the star in a thin disk. As planar configurations result naturally in most scenarios for cloud collapse and star formation, the observation of long wavelength emission from *visible* stars provides compelling, albeit indirect, evidence for the presence of circumstellar disks.

A standard mixture of gas (mostly hydrogen) and dust with a total mass of $0.01 M_{\odot}$ (minimum solar nebula), spread uniformly throughout a circular disk, 50 AU in radius (solar system dimensions), will be opaque at all wave-

lengths shortwards of $100\ \mu\text{m}$. We expect the disk temperature to *decrease* at increasing distances from the star. Near the stellar surface ($\sim 0.01\ \text{AU}$), it will be close to the several thousand degree stellar photosphere. It drops below $1000\ \text{K}$ within 10 stellar radii, approximately $0.1\ \text{AU}$ from the star. At the radii where terrestrial planets might originate, 0.2 to $2\ \text{AU}$, the temperatures are a few hundred degrees, and emission is primarily at the thermal infrared wavelengths, 5 to $20\ \mu\text{m}$. At larger distances, 2 to $50\ \text{AU}$, where the gaseous planets form, the disk is quite cold, radiating in the far-infrared and submillimeter range. As a result, the wavelengths from the thermal infrared and beyond are most important for identifying radiating disks which are potential sites for planet formation.

Because very little matter will make a disk optically thick at infrared wavelengths, the spectral energy distribution shortwards of $100\ \mu\text{m}$ depends entirely on the temperature distribution and is insensitive to the density structure and total mass (Lynden-Bell and Pringle 1974; Pringle 1981; Adams et al. 1987; Beckwith et al. 1990). In general, a power-law radial temperature dependence, $T(r) \propto r^{-q}$, leads to a power law spectral energy distribution, $\nu F_\nu \propto \nu^\alpha$, where $\alpha = 4 - \frac{2}{q}$; $T(r)$ is the temperature at distance r from the star, and F_ν is the flux density at frequency ν . Both the shape and normalization of νF_ν are uniquely determined by $T(r)$. The normalization depends on a high power of T ; typically, $\nu F_\nu \sim T^4$. We have ignored any azimuthal or vertical temperature variations but will return to those points.

The *minimum* temperature that a disk will have is that established by heating from the star; a flat disk will be colder than a flared disk, for example, because it subtends a smaller solid angle. At large distances from the star, the disk temperature, $T(r)$, is given by

$$T(r) = \left(\frac{2}{3\pi}\right)^{\frac{1}{4}} T_* \left(\frac{r}{R_*}\right)^{-\frac{3}{4}} \quad (1)$$

where T_* and R_* are the stellar temperature and radius, respectively (Adams et al. 1988). A flat, opaque disk which extends from the stellar surface to at least a few AU will emit at the very minimum the radiation implied by this thermal distribution. According to the discussion above, this emission will have a frequency dependence $\nu F_\nu \propto \nu^{\frac{4}{3}}$ and a total luminosity one-fourth of the stellar luminosity. In theory, a flat disk heated solely by viscous accretion at the midplane would have the same radial temperature dependence, $T(r) \propto r^{-\frac{3}{4}}$, but the emission would, of course, only add to that stimulated by stellar radiation.

Skrutskie et al. (1990) have shown that for most nearby T Tauri stars, at wavelengths of $10\ \mu\text{m}$ or less, this minimum emission is easily within reach of the largest telescopes. Likewise, Strom et al. (1989d) and Cohen et al. (1989b) have identified numerous disks from the IRAS database using measurements out to $100\ \mu\text{m}$. Our ability to detect circumstellar disks is therefore quite good, limited in most cases only by the amount of material in orbit around the stars.

It is useful to recall that the opacity for interstellar grains (typical size $<0.1 \mu\text{m}$) *decreases* as the wavelength *increases*. Even as particles grow, the opacity should be small at long enough wavelengths. Although it requires very little dust to make a disk optically thick in the near infrared ($\lambda \sim 1 \mu\text{m}$), rather a lot is needed to make the opacity greater than unity at 1 mm wavelength.

We expect, then, that at mm wavelengths the disks will be predominantly transparent. Owing to the low optical depth, the thermal emission depends equally on the material temperature and the column density (or, for a spatially unresolved disk, the total mass). This long wavelength emission is in the Rayleigh-Jeans limit. Where the surface density $\Sigma(r)$ is small enough to be optically thin, its intensity is given by the integral of the product of temperature and density over the surface of the disk

$$\nu F_\nu \propto \int \kappa_\nu(r) \Sigma(r) T(r) 2\pi r dr \quad (2)$$

where the mass opacity, $\kappa_\nu(r)$, is the most important unknown factor. Crudely speaking, νF_ν is a product of the total mass and the characteristic temperature, modified by a weighting factor that depends only on the *form* of the density and temperature distributions. As this weighting factor remains relatively constant over a plausible range of distributions of $\Sigma(r)$ and $T(r)$, the disk mass, M_d , can be established from the mm-wave flux. Beckwith et al. (1990) and Adams et al. (1990) have identified disks and determined masses from such measurements. The major uncertainty in M_d arises in the value adopted for the mass opacity coefficient κ_ν (see also Beckwith and Sargent 1991).

The opacity coefficient is usually assumed to be independent of r . It need not be: coagulation in the inner, dense parts of the disk may greatly decrease κ_ν relative to its value in the outer regions. This effect is minimized by estimating M_d from long wavelength observations because the opacity coefficient should be independent of particle size as long as the particles are smaller than the observing wavelength (see, e.g., Hildebrand 1983). In fact, the expected change in κ_ν with grain size might be turned to advantage by using short wavelength observations to search for disks where coagulation or clearing has already taken place.

The temperatures described above are characteristic of an ordinary T Tauri star. During periods of strong heating by rapid accretion, or by FU Orionis-type eruptions (see Chapter by Hartmann et al.), the disks may become considerably warmer, and the matter distribution may not fall off smoothly with distance from the star. Given the paucity of observations of such phenomena, these circumstances are probably rare. Thus, as we have argued, it is relatively straightforward to identify disks around typical pre-main-sequence stars of approximately solar mass, provided M_d is sufficiently large, $\gtrsim 0.01 M_\odot$.

III. THE OCCURRENCE OF DISKS

As discussed above, surveys for disks around pre-main-sequence stars may involve searches for either infrared or mm-wave emission. In either case, the arguments presented above show that the detection of such emission implies planar matter distributions. Four such surveys include large enough populations ($\gtrsim 50$) to permit significant evaluation of the frequency with which disks occur. Although, in principle, optical searches can discover relatively tenuous disks, no such searches have yet been undertaken.

Cohen et al. (1989*b*), Strom et al. (1989*d*), and Kenyon et al. (1990) examined the IRAS database for far-infrared emission from stars in the Taurus-Auriga dark clouds. Between 25 and 50% of the objects are detected in the far-infrared, implying a rather high probability for disk formation around solar mass stars. Kenyon et al. (1990) searched for pre-main-sequence stars not previously known to be associated with the clouds and so were able to estimate the completeness of the earlier surveys. They conclude that surveys for pre-main-sequence stars in Taurus-Auriga are essentially complete for luminosities $L > 0.5 L_{\odot}$. Almost all solar-mass stars younger than ~ 10 Myr fall into this category. The stars in these surveys are predominantly of the classical T Tauri type, with strong hydrogen emission lines, easily identifiable in objective prism plate surveys of dark clouds (Joy 1949; Herbig 1962*b*).

Beckwith et al. (1990) searched 86 stars in Taurus-Auriga for the 1.3 mm thermal radiation indicative of disks; André et al. (1991) made a similar survey of stars in Ophiuchus. Millimeter-wave observations have three distinct advantages over those in the far infrared; they may be made from the ground; the attainable spatial resolution is superior (11 arcsec vs ≥ 1 arcmin), and they are sensitive to the *mass* of emitting particles (as described in Sec. II). Disks were uncovered in approximately 40% of these samples, an almost identical detection rate to the far-infrared surveys. These samples are also biased toward the classical T Tauri stars.

Disks and potential pre-solar nebulae are evidently common around classical T Tauri stars. The best available evidence for completeness of the samples (Kenyon et al. 1990) indicates that the detection rate is unlikely to drop below 20%, even if few disks are found in more complete samples of pre-main-sequence stars. It is, in fact, likely that with improved observational sensitivity even more disks will be seen; many detections occur near the flux density limits of the extant surveys. Consequently, there is an ample supply of candidates to examine for possible planet formation. This is perhaps the biggest change since the Protostars and Planets II volume.

Another class of pre-main-sequence stars exhibits X-ray emission but *no* strong optical lines (Montmerle et al. 1983*a*; Walter 1986*a*; Feigelson et al. 1987). Initially called “naked” T Tauri stars (Walter 1986), and more recently referred to as weak-line T Tauris, these objects share the important characteristics of their classical sisters: ages < 0.1 Gyr, masses near that of the Sun, locations in dark clouds such as Taurus-Auriga, but no strong emission-

line signatures. Since T Tauri stars are identified most readily in objective prism surveys, a population of pre-main-sequence stars with very weak H α emission could easily go unnoticed. Despite the initial claim that there may be as many as 10 weak-line stars for every classical T Tauri star (Walter et al. 1988), it appears that weak-line stars are actually in the minority (Kenyon et al. 1990; Hartmann et al. 1991).

The samples of Strom et al. (1989) and Kenyon et al. (1990) contain quite a few weak-line T Tauris. Many of these have far-infrared flux distributions indicative of circumstellar disks. For the limited number of weak-line T Tauris observed by Beckwith et al. (1990) at 1.3 mm, the detection rate was 30%. On this evidence, it is clear that the weak-line stars are *not* necessarily “naked.” Indeed, they are quite likely to support disks; the masses of weak-line T Tauri disks are as large as those surrounding classical T Tauri stars (a few percent of a solar mass). Indeed, the disk densities may differ little between the classical and weak-line stars, although there is still insufficient evidence to reach strong conclusions.

On the other hand, none of the weak-line stars have very luminous disks. The infrared emission is in all cases relatively small. Part of the difficulty with searching for disks around weak-line stars is that they are faint at all wavelengths where the disk radiation dominates that from the star. There is certainly some connection between the strength of the emission lines and the properties of the disks, but “naked” appears to be a misnomer.

In our view, the major difference between the classical and weak-line stars is the level of energetic activity such as accretion, which occurs predominantly in the boundary layer between the disk and the star. There appears to be a good correlation between the disk luminosity, its accretion rate, and the strength of the emission lines (Chapter by Edwards et al.). Because the far infrared radiation depends on a high power of the local disk temperature, a lower level of heating will markedly decrease the infrared radiation emitted by the disk until it reaches the lower limit set by stellar heating. The visual emission lines originate in some fairly high temperature region, the boundary layer or the wind. Their intensity can have little bearing on the mass of the disk, which depends largely on the cool material extending many AU from the star.

Yet the accretion rate (or “energetic activity”) could depend on the reservoir of material. A low accretion rate may well signal the depletion of at least the inner regions of a disk, and so the class of weak-line stars could be important to understanding the full range of behavior in circumstellar disks. To assess the actual rate of planet formation, complete samples of pre-main-sequence objects are essential to statistical surveys. Over the next few years, more extensive searches for disks around the weak-line stars using long wavelength ($\lesssim 1$ mm) emission as a diagnostic will help elicit the variety of circumstances leading to the formation of a circumstellar disk.

IV. THE PROPERTIES OF DISKS

A. Disk Temperatures

Because of the nearly one-to-one relationship between disk temperatures and infrared emission, the infrared spectra imply specific radial temperature distributions. The observed spectral energy distributions are consistent with power-laws in frequency, thus implying temperature distributions which are power-law in disk radius. It is convenient to write $T(r) = T_1 \left(\frac{r}{1\text{AU}}\right)^{-q}$ and discuss the results in terms of the power-law index q , and the temperature at 1 AU, T_1 . For purely stellar heating of disks, $q = 0.75$ and T_1 is ~ 100 K for a typical T Tauri star.

For their sample, Beckwith et al. (1990) found disk temperatures, T_1 , ranging from 50 to 400 K, the average being 120 K. The majority of the disks have total luminosities smaller than those of their central stars but larger than expected from a disk heated only by stellar radiation. The hottest, and therefore, most luminous disks radiate more energy than their central stars by factors of 3 or more. Some additional heat input is required to explain these large luminosities; the prevailing view attributes the difference to accretion, but this is by no means firmly established.

Power-law indices q range from ~ 0.5 to 0.75 among the Beckwith et al. (1990) sample of *visible* stars, where there can be little uncertainty about the extinction corrections. A large number of disks have $q \sim 0.5$; the number rapidly decreases with increasing q . Only a few objects show spectra consistent with pure accretion or radiative reprocessing, $q = 0.75$; the temperatures in most of the disks decline more slowly with radius. There is no generally accepted explanation for the high temperatures in the outer parts of the disks. At least four quite different theories have been put forward to explain the low values of q : heating by wave dissipation of $m = 1$ instability modes (Shu et al. 1990); heating by spiral density waves in the disks (Chapters by Adams and Lin and Shu et al.); heating by the central star of flared disks (Kenyon and Hartmann 1987); and heating by winds emanating from the central regions (Safier and Königl 1992). The small values of q which lead to flat spectral energy distributions do not yet have an obvious explanation from simple considerations of disk physics. There is a correlation between q and T_1 in that the hottest disks all have $q = 0.5$. Evidently, whatever provides the additional heat input for those disks preferentially heats the outer radii (Beckwith et al. 1990).

The *observed* temperatures at radii of interest for planet formation, 0.5 to 20 AU, are cool, well below melting temperatures of refractory particles and often low enough to condense water ice from the vapor phase. It should be noted that high disk opacities may require temperature gradients in the direction perpendicular to the plane of the disk, and the midplane temperatures might be higher than those observed at the disk "photosphere." Nevertheless, these surface temperatures are low. Although it is possible that the disks might experience brief periods of high temperature from, for example, rapid

accretion “events” associated with FU Orionis eruptions (Chapter by Hartmann et al.), these events cannot occupy more than a tiny fraction of the disk lifetime, judging by the infrequency of FU Orionis stars among large samples. Therefore, conditions within the disks are favorable for the accumulation of solid planetesimals, consistent with theories of the early solar system.

It is noteworthy that the high temperatures in the inner disks, $T > 500$ K for $r \lesssim 0.3$ AU, are almost entirely responsible for near-infrared radiation between 2 and 10 μm . In some cases, this radiation is much weaker than expected from an optically thick disk heated by the central star (i.e., the *minimum* amount of radiation from a disk). The most straightforward conclusion is that the inner regions are optically thin and, by implication, virtually devoid of small particles (Skrutskie et al. 1990). Either gaps have developed (cf. Chapter by Strom et al.), or the particles have clumped into larger bodies whose opacity per unit mass is exceedingly low. Such would be the case during the early phases of planet formation.

There are other ways to explain the decreased near-infrared flux: flared disks viewed at high aspect angles can exhibit decreased emission from the inner regions (i.e., at near-infrared wavelengths) with little diminution of the outer disk radiation (S. J. Kenyon 1990, personal communication). Each concept merely adds another free parameter to the flat disk model. But there *is* economy of hypothesis in assuming that the inner disk opacity drops as the disk evolves. It is here that the densities are highest, promoting coagulation, and that dynamical time scales are shortest, implying a means to clear material relatively quickly. Gaps could be caused by the formation of small bodies whose gravitational perturbations make the orbits of particles unstable. The onset of coagulation into particles much larger than 10 μm . would serve equally to diminish the opacity and create the appearance of a gap. In principle, these cases can be distinguished by observations of the *gas* in the inner regions. The appearance of gaps may be the first vital signs of nascent planets, signaling an important leap in our ability to witness the birth of a planetary system.

B. Disk Masses

Derivations of disk mass depend on the relationship between the optically thin mm emission, the disk temperature, and the mass opacity. The long wavelength emission varies almost linearly with the disk temperatures; these can be determined rather accurately from the infrared spectra, as discussed above. The principal uncertainty in the mass estimates is introduced by the mass opacity κ_v . Nevertheless, if we assume κ_v does not vary much from disk to disk, the distribution of disk masses may be studied without precise knowledge of the normalization.

There have been several attempts to determine disk masses from mm-wave observations, the most extensive being that of Beckwith et al. (1990). More limited samples observed by Adams et al. (1990) and Weintraub et al. (1989b) are generally consistent with the larger survey results, although

the derived disk masses are higher owing to their different choices for κ_v . Beckwith et al. used an opacity coefficient approximately 5 times larger than that adopted by Adams et al. (1990), who had adopted the value proposed by Hildebrand (1983) and his co-workers. The range of κ_v is reflected in the derived masses, with the Beckwith et al. results biased toward the low-mass side.

Within these uncertainties, disk masses range from $\sim 0.001 M_\odot$ to approximately $1 M_\odot$, with an average value near $0.03 M_\odot$. Thus, the vast majority of disks detected in the mm-wavelength surveys are more massive than the minimum solar nebula, $0.01 M_\odot$ (see, e.g., Weidenschilling 1977b), and have sufficient material to form a planetary system like our own. At the lower end, the mass distribution is incomplete, limited by the sensitivity of the observations. A population of low-mass or low-temperature disks could have gone undetected. On the high end, there are very few disks which are comparable in mass to their central stars; in all cases, the uncertainties allow for disk masses much less than $1 M_\odot$. In one case (HL Tauri), constraints from the observed rotation curve of the gas at a few hundred AU suggest somewhat less mass than the estimate from the mm-wave thermal emission.

There are, as yet, no clear correlations between disk mass and other stellar characteristics such as stellar age (up to ~ 10 Myr), stellar mass (range 0.2 to $2 M_\odot$), $H\alpha$ equivalent width, and stellar luminosity (Beckwith et al. 1990). There are modest uncertainties in the stellar characteristics which do not exclude subtle effects, but pronounced trends (e.g., disk mass proportional to stellar mass) should have been seen in the present samples. There is a small inverse correlation between disk mass and disk temperature: hotter disks tend to have less mass. This correlation is probably an artifact of the mass derivation procedure, in which the mm-wave flux density is divided by the product of the average temperature and a calibration factor involving the opacity.

We can imagine that significant coagulation will change κ_v with time and will vary from disk to disk. The resulting scatter in derived M_d could mask evolutionary trends. The onset of coagulation *lowers* κ_v , and hence *decreases* the derived disk mass. If coagulation occurs preferentially in older disks, we still expect a correlation between the derived M_d and stellar age. None is seen, showing that significant coagulation does not always occur within the first few Myr.

Only a few of the weak-line T Tauri stars have been observed adequately to determine disk masses. Even for these, there is no clear trend of decreasing disk mass with decreasing $H\alpha$ emission. There is, as expected, no obvious correlation between the high-energy indicators of a disk ($H\alpha$ emission, X-rays, near-infrared excess) and its mass, most of which is probably an AU or more from the star (see Sec. III).

C. Evolutionary Characteristics

Rather massive disks surround many pre-main-sequence stars. Around main

sequence stars, such as Vega and β Pictoris, there are no known *massive* disks ($M_d \sim 0.01 M_\odot$), or at least none comprising small ($\lesssim 1$ mm) particles. The particle masses *observed* around main-sequence stars are orders of magnitude smaller than those detected around T Tauri stars (Backman and Gillett 1987; Chapter by Backman and Paresce). The disks must therefore evolve, in the sense of losing their small particles and (perhaps) associated gas. The process which drives this evolution is central to the issue of planet formation, since the buildup of large bodies naturally causes the disks to become transparent. But planet formation is not the only way: accretion onto the star or expulsion by strong winds may deplete the material independently, *preventing* the formation of large, solid bodies.

As described above, there is no obvious evolution of disk mass among a sample of stars <10 Myr old. Examination of either the average disk mass versus age or the fraction of stars with detected disks as a function of stellar age fails to demonstrate a decrease of disk matter within the first few Myr of a disk's lifetime. This result is interesting for two reasons. First, some disks must persist long enough for accumulation into planetesimals to begin, according to our best current theories for planet formation. The evidence shows that planet formation can certainly occur around some of these stars, and it could emerge as the dominant way to lower the disk opacity. Second, winds are most vigorous early in the T Tauri stage and decrease markedly after a few Myr. If disks persist well through the phase of strong mass loss (and, presumably, accretion), it is difficult to see how a T Tauri wind can later destroy a disk (Beckwith et al. 1990; Chapter by Edwards et al.). Although such a wind is commonly included in theories of early solar evolution as a means of clearing light elements from the solar nebula after the formation of the giant planets (Horedt 1978; Elmegreen 1978*b*), we have no evidence that *observed* winds from T Tauri stars can effect the clearing.

This interpretation presupposes that the disk matter is not continuously depleted, through accretion onto the star and mass loss in a wind and replenished, via accretion from the surrounding dark cloud, throughout its lifetime. If the very high mass loss rates inferred for some stars ($\dot{M} \sim 10^{-7} M_\odot \text{ yr}^{-1}$; Chapter by Edwards et al.) persist for several Myr *and* most of this mass originates from the circumstellar disks, the observed reservoir of material, $\lesssim 0.1 M_\odot$, is incompatible with the total mass lost, unless the disk mass is continually replenished. Of course, it is not clear if high mass loss rates are continuous or episodic, and the material could originate from the star itself. A greater understanding of the mass loss process is clearly needed. The high mass-loss rates are cited to buttress the case for high-mass disks (Shu et al. 1990).

Skrutskie et al. (1990) present good evidence for a decrease in the material in the *inner* regions of disks, the gaps discussed above, for stars older than 10 Myr. Old T Tauri stars generally display a paucity of near-infrared emission, characteristic of particulate matter within a few tenths AU of the stars. In future research, we might hope to examine these stars over a wide range

of wavelengths to understand how the more distant disk material evolves. Apparently, 10 Myr is approximately the time scale for significant changes in disk structure, a time scale which is not seriously at odds with our theoretical notions of planet formation. By focussing attention on these older stars, there is a good chance that we can quantify the evolutionary changes in sufficient detail to constrain our picture of planetesimal growth.

We have concentrated so far on the *particles* in the disks because they are responsible for the strong infrared and mm-wave emission. We might well ask whether the *gas* evolves on the same time scales. Gas certainly dominates the mass of the youngest disks, such as HL Tau (Sargent and Beckwith 1987), but there are no statistical assessments of gas content in the older disks. In principle, gas content can be observed directly in rotational transitions of the trace molecules such as CO using mm-wave interferometers. A survey for gas disks is an excellent future project for arrays with many ($\gtrsim 5$) telescopes but is impractical for the three-element arrays presently available. Gas might also be detected in absorption in disk “photospheres” with the next generation of infrared space telescopes such as SIRTf. The essential point is that the expected cool temperatures at disk radii a few AU from the stars mean gas signatures will appear at wavelengths $> 10 \mu\text{m}$.

D. Chemical Composition: Particle Opacities

The mass opacity of particles, κ_v , is of more than passing interest because it is primarily responsible for the assessment of disk mass and because compositional changes, mirrored by changes in κ_v , might yield valuable clues to the processes taking place during the growth of large particles in planet-building nebulae. There is considerable debate about the mass opacity for interstellar dust at mm and sub-mm wavelengths (Mathis et al. 1977; Hildebrand 1983, Draine and Lee 1984; Wright 1987). Compounding the problem is the observation that grain size distributions certainly vary among common interstellar environments (diffuse ISM, molecular clouds, condensations within clouds), and it is not known how the disk environment will affect the size and nature of growth of solid particles. Perhaps the only consensus is that the opacity of grains will decrease when the wavelength exceeds the grain size, but the exact form and value of that decrease is poorly known and difficult to determine.

Hildebrand (1983) showed that the sub-mm opacity of small ($\lesssim 100 \mu\text{m}$.) particles depends only on the total *volume*, and therefore mass, of the material, regardless of size distribution, *if* the particles are convex—that is, the ratio of volume to surface area scales linearly with the size of the particles. All spheroidal shapes (including needles, cylinders, pancakes, etc.) fall into this category. It appears also to be true for particles of fractal dimension (ratio of volume to surface area increases as size to the power α , where α is $< \text{unity}$) so long as the wavelength exceeds the largest constituents (Wright 1987). As a first approximation, we can ignore the size distribution so long as most of the mass is in particles smaller than the wavelength of observation. This removes much of the freedom in choosing a bulk opacity coefficient.

The complex index of refraction is then directly related to bulk opacity through the Kramers-Kronig relationship. In principle, measurements of the indices of refraction for the kinds of materials which should constitute astrophysical particles lead to an accurate characterization of the bulk opacity. Unfortunately, some of the most important constituents are poorly understood (e.g., amorphous silicates) and often lack measurements at suitable wavelengths. In many cases, the index of refraction is temperature dependent. The bulk opacities for interstellar particles are most uncertain at the mm-wavelengths of interest here.

This uncertainty has generated debate about the masses for disks derived from observations of the thermal emission. Until very recently, the standard opacities were assumed to fall as the inverse square of the wavelength, conventionally characterized as a power law: $\kappa_\nu \propto \lambda^{-\beta}$, with $\beta = 2$. The constant of proportionality is estimated (observed is, perhaps, too strong a word) at a wavelength of $350 \mu\text{m}$ in dark clouds and extrapolated to longer wavelengths (Hildebrand 1983). The resulting curve fits reasonably well with theoretical estimates of the behavior for a mix of silicate and graphite material (Draine and Lee 1984), subject to the rather large uncertainties inherent in these estimates. The bulk opacity at 1.3 mm given by Draine and Lee (1984) is $0.002 \text{ cm}^2 \text{ g}^{-1}$. Hildebrand (1983) indicates an opacity of $0.004 \text{ cm}^2 \text{ g}^{-1}$, and most other authors give higher values. The value could be enhanced by factors as large as 30 by conducting particles of fractal dimension, that is if the particle volume increased more slowly than the cube of the size (Wright 1987). It is perhaps worth noting that Meakin and Donn (1988) favor the formation of fractal particles in their models of the early solar nebula.

Figure 4. A histogram showing the distribution of sub-mm spectral indices ($F_\nu \propto \nu^{\beta+2}$) derived for 23 disk sources in Taurus-Auriga (Beckwith and Sargent 1991). The index β is the power-law assigned to the opacity coefficient κ_ν discussed in the text.

The wavelength dependence may be checked from sub-mm observations of disks, for example, but there is no straightforward means of establishing the constant of proportionality which is chiefly of interest. It is now apparent that most of these objects have solid particle emission with a weaker wavelength dependence than assumed in conventional models of interstellar particles (Beckwith et al. 1986; Sargent and Beckwith 1987; Woody et al. 1989; Adams et al. 1990; Weintraub et al. 1989*b*; Beckwith and Sargent 1991). Figure 4 is a histogram of the power-law β for a sample of 19 disks in Taurus-Auriga taken from Beckwith and Sargent (1991) showing the propensity toward $\beta \lesssim 1$. If we keep in mind that disks of high optical depth will appear to have $\beta = 0$, we might interpret the graph as showing a preference for $\beta = 1$, the distribution resulting from optical depth effects. This figure shows the standard opacity laws might need to be modified for the problem at hand, without indicating how the overall coefficient will change at 1.3 mm.

Pollack (personal communication) recently pointed out that long wavelength laboratory measurements have been made for a number of relevant materials, notably amorphous silicate, water ice, and graphite. At 1.3 mm, silicate will dominate the bulk opacity (assuming cosmic abundance) and will yield an index $\beta = 1$. By his estimate, the opacity coefficient at 1.3 mm is nearly identical to the Hildebrand value, but with a different power-law dependence. Different materials may dominate the opacity at different wavelengths, however, and water ice should become most important somewhere around 300 μm with a $\beta = 2$ dependence. Thus, it may be possible to assess the relative abundance of different materials through careful observations of the sub-mm spectrum, once good laboratory data are available.

If we adopt Pollack's value for κ_v at 1.3 mm, the disk masses derived by Beckwith et al. (1990) should be raised by a factor of 5, making the average disk mass 0.15 M_\odot for the objects in Taurus-Auriga. The larger disk masses alleviate the difficulty posed by inferred high accretion rates and lend credence to the ideas put forward by Shu and his collaborators regarding critical disk masses to make wave action in the disks important (Shu et al. 1990). The uncertainties in the opacity are not necessarily smaller, but the reasons for assigning a value to κ_v are, perhaps, on firmer ground (Beckwith and Sargent 1991).

V. CHALLENGES

At the time of *Protostars and Planets II*, a circumstellar disk was a theoretical concept required to explain the primitive solar nebula, but almost nothing was known about the existence or properties of disks around young stars. It is safe to say that the observational evidence for disks around many stars is now overwhelming, and we have assessed the gross characteristics (mass, temperature, size, velocity field) for a relatively large sample. Some important refinements must await the availability of very high angular resolution from mm arrays and the Hubble Space Telescope. In the interim, there are several

areas in which observers and theorists might make progress, and we pose these in the form of challenges to the respective camps.

Figure 5. The disk mass is plotted versus companion separation for 17 stars known to be in binary systems. Filled circles denote those disks detected at 1.3 mm; open circles indicate non detections, so the disk mass is an upper limit only. In many cases, infrared radiation from these non detections indicates the presence of disk material, but in smaller amounts than occur for the stars detected at 1.3 mm.

A. Observational Challenges

1. Binary Stars and Disks. There is weak statistical evidence that close companion stars do inhibit the formation of a disk. Zinnecker (1990a) presents a review of known multiple star systems among low-mass, pre-main-sequence stars with separations ranging from a few stellar radii to a few thousand AU. Figure 5 is a plot of disk mass versus component separation for those systems searched for circumstellar disks. The filled circles show stars detected at 1.3 mm, therefore having disk signatures; the open circles indicate upper limits. Almost every system with component separations $\lesssim 100$ AU has low mm-wave flux, indicated by the upper limits to disk mass, whereas all the large separation systems are detected. Unfortunately, the upper limits are only slightly smaller, on average, than the detections, so it is too early to make a strong statement about the dynamics. Yet the result is encouraging from a theoretical point of view. Gas orbits will be unstable at circumstellar radii of the same order as component separation in a multiple star system, and we expect to see a decrease in disk mass when the separations become smaller than the size of a typical disk, probably of order 100 AU.

The effect of binary separation on disk mass (or disk radius) is open to observational test. Speckle interferometry at near-infrared wavelengths has already demonstrated the binary nature of such pre-main-sequence objects as T Tauri (Dyck et al. 1982), Z Canis Majoris (Koresko et al. 1989), and XZ Tauri (Haas et al. 1990). The ever-continuing refinements to this technique which will enable systematic searches for pre-main sequence binaries at intermediate separations from a few to a few hundred AU should considerably enlarge the sample. The high resolution afforded by HST is an important part of these searches. Equally important, very deep observations of these systems at sub-mm wavelengths will detect low-mass disks, should they exist. The results will bear on the relative roles of disks and companions serving as reservoirs for the energy and angular momentum during the formation of a star.

2. Interior Gaps. Many of these stars have low 5- and 10- μm flux densities, yet detectable emission at 60 and 100 μm . It is very difficult to account for these spectral energy distributions unless the regions close to the stellar photospheres are devoid of small particles. The gaps apparently occur more frequently in stars older than 10 Myr, suggesting a clearing with age (Skrutskie et al. 1990). There are probably several ways to clear gaps in the inner disks; one of the more attractive and interesting is dynamical clearing through the gravitational influence of planet-sized bodies in the inner disks. Another is to deplete the small particles into larger bodies through coagulation, thus decreasing the opacity coefficient without changing the actual matter density.

Identification of gaps requires sensitive photometry in the thermal infrared, and this has already been carried out for limited samples of stars. Broadening these samples ought to quantify the stellar and disk characteristics which correlate well with clearing and firmly establish the evolutionary status of the gaps. Furthermore, it will be useful to affirm that gaps are cleared in the *gas* distribution as well as the distribution of small particles, as expected if the matter density is actually changed.

Theories of solar system formation usually have Jupiter forming first, clearing a narrow gap at 5 AU. At present, we lack the observational tools to distinguish a gap in the outer parts of disks, since the spectral energy distributions will change very little. It is conceivable that such gaps could be seen with long-baseline interferometers working in the thermal infrared regime. The development of aperture synthesis instruments of this sort could provide potentially powerful ways to examine planet formation in great detail.

3. Disks Around "Older" Pre-Main-Sequence Stars. We know the disks have largely disappeared by the time the stars reach the main sequence. The faint remnants seen around Vega and β Pictoris can be only tiny fractions of the original disks. The time scale for disk dissipation and the mechanism: stellar winds, accretion onto the stars; or creation of large, orbiting companions is open to observational test in the post-T Tauri stars. In all likelihood, it will be necessary to go beyond the proximate Taurus-Auriga and Ophiuchus clouds to identify significant numbers of these transition objects.

The Hubble Space Telescope is likely to be a potent instrument for study of tenuous disks around older pre-main-sequence stars, those between 10 and 100 Myr old. No longer opaque at visual wavelengths, the particles in these optically thin disks will scatter light from the central stars, enabling detection in high-dynamic range images. Although the amount of scattered light is small, the high optical mass opacity should make it possible to see very low-mass disks.

4. Particle Composition. At sub-mm wavelengths where most of these disks are optically thin, the spectral energy distributions reveal the wavelength dependence of the particle opacity. The large aperture sub-mm telescopes now in operation should provide a good sample of the distributions in the limited windows accessible from the ground. A large airborne telescope, such as SOFIA, or a cryogenic space telescope, such as SIRTf, might determine the continuous energy distributions for at least the brightest disks.

With continuous energy distributions, it may finally be possible to identify the substances which dominate the opacity in different wavelength regimes. Pollack's preliminary estimates suggest that silicates will dominate beyond a few 100 μm and water ice at shorter wavelengths, the relative contributions seen through the turnover wavelength, where we expect a change in the slope of the opacity coefficient. It is conceivable that large particles in older disks will be detected through their signature in the sub-mm spectra.

B. Theoretical Challenges

1. Gaps and the Influence of Companions. Just as the observers must refine the empirical evidence for gaps in the inner disks, so must the theorists address the issue of how different gap-clearing processes can be differentiated. Clearing by small companions is a particularly interesting case, since it is a natural byproduct of planet formation. The challenge will be to understand if the influence of planetesimals has uniquely observable characteristics or if a single means of creating gaps is so superior to all others as to provide strong indirect evidence of its handiwork. An assessment of coagulation is similarly interesting and, in principle, subject to observational test.

2. Heating of Disks. The almost inescapable conclusion from the observed far-infrared flux distributions is that the outer disk temperatures are elevated above those expected from the simplest ideas about disk heating. If the opacities are very high, it is possible that vertical temperature gradients bias the observational results to reflect the midplane temperatures improperly, where internal heating presumably occurs. As described above, we are aware of at least four quite different ways to heat the outer disks. The strongest observational clue, that the heating is most effective when the accretion is vigorous, perhaps favors disk flaring or heating by the winds, but there are other reasons for rejecting such scenarios. At this writing, the luminosity redistribution (since the luminosity should be dominated by processes occurring in the *inner* disk) appears to be an important unsolved problem.

3. Persistence of Disks. Disks persist for at least several Myr. Yet the time

scales to begin significant growth of planetesimals are relatively short, perhaps a few 10^5 yr or less. It is not clear whether this is a real problem or only reflects the uncertainty in modeling particle growth in the presence of complicating factors such as turbulence and electromagnetic forces. Persistence time scales are potentially important for assessing the means by which volatiles are lost in the latter stages of planet creation. Perhaps the ever-increasing observational constraints will allow a refinement of theory in ways useful to understanding our own origins.

4. *Disk Dissipation: Alternatives to Planet Formation.* In the same vein, there is an apparent mismatch between the standard model—disruption by a “T Tauri” wind—and the observation that the strongest winds shut off before the disks lose very much of their mass; nor is there evidence for a recurrence of energetic winds which could destroy the rather robust disks persisting beyond a few Myr (Chapter by Edwards et al.). Are there other or better ways of destroying these older disks? Or is planet formation our best hope?

T TAURI STARS AND THEIR ACCRETION DISKS

GIBOR BASRI

University of California, Berkeley

and

CLAUDE BERTOUT

Institut d'Astrophysique de Paris

The T Tauri stars are solar-type stars in their pre-main-sequence phase. The main distinguishing characteristics of the classical T Tauri stars are excess continuum emission from the ultraviolet to the far infrared and strong emission in selected lines, particularly $H\alpha$. These characteristics are thought to be due to both mass influx and mass loss in the systems. Such flows are now thought to be due to the presence of an accretion disk around the star—the final phase of star formation and possible precursor to planet formation. The stars themselves are both more rapidly rotating and more convective than their main-sequence counterparts, which leads to increased magnetic activity, a partner in producing the “T Tauri phenomena.” This chapter is focused on the evidence for accretion through a disk as the source of the emission excesses, particularly those seen in the continuum between 0.1 and $10\,\mu\text{m}$ and in the strong permitted emission lines. We present a brief overview of the classical T Tauri phenomena, and a detailed discussion of how accretion-disk models can explain them. We explore their relation to the weak-lined T Tauri stars, and mention some effects disk accretion could have on the evolutionary status of young stars. Finally, we suggest some directions that research in this area should take in the near future.

I. INTRODUCTION

Since the realization that the $H\alpha$ emission stars first studied by Joy (1945) are really solar-type pre-main-sequence stars, we have been presented with the opportunity to directly observe conditions that may have prevailed at the beginning of our own solar system. The principal defining characteristics of T Tauri stars currently in use (besides their late spectral types) are kinematic association with molecular complexes and presence of strong ($W_\lambda \gtrsim 100\,\text{m}\text{\AA}$) lithium absorption at $6707\,\text{\AA}$. Both characteristics presumably reflect the youth of T Tauri stars. $H\alpha$ emission, the historical defining criterion (Herbig 1962*b*), was shown over the last few years to signal only the most active fraction of young low-mass stars, now referred to as classical T Tauri stars (CTTS). Many late-type young stellar objects with $W_{eq}(H\alpha) \lesssim 10\,\text{\AA}$, discovered in X-ray surveys (see Walter et al. 1988; Feigelson et al. 1991), do not stand out at optical wavelengths but are relatively strong X-ray emitters

($L_X \approx 10^{-3} L_{bol}$). They are called weak-emission line T Tauri stars (WTTS) or sometimes naked T Tauri stars (NTTS), and may be several times more numerous than CTTS. The dividing line between these subclasses is somewhat arbitrary and ill defined; we suggest a physical division in Sec. V. The basic properties of WTTS are reviewed in the Chapter by Montmerle et al. Here, we are concerned mainly with properties and models of CTTS. Extensive reviews of these stars have recently appeared by Bertout (1989) and Appenzeller and Mundt (1989).

CTTS exhibit a number of spectral anomalies. In addition to H α and Ca II lines, the higher Balmer lines are often also seen in emission. In almost half of the CTTS, there is also forbidden line emission of [O I] and, less frequently, of [S II] (Cohen and Kuhi 1979). In extreme T Tauri stars, i.e., in the strongest emission-line cases, many other emission lines of iron, titanium, sodium, helium and calcium are present. Excess continuum emission (over the continuum flux level of main-sequence stars with comparable spectral types) is also quite common, particularly in the ultraviolet and infrared spectral ranges. The infrared excess is discussed in Sec. II. The ultraviolet excess often carries into the optical range, where it "veils" the photospheric absorption lines, sometimes so heavily that their spectral type cannot be determined from low-resolution spectrograms but only from high signal-to-noise, high-resolution data. Compared to their main-sequence counterparts, these stars rotate rapidly (5 to 30 km s⁻¹ or higher), but their rotation is quite slow compared to their breakup velocities (typically 250 km s⁻¹).

CTTS are irregular photometric variables at all wavelengths. The amplitude of the optical variability can be from a few hundredths of a magnitude to several magnitudes, and the lightcurves vary from star to star. The T Tauri class, as defined from spectroscopic characteristics (Herbig 1962*b*), indeed includes stars belonging to all three classes of nebular variables (see Glasby 1974).

There is a remarkable variety of unusual phenomena in T Tauri stars, which all fall into three basic categories: magnetic (chromospheric) activity, outflow phenomena, and accretion phenomena.

A. Magnetic Activity

From the outset, the superficial similarity of the emission spectrum in T Tauri stars to the solar chromosphere has been noted (Joy 1945). The line profiles, however, are typically much broader and more asymmetric than solar lines. Strong surface magnetic activity is established through a number of different diagnostics. The presence of light modulation with a period of a few days on some stars is thought to be a rotational modulation by sunspot-like concentrations of magnetic field in the photosphere; this interpretation is supported by detailed light-curve models in a few cases which suggest substantial surface coverage (Bouvier and Bertout 1989). The traditional chromospheric diagnostic, Ca II emission, is quite strong in T Tauri stars, and in WTTS the Ca II lines appear very much as they do on magnetically active

main-sequence stars. The amount and characteristics of the X-ray emission in WTTS are also entirely consistent with an origin in hot coronae such as those observed in RS CVn systems (see Chapter by Montmerle et al.). This conclusion is reinforced by evidence that the X-ray luminosity is a function of stellar rotation, accepted as a strong indicator of magnetic dynamo activity (Bouvier 1990). Finally, a technique for direct measurements of the total magnetic flux on T Tauri stars pioneered by Basri and Marcy (1991) indicates that it lies at the high extreme of the total magnetic flux seen on young main-sequence stars. Following a suggestion by Herbig (1970), it has been demonstrated that if the stellar chromosphere occurs deep in the atmosphere (at a continuum optical depth at 5000 Å of, say, 0.1 to 1), the fluxes of some emission lines might be reproduced and even the continuum jumps and veiling (Cram 1979; Calvet et al. 1984). Finkenzeller and Basri (1987) showed that differential filling-in of photospheric lines in WTTS is consistent with the deep-chromosphere explanation. The real difficulty with the hypothesis that the radiative excesses seen in T Tauri stars are caused by the presence of a deep chromosphere comes when one evaluates the total amount of excess energy present in the optical spectrum of CTTS with strong emission features. The true stellar photospheric contribution can be estimated by studying the absorption line spectrum (and the extent of veiling thereof). In some cases, the absorption lines are reduced substantially in depth across the spectrum, implying that major fractions or even multiples of the total photospheric luminosity appear as excess continuum light. These large radiative losses cannot be generated by solar-type magnetic dynamo processes alone even if one assumes complete coverage by active regions of the stellar surface (Calvet and Albarrán 1984).

B. Outflow Phenomena

The evidence for mass loss in young stellar objects is covered in the Chapter by Edwards et al. It suffices to recall here that mass-loss rates in the range 10^{-8} to $10^{-7} M_{\odot} \text{ yr}^{-1}$ were derived from simple models for the H α line of a few bright CTTS (Kuhi 1964). DeCampli (1981) was first to emphasize the difficulty for a late-type, low-luminosity star to eject mass at such high rates. He discussed the constraints on outflow models imposed by observations and concluded that although Alfvén-wave-driven winds could conceivably be driving mass losses of a few $10^{-8} M_{\odot} \text{ yr}^{-1}$ in T Tauri stars, no known physical mechanism involving the star alone could account for the strongest CTTS winds. Further computations of H α line profiles as produced by Alfvén-wave-driven winds by Hartmann et al. (1982) demonstrated that turbulent broadening was important in these winds, so that earlier models which neglected this effect systematically overestimated T Tauri mass-loss rates. The fact that only a few CTTS are detected at centimetric wavelengths (see, e.g., Bieging et al. 1984) apparently confirms that their typical mass loss is not greater than, say, a few $10^{-8} M_{\odot} \text{ yr}^{-1}$ in the wind's ionized component. But recent analysis of optical forbidden and neutral lines such as those of sodium have led to the belief that T Tauri winds

are mostly made up of atomic, rather than fully ionized gas, and the derived mass-loss rates soared again to much higher values (see Chapter by Edwards et al.). The exact mechanism by which the wind is driven out and collimated thus remains a major outstanding question in research on T Tauri stars and embedded young stellar objects.

C. Accretion Phenomena

First evidence for accretion in CTTS also comes from the shape of hydrogen line profiles. Walker (1972) identified a subclass of CTTS that he named YY Orionis stars after their prototype, which displayed (at times) inverse P Cygni profiles at their Balmer lines. Interestingly, another common property of these objects is their strong ultraviolet excess, which we now know is related to accretion (see Sec. III). Walker proposed that these stars were accreting matter, either through spherical infall or through disk accretion. Some of the work done in the framework of the spherical infall picture is summarized in the first *Protostars and Planets* book (Bertout and Yorke 1978). High-resolution spectroscopy later demonstrated that matter outflow was prevalent even in YY Orionis stars (see, e.g., Mundt 1984), and the spherical infall picture was abandoned. However, the evidence that mass accretion takes place in a number of CTTS at velocities in the 300 to 500 km s⁻¹ range, i.e., comparable to free fall, is clearly established. Simultaneous accretion and outflow of matter is also hard evidence that a successful model must reproduce. These two constraints originate from studies of YY Orionis stars, which thus appear to be primary test objects for realistic models of T Tauri stars.

Plausible explanations for all the different facets of T Tauri activity have appeared, vanished, and been resurrected several times. Most of the early models that were briefly mentioned above focus on one or the other of the above categories. However, a unifying picture has begun to emerge over the last few years. It involves a magnetically active, solar-type star, surrounded by the circumstellar disk that is the natural outcome of the gravitational collapse of a dense molecular core with nonzero angular momentum. In this picture, both CTTS and WTTS display the characteristic properties of the magnetically active central star, and the specific properties of CTTS result from interaction between the disk and the star. WTTS, on the other hand, have either lost their disks or do not interact with one.

The disk hypothesis has proved fairly successful in explaining many properties of T Tauri stars. The next section provides a review of the current observational evidence for disks, and Sec. III discusses existing accretion disk models compared with observed spectral energy distributions. Section IV deals with spectroscopic tests of the accretion disk model. Finally, Sec. V discusses some of the implications of accretion disks to the evolutionary status of young stars, with Sec. VI giving a summary. The obvious successes of simple disk models should not, however, hide the fact that very little is known about the underlying physics of disks, about the nature of the interaction between disk and star, and about the generation of protostellar winds. The

truly successful paradigm which self-consistently explains all observational facts, particularly the relationship between accretion and outflow, has yet to be worked out. Our aim in the following is merely to point out that the successful model is likely to involve an accretion disk. Whether accretion is driven by viscous torques, as envisioned in current models, or by another mechanism is, in our opinion, still debatable.

II. EVIDENCE FOR CIRCUMSTELLAR DISKS

A primary reason supporting a disk geometry rather than a more isotropic distribution of dust comes from the visual extinction towards T Tauri stars. If the line of sight passed through the amount of dust required to produce the observed infrared luminosity, it would produce much greater extinction than is measured by the optical reddening of the T Tauri stars (Myers et al. 1987). The line of sight therefore must miss most of the dust present, which instead absorbs a fraction of starlight not coming towards the observer and then re-emits it thermally at infrared wavelengths into the line of sight. While for a single system one could be looking through a gap or hole in the dust distribution, the fact that this condition applies to most CTTS leaves little choice but to conclude that the dust distribution is substantially flattened.

A. Direct Imaging

At the distance of the closest star-forming regions such as the Taurus molecular cloud, a solar-system-sized disk (say, 100 AU) subtends an angle of $1''.3$. The theoretical resolution of a 4 m telescope at $2\ \mu\text{m}$ is about a tenth of that. Unfortunately, the portion of the disk which emits thermally in the near infrared is much smaller than 1 AU, so one must rely on detection of scattered light from the whole disk. In order to take full advantage of the increased scattering at shorter wavelengths, one should ultimately employ space instruments like HST. Reaching the diffraction limit on the ground is possible today only in the infrared because the coherence length of atmospheric turbulent elements at these wavelengths is large enough to be corrected for by current technologies (e.g., adaptive optics, interferometry).

Both infrared speckle interferometric and imaging techniques have already begun to provide direct images of circumstellar structures (see, e.g., Beckwith et al. 1985; Monin et al. 1990), but distinguishing between disk and other geometries from deconvolution of the data is difficult. Millimeter-wave interferometry currently provides a resolution of a few arcseconds and has the advantage of directly mapping thermal emission without interference from the star. Sargent and Beckwith (1987) mapped a flattened cool circumstellar structure around HL Tau, but it is much more extended than the solar system. The relationship between this structure and the warmer smaller flattened object "seen" at shorter wavelengths is still unclear. In any case, resolving protostellar disks has become a topic of hot international competition which

should bear fascinating results in the next few years. This topic is also dealt with in the Chapter by Beckwith and Sargent.

B. Spectral Energy Distributions

The suggestion that the CTTS might be accretion disk systems was made by Lynden-Bell and Pringle (1974; hereafter LBP), who foresaw and also worked out the main details of the current paradigm. They developed the theory of flat optically thick viscous disks and showed that an infrared continuum distribution (λF_λ) flatter than a single temperature blackbody would result from the disk presence. It arises because the disk will be hotter nearer the star, due both to the increased absorption of stellar radiation by the disk and to the star's increasing gravity which increases the accretion power. The nearby dust contributes near-infrared light and the farther away cooler dust emits at increasingly longer wavelengths. The spectral slope is predicted by the LBP accretion disk model to vary as $\lambda^{-4/3}$. LBP also suggested that if the star were rotating slowly compared to breakup rotation (pure conjecture at the time), a strong ultraviolet excess would be generated in the boundary layer between disk and star. These ideas did not catch on at first, probably because the infrared and ultraviolet evidence that now makes them compelling was not then available. Thus, the previous edition of this volume (Black and Matthews 1984) shows the community feeling that disks may prove a very useful concept, but presents rather little hard evidence for them even at that time. An analysis of IRAS data by Rucinski (1985) then demonstrated that many CTTS had infrared spectral slopes that were more or less compatible with accretion disk models, and detailed analysis of CTTS spectral energy distributions at ultraviolet, optical, and infrared wavelengths confirmed the validity of the disk paradigm.

On the basis of a statistically significant study of the infrared sources in the ρ Ophiuchi star-forming region, Lada and Wilking (1984) suggested the existence of three main classes of young stellar objects according to their near and mid-infrared spectra: Class I stars are optically invisible and their spectra rise steeply to the infrared; Class II stars look basically stellar in the optical but have infrared excesses which decrease more slowly than a blackbody in the infrared; and Class III stars have very little near-infrared excess. Adams et al. (1987) then proposed an interpretation of these classes in evolutionary terms: Class I are protostellar, embedded objects still surrounded by infalling molecular gas; Class II are more evolved objects with circumstellar disks that have expelled their infalling envelopes with the help of their strong winds (i.e., they are the CTTS); and Class III objects are pre-main-sequence objects (the WTTS) that have lost much of their circumstellar material.

All three classes may actually have disks. The presence of a disk in Class I sources is difficult to assess because the infalling cloud is also still present, but spectral energy distributions of these objects have been shown to be consistent with the presence of disks by Adams and Shu (1986). Infrared sources with flat spectra (in the $\log \lambda F_\lambda$ vs $\log \lambda$ plane) are intermediate between Classes I

and II. Because many of these are not well extinguished, it is likely that a disk is present. The flatness of the spectrum may come from a nonclassical temperature distribution in the disk (see Chapter by Adams and Lin), or reprocessing from dust out of the disk plane (Kenyon and Hartmann 1987). Alternatively, the overall spectral energy distributions of some of these objects might be composite spectra of several unresolved sources, as demonstrated by Leinert and Haas (1989) for Haro 6–10 and by Maihara and Kataza (1991) for T Tau itself. High-resolution infrared imaging of flat spectra sources will help settle this dispute. Most Class I and II objects, as well as a number of Class III stars (see Chapters by Strom et al. and by Montmerle et al.), are detected in the submillimetric and millimetric continua (see, e.g., Beckwith et al. 1990). This is again consistent with the presence of circumstellar matter but does not imply by itself any given geometry of the dust. Detailed models of spectral energy distributions of Class II sources based on the presence of a disk are presented in Sec. III.

C. Spectroscopic Evidence for Disks

Analysis of the optical and near-infrared line spectra of FU Orionis objects gives evidence for the expected differential rotation in the disk (see Chapter by Hartmann et al.). The cool, molecular disks surrounding CTTS do not allow similar analysis. In these objects, the strongest spectroscopic piece of evidence for the presence of a disk comes from a wind tracer, the [OI] and [S II] forbidden lines that form in low electronic density regions. The shape of these optical forbidden lines is typically asymmetric, with the red wing quite diminished or missing. This has been interpreted by Appenzeller et al. (1984) and Edwards et al. (1987) as the signature of mass loss from the star in which our view of the receding flow is cut off by the presence of a disk (see Chapter by Edwards et al.). With a naive analysis, the size of the disk implied by the emission measure in the forbidden lines is about 100 AU, although it might be substantially smaller if the electron density is smaller due to partial recombination.

D. Polarization Maps

Although the origin of linear polarization in young stellar objects has long been a matter of debate, scattering by dust grains recently emerged as the most likely polarization mechanism. Bastien and Ménard (1990) demonstrated that polarization maps of young stellar objects can be understood in the framework of multiple scattering in a disk/lobe geometry. Both the disk size and its view angle can be determined from a comparison of observed and synthetic maps (Ménard, in preparation). So far, this analysis is restricted to embedded sources surrounded by extensive disks. High-resolution near-infrared polarization maps are, however, becoming possible with the advent of 256×256 detectors and adaptive optics, and will soon make it possible to determine the main physical properties of T Tauri disks independently from other methods.

III. MODELS OF T TAURI STARS

A. Basic Assumptions of Accretion-Disk Models

The current model of a T Tauri star consists of (i) a central late-type star surrounded by (ii) a geometrically thin, dusty accretion disk that interacts with the star via (iii) a boundary layer. Model spectral energy distributions emitted by such systems can be computed and compared to observations. The accretion-disk model devised by LBP and Shakura and Sunyaev (1973) assumes that *local* processes induce a viscous coupling between neighboring disk annuli, thereby transporting angular momentum through the disk. Note that there could be other, more global ways of redistributing angular momentum, e.g., through density waves. These are not considered in this model. Once a physical mechanism for transporting angular momentum is specified, the equations governing the disk structure, as well as its evolution in time, can be written down.

The basic angular momentum transport mechanism considered by LBP is kinematic viscosity. In a disk where the gas is rotating differentially, any chaotic motions in the gas will give rise to viscous forces (shear viscosity). Gas particles moving along two neighboring streamlines at R and $R+dR$ with angular velocities, respectively, $\Omega(R)$ and $\Omega(R+dR)$ have different amounts of angular momentum. Random motions then lead to angular momentum transport resulting in a viscous torque exerted on the outer streamline by the inner streamline. This in turn will result in local dissipation of energy by the gas, and hence to mass accretion at a rate \dot{M} that is assumed constant throughout the disk. This assumption is made for convenience only; there is no *a priori* reason why viscosity should adjust itself in such a way as to make a steady-state disk. If one assumes that the disk is not self-gravitating, then its rotation is quasi-Keplerian, i.e., $\Omega = \sqrt{GM_*/R^3}$, where M_* is the stellar mass and R the distance from the star's center. The hypothesis of a quasi-Keplerian disk can be shown to imply that the disk is geometrically thin. The expression for the energy dissipation rate $D(R)$ at $R \gg R_*$ is easily derived from first principles (see Adams et al. 1987). It is

$$D(R) = \frac{\dot{M}}{4\pi} R \Omega \frac{d\Omega}{dR} = \frac{3GM_*\dot{M}}{8\pi R^3}. \quad (1)$$

No assumption regarding the physical properties of the kinematic viscosity is necessary to derive the above equation. If a rotation law other than Keplerian was valid as would be the case, e.g., if the viscous torques were of magnetic rather than kinematic origin, then $D(R)$ would not necessarily be $\propto R^{-3}$.

In order to determine the disk density, one must, however, assume something about the viscosity because its magnitude determines the angular momentum flow. LBP derive the disk density under the assumption that the kinematic viscosity is constant within the disk. Shakura and Sunyaev (1973) derive another analytical solution based on the same basic assumption but viscosity is assumed to be proportional to the local scale height times the local

sound speed, with the proportionality constant (called α) being restricted to values ≤ 1 . Underlying this formulation are the ideas that turbulent eddies cannot be larger than the disk height and that any supersonic turbulence should rapidly become subsonic because of the formation of internal shocks in the disk. Both viscosity prescriptions are *ad hoc* parameterizations that reflect our ignorance of the nature of kinematic viscosity in disks; they give qualitatively comparable results for the run of density with radius.

The disk's temperature structure determines the emitted spectrum. To compute it, one must make an assumption about the radiative transfer. LBP presented their hypothesis that viscous energy released in a given disk annulus is radiated away through both faces of that annulus and that the radial radiative flux is zero. While justified for the optically thick, geometrically infinitely thin disks envisioned by LBP, this assumption must be abandoned in the more complex radiative transfer approaches that are now being developed.

Also important for the disk temperature is the heating by stellar photons. Note that there are two ways in which the central star influences disk properties. Its mass and radius determine the potential well seen by the disk, i.e., the viscous energy dissipation rate, and hence the disk temperature. But the local disk temperature also depends upon the stellar effective temperature, which together with geometrical factors determines the local rate of heating by the central star. Adams and Shu (1986) and others computed the resulting disk temperature at the photospheric level. At large distance R from the star, and assuming that the disk is flat and infinitely thin, one finds that the local rate of heating due to reprocessing of photons originating from a star with radius R_* and effective temperature T_* is

$$F(R) = \frac{2\sigma T_*^4 R_*^3}{3\pi R^3}. \quad (2)$$

This equation must be modified when the disk is not flat (Kenyon and Hartmann 1987; Ruden and Pollack 1991), or when a finite disk atmospheric structure is taken into account (Malbet and Bertout 1991). At large distances from the central star, the above assumptions lead to the following equation for the disk effective temperature $T_D(R)$:

$$\sigma T_D^4(R) = \frac{3GM_*\dot{M}}{8\pi R^3} + \frac{2\sigma T_*^4 R_*^3}{3\pi R^3} \quad (3)$$

where the first term on the right-hand side represents the viscous energy dissipation rate and the second term takes into account the reprocessing of stellar photons. Note that both terms are proportional to R^{-3} in flat, Keplerian disks. This means that it is difficult to determine whether a disk is passive (purely reprocessing) or active (accreting), from the infrared alone. Only when the infrared luminosity is more than 50% of the stellar luminosity (25% for a flat disk) can one be certain that accretion is taking place (see Hartmann and Kenyon 1987a), but in either case, the presence of a disk is indicated.

Analyses by Strom et al. (1988) and Cohen et al. (1989*b*) show that at least the most active of the CTTS can be shown to be accreting on that basis.

Equation (3) describes the temperature far away from the central star. When computing the inner disk structure, one must assume something about the inner boundary of the disk, and more specifically about the way angular momentum is transferred from disk to star. LBP imposed the condition that the star exerts no torque on the inner edge of the disk, which also implies the existence of a boundary layer between the slowly rotating T Tauri stars (typically 20 km s^{-1} at the equator; see Hartmann et al. 1986 and Bouvier et al. 1986*a*) and the inner edge of the Keplerian disk, where matter is circling the star at about 250 km s^{-1} .

The LBP inner boundary condition assumes that the extent b of the boundary layer is much smaller than the stellar radius and that the angular velocity at the inner disk edge is comparable to the Keplerian velocity at the star, i.e., $\Omega(R_* + b) \sim \sqrt{GM_*/R_*^3}$. Energetic properties of the disk/boundary layer system directly follow from this inner boundary condition. One finds for the disk luminosity L_D and the boundary layer luminosity L_{bl} :

$$L_D = \frac{GM_*\dot{M}}{2R_*} = \frac{L_{\text{acc}}}{2} = L_{bl}. \quad (4)$$

One thus concludes that half of the total accretion luminosity L_{acc} is advected from the disk into the boundary layer; this corresponds to the Keplerian kinetic energy rate at the inner disk radius. Now, however, this energy must be dissipated in a small region at the star's equator instead of over a disk many AU in extent. This means that the temperature of the radiating region will be far higher. While temperatures in the disk range from 10 K far from the star to about 3000 K near the star, the boundary layer's temperature will be from 7000 to 12000 K (Bertout 1986; Kenyon and Hartmann 1987), and will radiate in the ultraviolet and visible part of the spectrum. As seen below, this is probably the source of the ultraviolet excess and optical veiling observed in many CTTS.

It should, however, be emphasized here that the LBP inner boundary condition maximizes both the boundary layer's luminosity L_{bl} and its temperature. L_{bl} can be reduced in two ways. First, if the star rotates at some angular velocity Ω_* , then the boundary-layer luminosity is reduced to

$$L_{bl} = \frac{GM_*\dot{M}}{2R_*} - \frac{\dot{M}R_*^2\Omega_*^2}{2}. \quad (5)$$

Second, the boundary-layer size need not be infinitely small. The more general case of a finite boundary layer was recently considered in some detail by Duschl and Tscharnuter (1991), who demonstrated that the fraction of accretion luminosity dissipated in the boundary layer is indeed strongly dependent upon the assumed inner boundary condition. Finally, some of the

accretion energy could be released in nonradiative form, e.g., for driving a wind (see Pringle 1989*a*). One should therefore be aware that all comparisons of observed and computed spectral energy distributions done so far assume that half of the accretion luminosity is radiated away in the boundary layer.

B. Comparisons with Observations

Accretion disks and boundary layers in T Tauri systems have been reviewed several times in the last few years (Basri 1987; Kenyon 1987; Hartmann and Kenyon 1987*a*; Bertout 1989; Bertout et al. 1991*a*). Class II infrared sources turn out to be the best examples of "classical" accretion disks. Their infrared spectra are at least as shallow as demanded by the simple flat disk model; most are actually shallower (see Chapter by Beckwith and Sargent). Rydgren and Zak (1987) showed that the average slope of CTTS infrared spectra beyond $5\ \mu\text{m}$ or so is $\propto \lambda^{-3/4}$ rather than $\lambda^{-4/3}$, which probably means that the simple model discussed above needs refinement. Two basic suggestions have been made to explain the fact that the observed infrared spectra are flatter than the LBP disk model predicts.

Figure 1. The optical depth distribution in a typical T Tauri accretion-disk model. The heavy-lined contour corresponds to a Rosseland optical depth of 1, and successive contours differ by 0.5 dex. In the case illustrated here, the optically thick disk has a diameter of about 20 AU.

The first of these assumes that the disk flares up out of the plane at large radii, thus intercepting (and thermally re-emitting) more stellar photons in the outer parts than in a thin disk. Some flaring is expected even in classical accretion disks because the local disk height H determined from hydrostatic equilibrium scales as $R^{9/8}$. Kenyon and Hartmann (1987) showed that such a geometry would partially explain the infrared discrepancy if the disk remains opaque over its full height. However, flared-up disks do not really do an adequate job of explaining the truly flat infrared spectra. Also, the disks need to subtend a large part of the sky as seen from the star in these extreme cases

and then one would expect a greater incidence of large extinctions in CTTS. Furthermore, Malbet and Bertout (1991) computed the vertical structure of T Tauri disks in a self-consistent manner and found that the optically thick parts of the disk are confined to regions close to the central plane of the disk even if gas and dust remain mixed together for the required length of time, which is another problem. This result is illustrated by Fig. 1, which displays the optical thickness distribution in a typical T Tauri disk with mass-accretion rate $1 \times 10^{-7} M_{\odot} \text{ yr}^{-1}$ as a function of both disk radius and disk height over the midplane. The innermost contour corresponds to Rosseland optical thickness $\log \tau = 1.5$, and successive contours differ by 0.5 dex. The heavy-lined contour corresponds to $\tau = 1$, and thus approximately indicates the physical disk size, here about 20 AU in diameter. In order for the infrared spectrum to steepen up with respect to the usual $\lambda^{-4/3}$ law, the disk should be optically thick all the way out to the outermost contour, which roughly corresponds to $H \sim R^{9/8}$.

The second suggestion, made by Adams et al. (1988), assumes that the temperature distribution in T Tauri disks is flatter than in LBP disks, which implies that the disk's temperature distribution does not result from kinematic viscosity. Following this suggestion, it has become common practice to parameterize the temperature law index and to use different values of this parameter to model infrared distributions of young stellar objects, particularly those with flat infrared spectra (see, e.g., Beckwith et al. 1990). Using the temperature law as a free parameter is equivalent to implicitly assuming that the energy dissipation mechanism in the disk differs from star to star. A possible physical mechanism to accomplish this has been speculated on by Shu et al. (1990), who invoke a lowest-mode gravitational instability which would operate in disks which are more than 0.24 the mass of the star (see Chapter by Adams and Ruden).

At this point, one must conclude that the far-infrared spectral energy distributions of many T Tauri stars do not fully support the hypothesis that T Tauri disks are really classical accretion disks as proposed by LBP, although there are a few stars, such as DF Tau, which fit the classic model very well. A further problem is that the infrared spectrum alone does not allow one to distinguish between passive reprocessing disks and true accretion disks as long as the accretion luminosity is smaller than or comparable to the reprocessed luminosity, i.e., $\dot{M}_{\text{acc}} \lesssim 5 \times 10^{-8} M_{\odot} \text{ yr}^{-1}$.

Why then do we believe that accretion disks actually surround most CTTS even when the infrared luminosity excess is not decisive? The decisive argument comes from the blue and ultraviolet spectral ranges. The excess light there has all the properties expected of boundary-layer emission. At the same time, the accretion only occurs near the equator of the star and so avoids the problems that a strong accretion shock over the entire star posed for spherical accretion models. Even more important, the amount of energy available depends solely on the accretion rate and not on the star's resources. This resolves the mystery of how the photospheric spectrum can be so veiled in some cases.

The disk paradigm explains naturally the observed correlation between the respective amounts of infrared and ultraviolet excesses. Even the widespread observations of Balmer continuum emission jumps can easily be explained if the boundary layer is optically thin in the Paschen continuum (Basri and Bertout 1989). Of course, there are still questions regarding the actual geometry and extent of the interface region between disk and star, and to what extent it dissipates energy in nonradiative forms (e.g., material motions). For example, the maximum velocities present in the boundary layer are similar to those seen in the broad emission-line components, suggesting that the broad emission lines are partly formed in the boundary layer and connected regions; this is a topic of current work (see Sec. IV).

There are fairly few free parameters in the simple models that have been analysed so far. Some are associated with the star itself: the stellar mass, effective temperature and radius. In principle, these are all known from the comparison of the position of the star in the Hertzsprung-Russell (HR) diagram, with stellar pre-main-sequence evolutionary tracks. In practice, only the stellar temperature is known with reasonable accuracy. Even that is somewhat uncertain because some temperature estimates are based on the optical colors of the system, with no consideration of the boundary layer's effect on them. Other spectral-type estimates based on stellar spectral features should be more reliable. The effect of disk accretion on the luminosity of the system makes it difficult to estimate the stellar radius precisely. An additional constraint on the radius is provided when both the rotation period (through starspots) and the projected rotation velocity (through spectral line broadening) are known. These constrain the radius and inclination jointly. The mass is also uncertain, because the evolutionary tracks themselves are somewhat uncertain (Sec. V), and among the lower mass stars the convective tracks are crowded together. The central star is typically 0.5 to $1.3 M_{\odot}$, with a radius from 1.5 to $3.5 R_{\odot}$ and luminosity several times that of the Sun.

Another parameter not directly related to the disk is the external extinction to the system. It is difficult to distinguish between circumstellar extinction caused by dust which is near enough to the star to reprocess optical light into the infrared, and true extinction which is due to dust far enough away that the light is fully lost from the beam. A distinction must be made between them, because the latter changes the bolometric flux observed, while the former merely redistributes energy from one wavelength to another. Neither is directly associated with the disk, because a flat disk is unlikely to remove any light coming directly from the star toward the observer. Extinctions are estimated from the reddening of the observed light compared to the expected stellar intrinsic spectral energy distribution. Obviously the presence of the boundary layer makes such determinations uncertain, as its intrinsic spectral energy distribution is now not known *a priori*.

In addition to those, there are several parameters associated with the disk itself. Of these, the mass and size of the disk are not really a concern because it is assumed that the disk is optically thick, and that its size is sufficiently

large not to affect the infrared spectrum. Of course, if one were to consider the spectrum down into the sub-millimetric range these parameters become important, along with details of the grain opacity (see Chapter by Beckwith and Sargent). Another parameter in the disk is the value of the α parameter which is a measure of the strength of turbulent viscosity in the disk. Here there is little theoretical guidance. The largest values derived theoretically are of order 10^{-2} from convection (Lin and Papaloizou 1985). Inferred values of α range up to unity, or greater in cataclysmic variables (Lin et al. 1988). Basri and Bertout (1989) found that setting α to unity was acceptable for most cases, although for lower accretion rates it might easily be of order 10^{-1} to 10^{-2} . They adopted the philosophy that it should not be used as a free parameter, but fixed arbitrarily at a certain value. For optically thick disks, this leaves the mass accretion rate as the main free parameter for the disk. The other parameter associated with the disk is the inclination of the disk plane to the line of sight, which acts primarily as a scaling parameter on the observed flux, due to foreshortening.

Bertout et al. (1988) compared quasi-simultaneous sets of data in the ultraviolet/optical and optical/near-infrared ranges to synthetic spectra emitted by models of a T Tauri system made up of a late-type active star, an accretion disk and its boundary layer. They found that typical T Tauri disks are optically thick over most of their surface so long as $\alpha \leq 1$ and that the spectral energy distribution of typical CTTS can be reproduced from about 0.2 to $10 \mu\text{m}$ if emission from the (isothermal) boundary layer is confined to an equatorial region with width comparable to the local disk scale height ($\sim 2\%$ of the stellar radius).

Positive aspects of this simple model are its self-consistency and its small number of free disk parameters (essentially the disk mass-accretion rate and view angle), while a major drawback is the assumption of an optically thick boundary layer. Observed Balmer jumps indicate that the Paschen continuum is at least partially optically thin. Basri and Bertout (1989) therefore computed monochromatic gas opacities in the boundary layer, which is again assumed to be isothermal. They made the boundary layer width δ_{BL} an additional free parameter (rather than α) needed to control the optical depth, and computed emergent spectral energy distributions that they compared to observations of the Balmer and Paschen continuum regions. While the head of the Balmer continuum is optically thick in these models, the Paschen continuum is partially optically thin and the Balmer jump consequently appears in emission. A similar analysis by Kenyon and Hartmann (1990) leads to similar results. An example of the observations and fit to them for DF Tau appears in Fig. 2.

Line emission from the Balmer lines with high quantum number appears consistent with optically thick line emission from the boundary layer. The emitting area is at most a few percent of the stellar surface area. There is obviously a more extended region of emission which contributes to the flux in the lowest members of the Balmer series, as these are predicted to have very little emission contrast in the simple boundary-layer model.

Figure 2. Simple disk model fits for the classical T Tauri star DF Tau. *Upper panel:* The solid lines are spectrophotometry (with a gap in data near $\log \lambda = -4.3$) and the composite model fit in the optical range. The dashed lines are flux from the disk (lower right) and an optically thin boundary layer. The lower faint line is a model stellar spectrum by itself. The parameters discussed in the text have been chosen to give a good fit. *Lower panel:* The same model in the optical and near infrared. The data points are simultaneous photometric fluxes from the star, and the lines are as in the upper panel. Note how the star is not the dominant contributor to the light on either side of the optical range.

C. Derived Disk Parameters

Modeling the spectral energy distributions of T Tauri stars allows one to derive key parameters such as the accretion rate and disk mass. Finding accurate mass-accretion rates from the disk onto the star is important because: (i) if sufficiently high, accretion is expected to affect the evolution of the star in the HR diagram (Kenyon and Hartmann 1990); (ii) one also expects that accretion of disk matter (which possesses high specific angular momentum) will affect the evolution of rotation in CTTS; and (iii) there is growing evidence of a relationship between mass accretion and mass loss (Cohen et al. 1989*b*; Cabrit et al. 1990; Chapter by Edwards et al.). The efficiency of mass gain/loss conversion is important both for understanding the mass-loss mechanism and for issues (i) and (ii) above. By assuming a classical disk model, mass-accretion rates ranging from a few times 10^{-9} to a few times $10^{-7} M_{\odot} \text{ yr}^{-1}$ can be determined from models of individual stars (Basri and Bertout 1989). Crucial questions remain about the validity of these values: are they highly dependent on the assumed disk model, and are they more or less unique, or can we find several solutions leading to the same spectrum but with very different mass-accretion rates? These questions are discussed in detail by Hartmann and Kenyon (1987*a*), Basri and Bertout (1989), Bertout and Bouvier (1989) and Bouvier and Bertout (1991).

Bertout and Bouvier (1989) studied the uniqueness problem by constructing maps of the quantity $1/\chi^2$, which measures the goodness of the fit between observed and computed spectral energy distributions, for all possible pairs of parameters. They used 6 computational parameters: the stellar radius R_* , the visual extinction in front of the system A_V , the inclination angle i , the accretion rate \dot{M}_{acc} , the viscosity parameter α , and the width δ_{BL} of the emission region associated with the boundary layer. In their analysis of DF Tau, for example, the best solutions (with high $1/\chi^2$) span a small range of mass-accretion rates: $\dot{M}_{\text{acc}} \sim 1 \text{ to } 2 \times 10^{-7} M_{\odot} \text{ yr}^{-1}$. It thus appears that the mass-accretion rate can be estimated within a factor of 2 from these models. This result stems from the fact that the mass-accretion rate primarily reflects the relatively well-determined quantity of integrated excess flux in the near infrared.

The two parameters α and δ_{BL} contain most of the assumed physics for the disk and boundary layer. Given the large range of parameter values that the solution spans, it is reassuring that best fits to the overall spectrum (also including the Balmer jump) were obtained for values $\alpha \sim 1$ and $\delta_{BL}/R_* \sim 0.02$. This appears physically reasonable and gives us some confidence both in the validity of the underlying disk physics and in the α parametrization. Even more reassuring, the best fits produce continuum veiling compatible with the observed amount.

Similar computations were made for 10 CTTS (using new simultaneous data sets to be published by Bouvier, Basri and Bertout spanning the ultraviolet to the near infrared) in the spectral-type range K1–M1. They yield an average

mass-accretion rate of $\langle \dot{M}_{\text{acc}} \rangle = (1.4 \pm 1.2) \times 10^{-7} M_{\odot} \text{ yr}^{-1}$. Because these systems are rather variable (due to unsteady accretion?), observations from the ultraviolet, optical, and near infrared must be gathered at the same time to make confident determinations of system parameters.

Approximate estimates of the mass and maximum radius of CTTS disks can be made by modeling the spectral energy distribution in the sub-millimeter and millimeter range, using the sharp turnover of the spectrum that occurs in that spectral range because the outer disk becomes optically thin. Adams et al. (1990) and Beckwith et al. (1990) recently presented such computations, based on the assumption discussed above that the temperature distribution in the disk is a free parameter that can be adjusted to get an overall fit to a given spectral energy distribution. While this *ad hoc* assumption introduces some uncertainty in derived disk masses, the main source of uncertainty stems from lack of knowledge of dust opacities in the millimeter range: depending on the assumed opacity law, mass estimates can vary by up to 1 order of magnitude. One thus finds that masses of CTTS disks may range from $<10^{-2}$ to perhaps as much as $1 M_{\odot}$.

IV. SPECTROSCOPIC DIAGNOSTICS OF DISK ACCRETION

It is clear from the last section that further observational constraints on the parameters of the disk models will be very helpful. One clearly relevant accretion diagnostic is the amount of spectral veiling (actually the amount of excess continuum light) in the optical spectral lines. The strong broad optical emission lines are a second such diagnostic; they should in principle reflect the physical properties of the region where the mass loss originates.

A. Spectral Veiling

Veiling is defined by

$$r(\lambda) = \frac{f_{\text{obs}}(\lambda)}{f_{*}(\lambda)} - 1 \quad (6)$$

where f_{obs} is the observed flux and f_{*} the photospheric flux. It can be estimated by comparing the veiled (observed) spectrum with an appropriate spectral standard. One then finds that all the same lines are present and in the same ratios, but all the line depths are reduced in the CTTS. This was done quantitatively at one wavelength by Hartmann and Kenyon (1990), and over a broad spectral range for one star by Hartigan et al. (1989a) and for an extensive sample of stars by Basri and Batalha (1990) and Hartigan et al. (1991). Their efforts yield excess light as expected from accretion disk models, with wavelength dependence as predicted by hot boundary-layer models. The excess light does not show features unexpected for the optically thin emission that has been postulated.

A measurement of veiling is useful for several reasons. It allows one to correct the observed spectrum for nonstellar emission independent of extinction corrections. This allows in turn a proper estimation of the extinction from

the remaining reddened stellar spectrum (Hartigan et al. 1991), and thereby a constraint on the radius of the star (assuming distance is known). It also fixes the level of the boundary-layer emission. Thus, one should demand that disk models produce the observed veiling in detail, constraining the boundary-layer temperature and size along with the extinction, accretion rate and stellar radius. Obviously veiling by itself does not determine all these parameters, but inasmuch as it acts as a further constraint on disk models, it significantly improves the uniqueness of solutions. As veiling is the result of a particular disk model rather than an input parameter, there is no *a priori* guarantee that models which fit the overall spectral energy distribution best will also give the right veiling value.

In their detailed study of DF Tau, Bouvier and Bertout (1991) compare model predictions with empirical average veiling values of 1.6 ± 0.3 at 5000 \AA and 1.0 ± 0.3 at 6500 \AA (Basri and Batalha 1990). The acceptable solutions that were found for the disk parameters, after the χ^2 minimization procedure mentioned above, produced veiling values ranging from 1.55 to 1.9 at 5000 \AA and from 0.6 to 0.75 at 6500 \AA , in fair agreement with the observations although they were not obtained simultaneously with the spectral energy distributions. Veiling varies in time by factors which can be as large as 10 in some stars (Basri and Batalha 1990). In order to take full advantage of this additional constraint on the models, it is thus mandatory to measure veiling at the same time as the spectral energy distribution.

Basri and Batalha (1990) and Hartigan et al. (1990a) showed that the measured veiling has the relation to infrared excess expected if both are due to accretion and also that $H\alpha$ emission flux is closely related to veiling. Cabrit et al. (1990) and Bertout et al. (1991b) showed that the emission lines in general are correlated with infrared excess, as expected from accretion (and not from a chromospheric origin).

B. Broad Emission Lines

$H\alpha$ in particular has the breadth and profile expected from a moving extra-stellar region, yet it remains one of the least understood aspects of the T Tauri phenomenon and one of the most fascinating because of the variety of line profiles and their temporal changes. First statistics of line shapes were presented by Kuhi (1978) in the first volume of *Protostars and Planets* (Gehrels 1978) and by Ulrich and Knapp (unpublished catalog). It has recently become possible to monitor emission lines spectroscopically with high resolution and signal to noise, which will hopefully allow clarification of our understanding of the emission lines in the next few years. A first important result of this monitoring is the fact that the $H\alpha$ line comes in three basic shapes.

1. The most common is broad emission with fairly symmetric far wings extending to 200 to 400 km s^{-1} and a blueshifted absorption feature near 100 km s^{-1} that usually does not go below the continuum. This yields emission peaks with the red usually brighter than the blue.

2. Less common is a more or less flat-topped emission feature, possibly with central absorption that can be unshifted or shifted to either side.
3. Finally there are fairly symmetric triangular (more sharply peaked than gaussian) shaped emission lines, often with little or no absorption.

These shapes can be seen in the other Balmer lines (although for these, the absorption goes more often below the continuum) and in other strong emission lines. The weakest of these seem to have a preference for the triangular shape with little absorption. The large degree of symmetry seen in broad lines argues for a substantial orbital or turbulent component in the velocity broadening. Although the origin of triangular lines is still controversial, such shapes may well arise due to variable turbulent velocities of comparable brightness (Basri 1990). In some cases (see, e.g., Basri 1987), especially in weaker lines like the Ca II infrared triplet or He I lines, one clearly sees both a low-lying broad component and a narrow, undisplaced emission peak. The less active stars tend to show only the narrow component. It is tempting to associate this component with the chromosphere or with filled magnetic loops on the star.

The variability of broad emission lines is puzzling. The same line can have quite a stable appearance in some objects, while in others it undergoes large intensity changes with little change in its profile (e.g., H α in DF Tau); and still again in others, it changes its shape dramatically. Figure 3 shows an example of H α line profile variations seen in twice nightly observations of DR Tau and obtained by Basri with the 24" coude feed and the Hamilton echelle spectrograph at Lick Observatory. They show that the intensity of the line varies substantially within a few hours, and also that the absorption velocity structure is quite changeable. The appearance of a true P Cygni absorption feature is ephemeral, as is the more usual lower-velocity feature common to T Tauri stars. This means that these features arise in a fairly small region themselves, and the mass outflow is probably very clumpy and changes its structure.

A smooth axisymmetric outflow is probably not a good model, although it may be a useful first approximation. The blue-displaced absorption components do not vary as much as the emission intensity and probably arise in a larger, more distant region. One can look for correlated changes in accretion and outflows in such data, which could establish a direct connection between them. As another example of an extreme case, the same Ca II line in the same star (RW Aur) has shown all three basic shapes discussed above (Bertout et al. 1991*b*), which may mean that they are compatible with different manifestations of a common underlying structure. The Balmer decrement can be very large, i.e., H α can be much brighter than the higher Balmer lines relative to the local continuum. This probably means that H α arises from a substantially larger geometrical area than other Balmer lines. These lines can vary in intensity and shape on time scales down to an hour or less (see, e.g., Mundt and Giampapa 1982; Basri 1990), indicating that they most likely arise in small regions quite near the star.

Figure 3. A time series of $H\alpha$ profiles from the classical T Tauri star DR Tau. The dotted line in each panel is the preceding profile repeated for comparison. The numbers are the Julian date (without the initial 244), corresponding to 27–31 Oct. 1989 (twice nightly). Each profile is in the same continuum units, and all the abscissas are stellar rest velocities from -500 to 500 km s^{-1} . The profile has both low and high velocity blueshifted absorption for the first half of the run, with the typical simpler T Tauri profile in the latter part. There is a pronounced P Cygni character on 7827.1 JD, and almost no absorption at 7830.6 JD. The red wing is much less variable than the blue side or peak. The total equivalent width is also rather variable, due to changes in both absorption and emission levels.

The boundary layer is an obvious candidate for the line emission region (Basri and Bertout 1989), as it is small, fast moving, turbulent, and energetic. However, inverse P Cygni line profiles seen in YY Orionis stars indicate infall velocities of several hundred km s^{-1} which cannot arise in the boundary layers of classical disk models, where accretion velocities are restricted to the subsonic. It is our intuition that strong stellar magnetic loops may interrupt the flow of the disk within a few stellar radii of the surface, generating the shocks, turbulence and heating that we have been designating as the boundary layer. Flow down such tubes could reach near free-fall velocities, and a modulation of the accretion (emission intensity or veiling) with the stellar rotation period

would establish that the emitting region was in the interface between star and disk. There have already been a few reports of “hot spot” modulations (see, e.g., Bertout et al. 1988; Simon et al. 1991) which could be interpreted as accretion columns onto magnetic stellar regions.

It may well be the same thing to say that the lines arise in the boundary layer (now being used in the less restrictive sense of the interface region between star and disk) or that they arise in the base of the wind. In this picture, some material would accrete down through the magnetic loops, while other material would be turned back and flung out in the T Tauri wind. Some relevant theoretical ideas on this still controversial view can be found in the Chapter by Königl and Ruden. The development of this picture, where magnetohydrodynamic processes are probably dominant, will be a major task of the coming decade.

V. IMPLICATIONS OF DISKS AND ACCRETION

One must be careful about what is meant by “classical” T Tauri stars and “weak line” T Tauri stars, because there is really a continuum of stars between the two classes as defined by $H\alpha$ strength. If there is (i) a substantial near-infrared excess (and this is best measured from 2 to $10\ \mu\text{m}$) compared to the flux expected from a star alone, (ii) Balmer continuum emission, or (iii) strong $H\alpha$ emission (say more than $10\ \text{\AA}$ equivalent width in a late K star), then we conclude from the evidence discussed above that an accretion disk is present. Its presence could serve as the (physical) definition of a CTTS. Note that accretion is the crucial part of this definition. Stars without disks or with disks which do not reach their surfaces will appear as WTTS, while a lack of excess emission at any wavelength is required for the star to truly be a naked (and thus diskless) T Tauri star.

The exact relationship between CTTS and WTTS is unclear at present, and work to clarify it should be encouraged as it is one major key for understanding the formation of low-mass stars. A crucial fact is that WTTS are well intermingled with the CTTS both spatially and on the HR diagram (i.e., temporally). Also, the WTTS have lithium lines similar to the CTTS (Strom et al. 1989*e*; Basri et al. 1991) after correction for continuum veiling. This result also points toward similar ages in the two populations. Furthermore, the distributions of rotational speeds in WTTS and CTTS are similar (see Feigelson et al. 1991). These findings are curious because if steady-state accretion proceeds during a sizable time, then disk accretion could contribute a significant fraction of the stellar mass in CTTS, with noticeable consequences in the star’s evolution, and should also alter its angular momentum history. Königl (1991) has suggested that if the stellar magnetic fields are strong enough and stretch well beyond the corotation radius, the disk will not transfer much angular momentum to the star anyway.

Current estimates based on classical convective-radiative evolutionary tracks indicate that accretion disks last up to a few Myr (Strom et al. 1989*d*;

Chapter by Strom et al.), and are a relatively common phenomenon among young solar-type stars, with perhaps less than one-half and more than one-fifth of them appearing currently as CTTS. This is cause for optimism if one had been hoping that planetary systems are a relatively common phenomenon, although it remains to be seen how many of these "solar nebulae" actually give rise to planets.

Two reasons make it difficult at this point to estimate the actual amount of mass that is ultimately accreted by the star even if we were optimistic enough to believe that the average mass-accretion rates derived from our disk models were representative of accretion during most of the CTTS phase. First, it is becoming increasingly clear that either the disk or the boundary layer is also driving the strong wind that characterizes the CTTS phase (see Chapter by Edwards et al.). Second, disk lifetime estimates depend crucially on the validity of the convective-radiative evolutionary tracks, which may not be relevant for accreting CTTS. The evolution of mass-accreting pre-main-sequence stars was recently computed by Stringfellow (1989), who indeed finds that their paths in the HR diagram bear little resemblance to classical convective-radiative tracks. Furthermore, even if classical tracks are approximately correct, previous determinations of the position of CTTS in the HR diagram (see, e.g., Cohen and Kuhi 1979) did not take into account the presence of the disk and must, therefore, be regarded as uncertain by a factor of 2 or more. These issues have been addressed most directly by Kenyon and Hartmann (1990). For these reasons, age estimates of T Tauri stars based on the HR diagram appear suspect, as do derived disk lifetimes.

Even though the absolute age of T Tauri stars is doubtful, we assume here the conservative point of view that pre-main-sequence stars sharing the same region of the HR diagram have similar masses and ages, i.e., that young stars do not loop through the HR diagram during pre-main-sequence evolution. The observational evidence reviewed above then implies that accretion has little effect on the global stellar properties, perhaps because most of the disk matter is turned into a wind rather than accreted and/or because disk lifetimes are shorter than estimated on the basis of classical evolutionary tracks. Several different possibilities can then be envisioned for the evolutionary status of CTTS and WTTS:

1. WTTS may simply be CTTS which have stopped accreting. Of course, every CTTS must eventually lose its accretion disk because main-sequence stars are never observed to have active disks. But if all WTTS were once surrounded by disks with comparable physical properties, WTTS should be older than CTTS on the average, which is not the case. Thus, data demand a range in disk masses and lifetimes that may represent a variety of initial conditions for star formation.
2. Alternatively, WTTS may be young stars which never had disks. Some of the WTTS are near the "birthline" for optically visible stars and so may never have been CTTS if one believes in the validity of Stahler's (1983a)

scenario. The existence of Class III radio sources deeply imbedded in the core of the ρ Ophiuchi cloud where the expectation is that they are very young, might also support this possibility (see André et al. 1987).

3. Another possibility is that many T Tauri stars go through CTTS and WTTS phases several times during early pre-main-sequence evolution. In this picture, one could speculate that disk instabilities lead to a large range of recurrent eruptive phenomena from FU Orionis events down to “normal” T Tauri aperiodic variability or even weak-lined phases. Temporal spectroscopic changes seen, e.g., in RY Tau, where the optical spectrum can range from pure absorption to relatively strong emission, perhaps support this hypothesis.

These are probably the three most conservative scenarios for the evolution of CTTS/WTTS. If it turns out that the evolution of T Tauri stars in the HR diagram is very different from what we think today, more radical options follow. Obviously, much remains to be done to test all possibilities. Realistic (magnetohydrodynamic) simulations of T Tauri systems’ evolution would of course be extremely useful, but because of the complexity of this approach, less ambitious projects such as investigations of the stability and evolution of protostellar disks and boundary layers are welcome first steps. An observational approach to these problems based on systematic spectroscopic and photometric monitoring of some T Tauri stars is also possible, and will offer some clues about the basic physical mechanisms of aperiodic variability in pre-main-sequence objects.

VI. CONCLUSIONS

Both direct and indirect evidence that visible young stars are sometimes still surrounded by disks is now available. Disks seem to be found around a substantial fraction of newly born low-mass stars, and apparently are the agents responsible for their continuum excesses in the ultraviolet, optical and infrared, for their strong broad emission lines, and indirectly for their strong winds.

Unified steady-state accretion-disk models have been constructed which self-consistently and simultaneously satisfy many of the observational constraints which differentiate CTTS from normal stars. The disk has dimensions comparable to our solar system and contains perhaps 0.01 to 1.0 M_{\odot} of dust and gas. The overall continuum shape and observed luminosity between 0.1 and $10\ \mu\text{m}$, as well as the Balmer jump and some emission-line fluxes, can be accounted for by simple disk models. The disk is optically thick at these wavelengths, but the boundary layer is often partially optically thin. The accretion rates lie between 10^{-8} and $5 \times 10^{-7}\ M_{\odot}\ \text{yr}^{-1}$ for the CTTS. The models are both very simplified and parameterized, and do not do a good job of matching the slope of the infrared continuum beyond $10\ \mu\text{m}$ without some modification to either the disk geometry or internal heating mechanisms.

While first results on the stability of the boundary layer and on the detailed structures of both boundary layer and disk are now becoming available, more work is needed on some fundamental aspects of disk theory, particularly on the angular momentum transport mechanism, as well as on details of the interaction between disk and star and on the production of protostellar winds. High-resolution infrared imaging, as well as high-resolution spectroscopy in the ultraviolet, optical and near infrared, will provide major constraints for further work along these lines.

Accretion disks appear responsible in some way (along with the resulting strong mass outflow) for most facets of the "T Tauri phenomena." None of these characteristics hold for the weak emission-line T Tauri stars, and therefore the presence of an *accretion* disk delineates the difference between the two classes of young stars. The underlying stars are probably similar in both cases, and both exhibit very strong magnetic activity. The accretion disks may well be examples of "solar nebulae" that hold the exciting potential for allowing current observations relevant to the planetary-formation process.

ENERGETIC MASS OUTFLOWS FROM YOUNG STARS

REINHARD MUNDT

Max-Planck-Institut für Astronomie

Energetic winds emerge from young stars in two seemingly distinct stages of evolution: the youngest known stars still deeply embedded in their molecular cloud cores and their progeny, the optically visible T Tauri and Herbig Ae/Be stars. In the first section, we focus on winds from low-mass optically visible T Tauri stars, and show that (1) the presence of energetic T Tauri winds is coupled with the presence of solar system-sized circumstellar disks which are optically thick in their inner regions and that (2) it is likely that these disks are in a state of mass accretion and that the source for the T Tauri winds probably derives from the innermost region of the accretion disk. We conclude this section by noting that energetic T Tauri winds are unlikely to be the primary agents in the final clearing of gas and other debris in forming planetary systems, as the cessation of energetic winds apparently coincides with the cessation of inner disk accretion. We then compare the wind energetics of the optically visible classical T Tauri stars and their presumed precursors, low-luminosity embedded infrared sources with molecular outflows. It is a common misconception that T Tauri winds are fundamentally different from, and less energetic than, those from embedded infrared sources, where fast neutral winds are thought to drive molecular outflows. While many of the outward manifestations of the outflows from embedded infrared sources and classical T Tauri stars differ, it is shown that they possess remarkably similar wind velocities, and wind energy and momentum fluxes when objects of the same bolometric luminosity are compared. In addition, optical outflow diagnostics, such as collimated jets and Herbig Haro objects, are found associated with both types of objects. Both also possess spectral energy distributions which require a contribution from an optically thick circumstellar disk. These similarities in outflow and disk properties suggest that energetic winds from both embedded sources and T Tauri stars share a common origin. Finally we examine one of the outflow diagnostics shared by the optically visible classical T Tauri stars and the embedded infrared sources—the spatially extended optical outflows characterized by collimated jets and Herbig Haro objects. While these optical phenomena do not dominate the wind energetics, their collimated structures, extending up to a parsec from their source, raise important issues in the quest to understand energetic mass outflows from young stars. We review the current observations of jets and Herbig Haro objects emerging from young stellar ob-

jects, including their morphology, kinematics, formation and propagation, and discuss their relation to other outflow phenomena.

I. INTRODUCTION

The ubiquity of energetic winds from the youngest known stars, deeply embedded in their molecular cloud cores and believed to be in a state of vigorous mass accretion, suggests that the energetic winds are as intrinsic a part of the star formation process as is gravitational collapse. In fact, it has been suggested that a star cannot form without them: they may provide the only means for a collapsing and rotating object to shed sufficient angular momentum to grow to stellar dimensions (see Chapter by Shu et al.; Hartmann and MacGregor 1982). An additional impact which these energetic winds may have on forming stars is reversing the infall of core material and thereby determining the final mass of the star (Shu et al. 1987). Energetic winds also affect the circumstellar environs by dispersing remnant core material and providing pressure support to parent clouds.

In addition to the embedded sources, energetic winds are also observed from optically visible pre-main-sequence stars of ages on the order of a few million years, including both those low-mass stars which exhibit strong excess emission at all wavelengths, known as classical T Tauri stars (Chapter by Basri and Bertout) and their higher-mass analogs, the Herbig Ae/Be stars (see Catala 1989). T Tauri winds are widely invoked, in the case of our own youthful Sun, as a means of clearing debris from the solar nebula during the early stages of planet formation (Horedt 1978; Elmegreen 1978*b*).

In this review we discuss energetic winds from these two seemingly distinct phases in the evolution of young stars, focusing primarily on the more thoroughly studied low-luminosity ($\leq 100 L_{\odot}$) sources. Although the wind signatures from low-luminosity embedded infrared sources and optically visible classical T Tauri stars (CTTS) can be very different, they possess remarkably similar wind velocities, mechanical energies and momentum fluxes. Collimated jets and Herbig Haro (HH) objects are found associated with both types of object. Both possess spectral energy distributions that require a contribution from a solar system-sized optically thick circumstellar disk. Evidence is beginning to suggest that the powering mechanism for the energetic winds from both the embedded infrared sources and the CTTS derives from the same source, namely energy released in the innermost regions of a circumstellar accretion disk.

In Sec. II, we address the issue of the powering mechanism for energetic winds from young stars by focusing first on T Tauri winds, because these optically visible stars have spectral energy distributions which are most easily separated into a stellar and a disk contribution. By examining both wind and disk diagnostics for the T Tauri stars we show (1) that energetic winds are *only* present in those systems with optically thick circumstellar disks; (2)

the energy source for the T Tauri winds is non-stellar in origin and probably derives from the innermost regions of an accretion disk; and (3) energetic T Tauri winds are unlikely to be the final clearing agent for gas and other debris in forming planetary systems, as the cessation of energetic winds in T Tauri stars apparently coincides with the cessation of disk accretion.

In Sec. III, we compare the wind energetics from low-luminosity embedded infrared sources, where fast neutral winds drive molecular outflows, with those from the optically visible CTTS. We show that the winds from these sources are comparably energetic when objects of similar bolometric luminosity are examined. Winds from both types of objects are likely to derive from an energy source related to disk accretion.

In Sec. IV we discuss the spatially resolved optical outflows from young stars: jets and HH objects. These outflow signatures, found both from embedded sources and from the youngest optically visible CTTS and Herbig Ae/Be stars, are highly collimated, enigmatic structures which delineate regions where the energetic wind is being shocked, often along the axis of the larger-scale bipolar molecular outflow. Their morphology, kinematics, formation and propagation is discussed, and their relation to other outflow phenomena examined.

II. THE T TAURI STARS

A. Classical and Weak Emission T Tauri Stars

Optically visible low-mass pre-main-sequence stars with ages $\leq 10^7$ yr show spectral energy distributions of modestly reddened, late-type photospheres overlaid with varying degrees of excess X-ray, ultraviolet, optical, infrared and radio emission. Those with the strongest emission excesses were the first low-mass pre-main-sequence population to be identified, largely on the basis of strong H α emission detected in objective prism surveys, and are known today as the “classical” T Tauri stars (CTTS; Joy 1945; Herbig 1962*b*; Bertout 1989; Appenzeller and Mundt 1989; Chapter by Basri and Bertout). For decades, the source of the excess emission from the CTTS remained elusive, although the possibility that it was fundamentally stellar in origin, deriving from a youthful analog of a solar-type magnetic dynamo seemed very plausible (Herbig 1970; Bertout 1989). However, repeated attempts to account rigorously for the emission excesses with active chromospheric models fell short in the more extreme members of the CTTS class, leaving nagging doubts regarding the general applicability of this picture (Calvet et al. 1984; Calvet and Albarran 1984). Recently, the discovery of a significant population of additional low-mass pre-main-sequence stars with masses and ages overlapping those of the CTTS but with much weaker emission excesses (the “weak” emission T Tauri stars, WTTS) allowed the CTTS to be viewed in a new perspective (Walter et al. 1988; Strom et al. 1989*d*; Montmerle and André 1989).

Although these two groups share similar masses and ages and appear nearly identical in terms of their stellar properties (see Sec. II.D), the CTTS possess energetic winds, diagnosed by “P Cygni-like” profiles at $H\alpha$, Ca II and Na D (Kuhi 1964; Hartmann 1982; Mundt 1984) and more recently, by broad blueshifted low excitation metallic forbidden lines of [OI] and [SII] (Appenzeller et al. 1984; Edwards et al. 1987). Some also show spatially extended optical outflow diagnostics, as is discussed in Sec. IV. None of these wind signatures are found in their less demonstrative siblings.

Additionally, the CTTS possess other emission excesses not shared by the WTTS. These excesses include: (1) infrared emission from $\lambda = 1 \mu\text{m}$ to 1 mm that can only be explained as originating in a flattened optically thick solar system-sized circumstellar disk (Rucinski 1985; Adams et al. 1987; Kenyon and Hartmann 1987; Bertout and Bouvier 1989; Chapter by Beckwith and Sargent); (2) optical and ultraviolet continuum “veiling” emission which has been attributed to boundary layer emission arising as material from the inner regions of a Keplerian accretion disk falls onto the slowly spinning star (Lynden-Bell and Pringle 1974; Basri and Bertout 1989, also see their Chapter; Hartigan et al. 1989*b*, 1990, 1991).

In the following sections we first examine the wind diagnostics and the determination of the mass loss rates for the CTTS, then present the evidence that energetic T Tauri winds are found only in those stars with optically thick circumstellar disks, and finally present evidence that the T Tauri winds likely derive from a source related to disk accretion.

B. Wind Diagnostics and Mass Loss Rates from T Tauri Winds

Strong winds from CTTS have long been inferred on the basis of “P Cygni-like” profiles in optically thick lines of hydrogen, Na D, Ca II and Mg II (Kuhi 1964; Hartmann 1982; Mundt 1984; Imhoff and Appenzeller 1987). However, determination of mass loss rates from these optically thick lines presumably formed in the dense inner wind ($r < 5R_*$), has been plagued by the sensitivity of these lines to the thermal and dynamic properties of the wind (DeCampli 1981; Hartmann 1986). Modeling efforts have also been hampered by the wide variety of line profile shapes found at $H\alpha$, with between 10 to 20% showing classic type I P Cygni structure.

The most common $H\alpha$ profile is the type III, with broad wings and a blueshifted reversal, at a velocity less than that of the blue emission wing. A representative type III line profile from the CTTS, DO Tau is shown in the upper left panel of Fig. 1. The line is strong, with broad symmetric wings, and is cut by a deep reversal with a centroid velocity of about -100 km s^{-1} . While the depth and velocity of the central reversal vary among the observed stars, one characteristic common to $H\alpha$ in all CTTS is the broad, symmetric emission wings. It has been suggested that a large turbulent component in the inner wind, as would occur if MHD waves were dominant in this region, might account for this symmetry (DeCampli 1981; Hartmann et al. 1982).

Spherical wind models have met with some success in accounting for

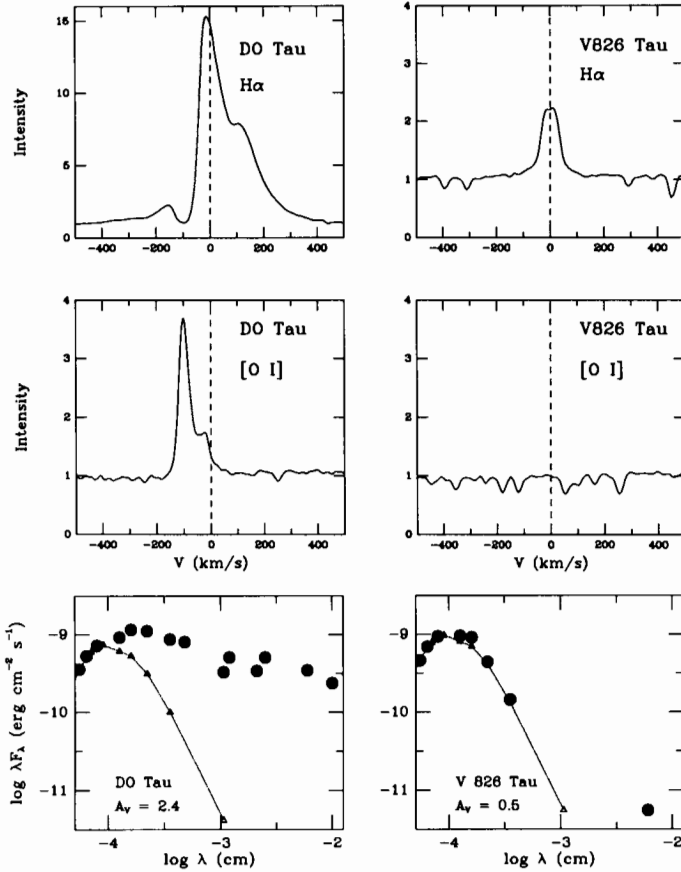

Figure 1. Representative H α and [O I] λ 6300 line profiles (Edwards et al. 1989) and de-reddened spectral energy distributions (K. Strom, unpublished) for the CTTS DO Tau and the WTTS V826 Tau. The line profiles are plotted as relative intensity against velocity, measured with respect to the stellar rest velocity. The open triangles connected by dotted lines in the spectral energy distributions represent the expected stellar contribution to the luminosity.

the fluxes in the hydrogen and low excitation metallic lines (Hartmann et al. 1982,1990; Natta et al. 1988; Natta and Giovanardi 1990). In these models, the atomic rate equations and radiation transfer equations for optically thick lines of several different elements are solved in an expanding spherical wind. Those stars with the most reliably determined mass loss rates are those with deep blueshifted Na D absorption features, representing $\sim 10\%$ to 20% of the CTTS, and requiring \dot{M}_w on the order of $10^{-7} M_\odot \text{ yr}^{-1}$ (Natta and Giovanardi 1990). Lower-mass loss rates, on the order of $10^{-8} M_\odot \text{ yr}^{-1}$, seem to be more representative of the class (Hartmann et al. 1990).

A nagging problem with the spherical wind models is their difficulty in reproducing the line profile structure in the optically thick lines such as $H\alpha$. While the models of Hartmann and collaborators have been able to generate a type III P Cygni profile in a spherical wind characterized by both an expansion and a turbulent velocity, the blueshifted absorption is too broad and deep to be representative of most CTTS spectra, especially in the higher Balmer lines. Recent investigations by Calvet et al. (1991*b*) calculate hydrogen line profiles in an optically thick cone wind, as might be expected for a wind arising in the inner part of an accretion disk or a boundary layer. The strong aspect dependence of the resultant line profiles provides a simple means of producing a variety of profile types, many of which are qualitatively similar to those observed.

In addition to the optically thick hydrogen and permitted metallic lines with wind signatures, the low excitation forbidden lines common in CTTS spectra are also important wind diagnostics. These optically thin lines are formed in low-density, shock-ionized outflowing gas far from the star ($r > 1$ AU), as determined from the density-sensitive [S II] lines and the forbidden line emission measure (Appenzeller et al. 1984; Edwards et al. 1987). A representative [O I] $\lambda 6300$ Å line for the CTTS DO Tau is shown in the middle left panel of Fig. 1. While the forbidden lines are also broad, their width is considerably less than the $H\alpha$ lines, indicating that they are formed well beyond the turbulent inner wind region, after the wind has reached terminal speed. Evidence supporting this is provided by the correspondence in velocity of the maximum in the blueshifted forbidden line emission with the absorption reversal at $H\alpha$. Particularly noteworthy is the lack of redshifted emission, characteristic of nearly all T Tauri star forbidden lines, which is attributed to occultation of the receding hemisphere of the outer regions of the outflow by a highly flattened, opaque circumstellar disk.

While the forbidden lines, with fluxes presumably proportional to wind mass loss rates, are important diagnostics of CTTS winds and disks, quantitative mass loss rate determinations from these optically thin lines are not feasible due to uncertainty regarding their formation mechanism. Several suggestions have been put forth to account for the re-heating of the outer wind regions to the requisite temperatures for forbidden line emission, including oblique shocks as winds impact outer, raised disk surfaces (Hartmann and Raymond 1989), ambipolar diffusion (Safier and Königl 1991, in preparation), or shocks in spatially unresolved collimated jets (Kwan and Tademaru 1988; Edwards et al. 1989; Mundt et al. 1990).

C. Coupling of Winds and Disks in T Tauri Stars

A comparison of wind and disk diagnostics for a representative sample of low-mass pre-main sequence stars in the Tau-Aur star-forming complex reveals the intimate relation between these two aspects of T Tauri activity. Wind/disk relations have been explored by various workers (see, e.g., Strom et al. 1988; Cohen et al. 1989*b*; Cabrit et al. 1990; Bertout et al. 1991*a*; Hartmann 1990;

Hartmann and Kenyon 1990). In what follows, the discussion of wind/disk relations is based on an unpublished set of sky subtracted echelle spectra from the KPNO 4 m Mayall telescope and published infrared photometry for 40 stars of comparable age (< 10 Myr), spectral type (K7/M0 or cooler), and inferred mass ($\sim 1 M_{\odot}$), which cover the full range of emission excesses found among the (classical to weak) T Tauri stars.

For wind diagnostics, we use the equivalent widths of $H\alpha$, probably formed, at least in part, in the inner wind region, and $[O I] \lambda 6300 \text{ \AA}$, from the outer reheated wind. In Fig. 1, we display representative $H\alpha$ and $[O I]$ profiles from stars at opposite extremes of the emission excesses characterizing the T Tauri stars. The $H\alpha$ and $[O I]$ profiles for the CTTS DO Tau, discussed in the previous section, show evidence of energetic winds. In contrast, the same lines in the representative WTTS, V826 Tau, of the same spectral type and apparent age, show no evidence for energetic winds. In the WTTS, the $H\alpha$ emission, weak, narrow and symmetric, is presumably chromospheric in origin (see Walter et al. [1988] for additional examples of $H\alpha$ profiles in WTTS). The $[O I] \lambda 6300 \text{ \AA}$ line is not seen (equivalent width $< 0.02 \text{ \AA}$). Note also the greater depth of the photospheric features in V826 Tau, which are filled in by continuum “veiling” in DO Tau.

Disk diagnostics are provided by the infrared excess emission from these young stars. The lower panels in Fig. 1 contrast the reddening-corrected spectral energy distributions for the representative CTTS and WTTS. The significant infrared excess for the CTTS must originate in a region that covers a wide range of temperatures, from photospheric values down to 100 K, extending close to the stellar surface, yet still providing a relatively clear line of sight to the star (see Chapter by Basri and Bertout). In contrast, essentially photospheric emission out to at least $10 \mu\text{m}$ is found for the WTTS.

For a simple diagnostic of the inner disk, we use the near infrared $K - L$ color of the stars in our sample (see Kenyon and Hartmann 1990). This color index provides a means of probing two distinct aspects of TTS inner disks: (1) whether the inner disk is optically thin or thick (Chapter by Strom et al.); and (2) the radial temperature gradient in the inner disk. Only the former aspect is discussed here; the latter, which depends on accretion disk physics, is discussed in the following section.

The discrimination between an optically thin or thick inner disk depends on whether $K - L$ is less or greater than ~ 0.3 to 0.5 . For the range of spectral types represented here, the photospheric $K - L$ colors should all be constant, $\sim 0.2 \pm 0.1$, and extinction corrections will be small. When inner disk material is present, the relative contribution of disk to photospheric emission will increase between $2.2 \mu\text{m}$ and $3.4 \mu\text{m}$, so that $K - L$ becomes progressively redder as the disk optical depth increases. Thus TTS with optically thin inner disks will have $K - L$ values between those indicative of photospheres and those from flat, optically thick reprocessing disks, which have $K - L$ colors between 0.4 ($i = 80^\circ$) and 0.7 ($i = 0^\circ$), depending on the viewing angle (Kenyon and Hartmann 1987, 1990). If the disk is not only optically thick but

is also heated by nonsteady accretion, $K - L$ values can be even higher, as discussed in the the next section.

Figure 2. Evidence for the coupling of energetic T Tauri winds and optically thick T Tauri disks ($K - L > 0.3$) for a representative sample of 40 CTTS and WTTS in Tau-Aur, with spectral types between K7 to M5. In the upper panel (a), a diagnostic of the outer wind, the equivalent width of [O I] $\lambda 6300$, is plotted against $K - L$. In the lower panel (b), a diagnostic of the inner wind, the equivalent width of H α , is plotted against $K - L$. The equivalent widths come from echelle spectra (Edwards, unpublished) and the $K - L$ values are from the literature. Vertical lines connect the same stars observed spectroscopically at different epochs. In both panels, open symbols denote those (WTTS) stars with upper limits on the [O I] equivalent widths, < 0.02 Å.

In Fig. 2 the wind and disk diagnostics discussed above are compared for this sample of 40 T Tauri stars in Tau-Aur (see also Hartigan et al. 1990; Hartmann and Kenyon 1990; Cohen and Kuhi 1979; Strom et al. 1973 for

related figures). This figure discriminates between optically thin and thick TTS disks, and allows one to distinguish between the presence or absence of an energetic TTS wind. In the upper panel, where the equivalent width of [OI] is plotted against $K-L$, it is seen that those stars with $K-L$ values indicative of optically thick inner disks all exhibit forbidden line emission from shock-heated outflowing gas, while those with $K-L$ values indicative of optically thin or absent inner disk material do not. In the lower panel, where the equivalent width of $H\alpha$ is plotted against $K-L$, it is seen that those stars with optically thick $K-L$ values and detectable [OI] have $H\alpha$ equivalent widths ranging from 10 Å to 100 Å while those stars with photospheric $K-L$ values and no [OI] have $H\alpha$ equivalent widths ≤ 10 Å. An examination of the corresponding $H\alpha$ profiles shows that, while stars with optically thick inner disks have $H\alpha$ velocity structure indicative of outflows, the stars with optically thin or absent inner disk material and weaker $H\alpha$ emission have narrow $H\alpha$ lines with no evidence for mass loss, as shown in the example in Fig. 1.

This simple comparison of wind and disk diagnostics for a representative sample of CTTS and WTTS of comparable inferred mass and age demonstrates that *the presence of energetic winds is coupled with the presence of optically thick circumstellar disks* in all stars which were examined. In the next section we will examine the arguments that this is a causal relation, where the optically thick disks appear to be in a state of active accretion, which is likely to provide, at least in part, the energy which is the driving force for T Tauri winds.

The ubiquitous coupling of energetic TTS winds and optically thick inner disks has an important implication for the interaction of T Tauri winds with forming planetary systems: energetic T Tauri winds with mass loss rates of 10^{-8} to $10^{-7} M_{\odot} \text{ yr}^{-1}$ cannot be the final debris-clearing agent in forming solar systems, including our own, because once the inner disk has become optically thin, such energetic winds no longer exist. Presumably it is the WTTS, with optically thin or absent ($r \leq 1$ AU) disks, which are in the process of scouring clean any planetary systems. These stars are still very active by solar standards, however, and should have enhanced analogs of a solar-type wind, as well as other forms of solar activity, producing strong ultraviolet radiation fields and high-speed particle ejection. Detection of the expected lower-density, higher-temperature solar-type winds ($T \sim 10^5$ K) from WTTS will require high-resolution ultraviolet spectroscopy to search for P Cygni features in transition region lines such as N V or C IV. If present, their mass loss rates will be much lower than those characterizing the energetic CTTS winds.

D. Evidence That Energetic CTTS Winds Are Powered by Accretion

While a comparison of the wind and disk diagnostics of the CTTS and WTTS shows that the presence of energetic winds and optically thick circumstellar disks appear to be coupled in low-mass pre-main-sequence stars, a comparison of the stellar properties of these siblings argues for an external, rather than

an internal (stellar) source for the energetic CTTS winds. When WTTS and CTTS of similar inferred mass and age are compared, their apparent underlying stellar structure and surface angular momentum appear similar. Thus their level of internally generated magnetic dynamos would be expected to be similar as well. That this appears to be the case is indicated by examination of the traditional diagnostics of solar/stellar chromospheric and coronal activity (rotational velocities, the presence of dark starspots and the properties of those spots, and the X-ray flux level and its correspondence to the rotational period of the star), which are found to be similar in both the WTTS and the CTTS (see Cabrit et al. 1990; Montmerle and André 1989). Moreover, their stellar activity levels are comparable to those found for evolved stars with similar photospheric temperatures, luminosities, $v \sin i$, and surface gravity, such as the RS CVn stars (Bertout 1989). While both the WTTS and CTTS clearly have significantly enhanced solar-type magnetic dynamo activity, the similar levels in both groups implies that an additional external energy source is required to explain the CTTS winds.

The evidence that CTTS with energetic winds are also surrounded by solar system-sized disks which are optically thick in their inner regions ($r < 1$ AU), suggests that it is the presence of those disks which is somehow responsible for driving the winds. Evidence is growing that the optically thick CTTS disks are in a state of active accretion. A compelling case for accretion is made by the successful modeling of the optical and ultraviolet continuum veiling in CTTS as boundary-layer emission, which is expected at the star/accretion disk interface (Lynden-Bell and Pringle 1974; Bertout et al. 1988; Hartigan et al. 1991; Chapter by Basri and Bertout). Furthermore, the magnitude of this veiling has been found to correlate with the infrared excess from the inner disk (Hartmann and Kenyon 1990). In the remainder of this section, we examine the empirical evidence that links diagnostics of wind energetics with diagnostics of disk accretion, and then briefly discuss some of the theoretical models proposed to account for the dynamical origin of these winds.

If accretion disks, possibly in conjunction with the stellar magnetic field, do provide the energy source for driving CTTS winds, then a correlation of wind mass loss rates \dot{M}_w and disk accretion rates \dot{M}_{acc} , might be expected. Because each of these rates is difficult to quantify, appropriate surrogate diagnostics for \dot{M}_w and \dot{M}_{acc} must be selected which will be proportional to the desired physical quantities. As in Cabrit et al. (1990), we adopt the reddening corrected luminosities for lines presumably arising in the inner wind ($H\alpha$) and the outer wind ($[O I] \lambda 6300$) as diagnostics of \dot{M}_w .

Selection of a surrogate diagnostic for \dot{M}_{acc} is less straightforward, especially as the physics of accretion disks is poorly understood at present. In theory, one could use either the excess luminosity in the optical and ultraviolet, arising in the boundary layer, or the excess luminosity in the infrared, arising in the optically thick CTTS circumstellar disks, to compare with the surrogates for \dot{M}_w . The former is not well determined for a large sample of stars (see Hartigan et al. 1991) and the latter suffers from the complication that

the disk radiation comes from two distinct, but difficult to disentangle, effects, only one of which is \dot{M}_{acc} . The component of the infrared excess luminosity due to accretion, L_{acc} , will be proportional to $\dot{M}_{\text{acc}} (M_*/R_*)$ and will be comparable to the stellar luminosity for a typical T Tauri star if $\dot{M}_{\text{acc}} = 10^{-7} M_{\odot} \text{ yr}^{-1}$ (Kenyon and Hartmann 1987). A second contribution to the excess infrared luminosity will arise, however, in a flat dusty circumstellar disk which will “reprocess” stellar photons into the infrared, with resultant infrared luminosities due solely to reprocessing that can be 25% of the stellar luminosity. Moreover, if pure reprocessing disks have flared surfaces, with surface heights scaling as r^2 , then the infrared excess luminosity from reprocessing will grow to 50% of the stellar luminosity for $z = 5/4$ (Kenyon and Hartmann 1987). The fact that reprocessing T Tauri star disks with variable morphology and inclination can potentially account for ratios of disk to stellar luminosity up to 0.5 requires that this ratio not be the sole discriminant in searching for evidence for disk accretion (Kenyon and Hartmann 1989).

Given these caveats, it is best to explore as many potential accretion diagnostics as possible. A simple test is to examine the relation between the \dot{M}_w diagnostics, the line luminosities of $H\alpha$ and [O I], and $K-L$, an observable quantity. As discussed in the previous section, for optically thick reprocessing disks, this color index will range from ~ 0.4 to 0.7 , depending on aspect. In a classic, steady viscous accretion disk, with $T \sim r^{-3/4}$, $K-L$ values range from 0.4 to 0.9 , depending on both the inclination and mass accretion rate (Bertout et al. 1988; Hartigan et al. 1990). An accretion disk which departs significantly from the standard model in generating its luminosity may have considerably higher values of $K-L$, which will be determined by the radial temperature gradient (see the Chapter by Adams and Lin).

The comparison of the \dot{M}_w diagnostics with $K-L$ is shown in Fig. 3 for the identical set of 40 T Tauri stars in Tau-Aur shown in Fig. 2. When line luminosities rather than equivalent widths are compared with $K-L$, not only do the T Tauri stars sort between the presence and absence of a wind and the optical depth of the disk, as in Fig. 2, but a correlation of the \dot{M}_w diagnostics is seen with $K-L$ as well. While this approach makes no effort to disentangle reprocessing and accretion contributions in the near infrared, the observed correlation of \dot{M}_w diagnostics with $K-L$ beyond the regime allowed either by reprocessing or standard viscous accretion disks ($K-L > 0.9$) rules out reprocessing dominated effects and also suggests that standard accretion disk models are likely to be oversimplifications of the real situation. In the following, we show that the directly observable quantity $K-L$ is also well correlated with two quantities that are likely to be good surrogate diagnostics for \dot{M}_{acc} : the mid-infrared excess luminosity and the ratio of the mid-infrared excess luminosity to the stellar luminosity. This, in turn, will support the suggestion that in CTTS, \dot{M}_w is proportional to \dot{M}_{acc} .

As discussed in Cabrit et al. (1990), isolating the mid-infrared excess luminosity from the total infrared excess luminosity will provide a diagnostic less sensitive to reprocessing effects, and consequently more sensitive to \dot{M}_{acc} .

Figure 3. Evidence for a correspondence between mass loss rates from T Tauri winds and the temperature structure in optically thick T Tauri disks. The dataset and symbols are identical to those shown in Fig. 2; in this case, however, the luminosities of the [O I] and H α lines are plotted against $K - L$. These \dot{M}_w diagnostics are seen to correlate with $K - L$ for the CTTS (filled symbols); the correlation extends to $K - L$ beyond the regime explained either by flared reprocessing disks or classic, steady viscous accretion disks ($K - L > 0.9$).

This follows because of the geometry of flared reprocessing disks; even in a very flared disk, the inner disk ($r < 1 \text{ AU}$; $\lambda = 1$ to $10 \mu\text{m}$) will remain relatively flat, in contrast to the outer disk regions, which can intercept significantly more stellar photons from raised surfaces. Thus the large variations in excess infrared luminosity which can arise due to reprocessing effects alone are most significant at $\lambda > 10 \mu\text{m}$.

In a method similar to that of Cabrit et al. (1990), we have calculated mid-infrared excess luminosities, L_{mir} ($\lambda = 0.9$ to $10.6 \mu\text{m}$) and stellar luminosities, L_{\star} , for the 40 T Tauri stars in Figs. 2 and 3. (In this compilation,

J is the “normalization” wavelength, in which it is assumed that the flux at J is entirely photospheric [see Kenyon and Hartmann (1989); reddenings are from K. Strom].) Figure 4a shows the relation between L_{mir} and $K - L$, and Fig. 4b shows the relation between L_{mir}/L_* and $K - L$.

Figure 4. Evidence for a correlation between $K - L$ and quantities proportional to \dot{M}_{acc} . (a) The mid-infrared excess luminosity, L_{mir} , and (b) the ratio of mid-infrared excess luminosity to stellar luminosity, L_{mir}/L_* . The data and symbols are for the same stars shown in Figs. 2 and 3.

In Fig. 4, it is seen that the observed $K - L$ values for these 40 T Tauri stars correlate remarkably well both with L_{mir} , a quantity which will be sensitive to \dot{M}_{acc} , and with L_{mir}/L_* (which should be limited to values of 0.1 to 0.2 for a reprocessing disk [Kenyon, personal communication]). The extension of the L_{mir}/L_* correlation beyond the regime of reprocessing provides strong evidence that the observed correlations are dominated by effects due to disk accretion. The combination of Figs. 3 and 4 suggests that the surrogate

diagnostics of \dot{M}_w are correlated with diagnostics of \dot{M}_{acc} .

The arguments presented above implicate accretion disks as the source of energetic CTTS winds. However, the physical mechanism by which an active accretion disk might drive an energetic T Tauri wind is still controversial (see Bertout et al. [1991a] and Chapter by Königl and Ruden for a discussion of mechanisms under consideration). The terminal wind speeds of several hundred km s^{-1} suggest that the winds originate in the near-stellar regions of the gravitational potential well.

The possibility that the wind derives from hydromagnetic flows in strong toroidal magnetic fields produced by shear in the boundary layer regions has been investigated by Pringle (1989a). Other possibilities under theoretical investigation include magnetized accretion disks that power centrifugally driven outflows (Blandford and Payne 1982; Königl 1989; Chapter by Königl and Ruden; Camenzind 1990), and an interaction of the stellar magnetic field with that of the inner disk (Shu et al. 1988; Chapter by Shu et al.). Detailed pursuit of each of these models should soon provide sufficient observational diagnostics to begin discriminating among them.

III. COMPARISON OF WINDS FROM LOW-LUMINOSITY EMBEDDED INFRARED SOURCES AND OPTICALLY VISIBLE T TAURI STARS

A. Fast Neutral Winds and Molecular Outflows

Energetic winds emerge from low-luminosity young stars in two seemingly distinct stages of evolution; in addition to the winds diagnosed from the optically visible CTTS described in the previous section, powerful winds also emerge from objects believed to be T Tauri star predecessors—low-luminosity youthful stars still deep in their cloud cores, known as embedded infrared sources (EIR). Like the CTTS, interpretation of the spectral energy distributions of the EIR suggests a contribution from an optically thick circumstellar disk to explain the large mid-infrared excesses. (Adams et al. 1987; Myers et al. 1987; Chapter by Adams and Lin). The likelihood is that the EIR are in a state of vigorous accretion, with low angular momentum material infalling directly onto the stellar surface and high angular momentum material accreting through the circumstellar disk (Shu et al. 1987a).

Unlike the CTTS, however, the EIR with outflows are observed over a very wide range of bolometric luminosities (0.1 to $10^5 L_\odot$), indicating that energetic winds emerge from embedded, forming stars of all masses. The progeny of the higher mass EIR are presumably the optically visible Herbig Ae/Be stars, which appear to share many properties in common with the lower mass classical T Tauri stars, including broad and strong $H\alpha$ lines with velocity structure indicative of mass loss, broad low excitation metallic forbidden emission lines, and large infrared and mm-continuum excesses which are compatible with emission from optically thick circumstellar disks (Finkenzeller and Mundt 1984; Thé et al. 1986; Hu et al. 1989; Dent et

al. 1989; Hamann and Persson 1989; Hessman et al. 1991; see Chapter by Strom et al.). Because mass loss rates and disk diagnostics for these higher-mass analogs of the CTTS are not as well determined at the present time (Catala 1988,1989), in this section we will confine our comparison of the wind energetics from embedded and optically visible young stars to those of low luminosity (see also Sec. IV.E).

The energetic outflows from the EIR are primarily traced by swept-up shells of high velocity molecular gas (tens of km s^{-1}), often exhibiting a bipolar morphology, extending to scales of up to several pc (see Chapter by Fukui et al.). In a few cases, the driving wind interior to the molecular shells has been detected as a very high speed, predominantly neutral wind with velocities on the order of hundreds of km s^{-1} (Lizano et al. 1988; Koo 1989; Margulis and Snell 1989). Additional outflow signatures from EIR include jets and HH objects (see next section) and knots of shocked molecular hydrogen (Lane 1989). The determination of the mechanical luminosities and momentum fluxes from molecular outflows is discussed by Lada (1985).

B. Comparison of Energetic Winds

It is a common misconception that CTTS winds are fundamentally different from, and less energetic than, those from EIR, where fast neutral winds drive molecular outflows. While many of the outward manifestations of the outflows from T Tauri stars and EIR differ, a comparison between the two reveals many similarities. Not only are (1) the wind velocities for the T Tauri winds and fast neutral winds from EIR very similar; (2) jets and HH objects found emerging from both types of objects (see next section); and (3) molecular outflows found from some CTTS (Edwards and Snell 1982; Calvet et al. 1983); but also (4) the wind luminosities and momenta from these two types of objects are similar as well, when objects of similar bolometric luminosities are compared.

The comparison of the wind mechanical luminosities L_w and momentum fluxes \dot{P}_w between T Tauri winds and fast neutral winds from EIR is best made by using molecular outflows as a surrogate diagnostic for the fast neutral wind, as few fast neutral winds have been directly detected to date. The comparison is shown in Fig. 5a and 5b, where L_w and \dot{P}_w are shown as a function of the bolometric luminosity of the source, either EIR (data points) or CTTS (locus within dashed box).

As seen in Fig. 5, *the winds from EIR and from CTTS have similar energies when objects of similar luminosity are compared* (see also Edwards and Strom 1987).

Additionally, some evidence suggests that while the CTTS and EIR winds from objects of similar source luminosity share much in common, in contrast to the CTTS, the molecular outflows swept up by the fast neutral winds from EIR have the momentum, but not the energy originally carried by their driving wind:

1. Close inspection of Fig. 5 reveals that while the average \dot{P}_w of T Tauri winds and EIR molecular outflows for sources of comparable luminosity is very similar, the L_w for the CTTS winds with \dot{M}_w between 10^{-7} and $10^{-8} M_\odot \text{ yr}^{-1}$ appears to be systematically larger than typical values for molecular outflows. If this offset is real, it might imply that the (inferred) fast neutral winds from the EIR are originally comparably energetic to the CTTS winds, but when they impact the wind/molecular shell boundary, momentum is conserved but mechanical energy is not. This conclusion must be viewed with some caution, as the error in determining L_w and \dot{P}_w for the molecular outflows is large (Cabrit 1989).
2. Comparison of the momentum and energy between the fast neutral wind and the swept up molecular shell from L1551 IRS-5 shows that while their momentum fluxes are identical, the energy deposition rate is an order of magnitude greater in the fast wind than in the molecular outflow (Natta 1989). The energy deficit is comparable to that seen radiated away in the far infrared as diffuse emission with a morphology similar to the molecular outflow (Edwards et al. 1986; Clark and Laurejis 1986; Natta 1989). Unfortunately, additional examples of extended far infrared emission from molecular outflows comparable to that found from L1551 IRS5 are not easily studied with the IRAS data, which is too severely constrained in angular resolution and sensitivity (Jarrett et al. 1987; see also Hughes et al. 1989).
3. Comparison of the momentum and energy between directly observed CTTS winds and their accompanying molecular outflows for the two stars in which both are observed (Natta 1989), shows that while the momentum assessed from the optical and molecular line diagnostics for the same star is identical, the wind mechanical luminosities are again more than a magnitude lower in the molecular outflow than in the optically visible T Tauri wind (this follows from the identical \dot{M}_w found for the optical and molecular flows, but wind and outflow velocities differing by an order of magnitude).

This comparison of the EIR and CTTS winds shows no evidence that the winds from CTTS are less energetic than those from their more deeply embedded, and presumably younger, counterparts when objects of the same luminosity are compared. This argues that a similar wind generation mechanism is operating for young stellar objects over a wide range of ages. Further support for similar wind origins from the EIR and the CTTS is given in the next section. The lack of observed molecular outflow diagnostics from the majority of CTTS is likely to be attributed to cleaner circumstellar surroundings, not to less energetic winds.

C. Evolution of Wind and Accretion Disks

The likelihood that the energetic winds from CTTS derive from a process related to disk accretion is based on the correlation of surrogate diagnostics for

Figure 5. (a) A comparison of wind mechanical luminosities for embedded sources with those from optically visible CTTS. The plotted points are data for 69 molecular outflows taken from the list of Fukui (1989) for which published data are available. The locus of (L_w, L_{bol}) points for typical CTTS with mass loss rates of 10^{-7} to $10^{-8} M_\odot \text{ yr}^{-1}$ and wind speeds of 200 km s^{-1} is enclosed by a dashed box. (b) A comparison of wind momentum fluxes for molecular outflows from embedded sources with those from optically visible CTTS. The plotted points are from the same molecular outflows from the list of Fukui (1989) shown in Fig. 4a and the locus of CTTS points for the wind properties in Fig. 4a are shown by the box. In each panel, the dotted line corresponds to a linear fit to the displayed data, illustrating the correlations of L_{bol} with L_w and \dot{P}_w . The proportionalities are very similar to those found by Lada (1985) and Levreault (1988b).

\dot{M}_w and \dot{M}_{acc} in these stars (Sec. II). The embedded nature of the EIR prevents the separation of photospheric and excess luminosities. Thus correlations of \dot{M}_w and \dot{M}_{acc} similar to those presented in Figs. 3 and 4 for the CTTS are not easily made. It is certainly possible, however, that the observed correlation of L_w and \dot{P}_w with L_{bol} for the molecular outflows (Lada 1985; Levreault

1988*b*) shown in Fig. 5 derives at least in part from an $\dot{M}_w/\dot{M}_{\text{acc}}$ correlation, provided that a significant fraction of L_{bol} comes from L_{acc} .

Associating the winds from deeply embedded EIR and optically visible CTTS with the presence of an accretion disk does not speak to the evolution of the wind as a given object emerges from its embedded phase to become an optically visible object. For example, if higher disk accretion rates are found in the earlier EIR phase compared to the CTTS phase, then a given object might evolve down the L_w/L_{bol} relation shown in Fig. 5 as it becomes optically visible. This would follow if L_{bol} is dominated by L_{acc} from infall and accretion luminosity in the EIR stage, overwhelming the stellar luminosity produced by the release of gravitational energy from stellar contraction L_* . Even for the optically visible T Tauri stars, where the stellar and disk contributions can be distinguished, many examples are found where the disk contribution to L_{bol} is comparable to or greater than L_* (Cabrit et al. 1990; Cohen et al. 1989*b*).

As yet we know little about the evolution of the mass loss rate in the energetic wind (which might in turn trace the evolution of the accretion rate through the disk) as a given source moves from an embedded state to an optically visible, but still accreting, object. Study of the spatially resolved optical outflow diagnostics, the jets and HH objects, which are found both from embedded and optically visible sources, gives some insight into the wind (and disk) evolution, as described in the next section.

IV. OPTICAL OUTFLOWS: JETS AND HH OBJECTS

A. Background

When Herbig (1951) and Haro (1952) discovered the first HH objects in Orion, the nature of these nebulous semi-stellar knots with emission line spectra was far from understood although it was clear from the start that they were associated with star formation. Schwartz (1975) was the first to suggest that HH spectra probably arise in the cooling region of a high-velocity shock, the shock itself being located in the wind from a young stellar object (YSO). At the time this idea was put forward, spherically symmetric YSO winds were assumed but later it became apparent that HH objects, far from tracing spherical outflows, instead delineated high surface brightness knots in or at the leading edge of collimated bipolar optical outflows with velocities of several hundred km s^{-1} . The possibility that at least some HH objects result from the interaction of high-velocity jets with their environment was proposed by Königl (1982) who discussed several possible shock excitation mechanisms. That jets are indeed a relatively frequent phenomenon was first demonstrated by Mundt and Fried (1983) and Mundt et al. (1984) with the help of deep CCD imaging of known YSO and HH objects. Because of their spectral similarity to HH objects, these jets are sometimes referred to as HH jets, but the link between jets and HH objects goes much deeper.

We now know that together they delineate those parts of the energetic outflows from YSO with the highest degree of collimation and velocity. They are frequently found along the outflow axis defined by the swept-up bipolar molecular flows, which have velocities that are an order of magnitude slower and are considerably less collimated. In at least two well-documented cases, the axes of the optical and molecular outflows have been shown to be perpendicular to the equatorial planes of 500 to 1000 AU diameter disks traced by dense molecular gas (Sargent 1989). The realization that the optical outflows traced by the jets and HH objects do not carry the energy and momentum necessary to drive the molecular outflows (Mundt et al. 1987) was instrumental in instigating a search for the dominant, neutral component of the winds from embedded YSO; this was carried out successfully by Lizano et al. (1988). More recently it has been realized that HH objects and jets, like molecular outflows, are associated not only with low-luminosity YSO ($L_{\text{bol}} \leq 10^2 L_{\odot}$) but high-luminosity YSO ($L_{\text{bol}} \sim 10^3 - 5 \times 10^4 L_{\odot}$) as well (see, e.g., Hartigan et al. 1986; Poetzel et al. 1989; Ray et al. 1990).

The origin of jets and HH objects and in particular their connection with other outflow phenomena is still controversial. Below we discuss these problems and examine jets and HH objects in detail.

B. Morphology

Both jets and HH objects display a wide range of morphologies. In Figs. 6, 7 and 8 we illustrate the morphological variety among YSO jets. Figure 6 shows an image of the HH 34 jet, which is one of the best examples of a straight, knotty jet emanating from a low-mass YSO (Reipurth et al. 1986; Bührke et al. 1988). Like several other known jets, it is pointing towards a bow shock-like HH object (HH 34S). In this case, we can even observe a “counter bow shock” on the opposite side (HH 34N). Radial velocity measurements show that HH 34N is redshifted, while the brighter object HH 34S is blueshifted. In contrast the HH 110 jet (Fig. 7; Reipurth 1989c) shows strong wiggles and its knots are irregularly spaced. A similar knotty but straight jet is associated with the bright bow shock-like HH object RNO 43N (see Fig. 8).

HH objects also come in a variety of morphologies. For example, some sources are linked with only one small and nearly circular HH object such as HH 57 (Reipurth 1989c), while others are associated with extended and highly-structured HH objects consisting of many condensations, e.g., GGD 37 (Lenzen 1988) or HH 2 (Herbig and Jones 1981).

If one studies a large sample of jets and HH objects the following general features are found:

1. All known jets have a knotty structure and in many cases these knots are spaced periodically or quasi-periodically.
2. Bow shock-like HH objects or bright knots often mark the end of a jet. As discussed below these sometimes rather prominent features are almost certainly the “working surface” of the jet where part of its kinetic energy

is transferred into heat via shock waves. Often these bright features were recorded photographically, and noted as HH objects, long before the first deep CCD studies of their surroundings.

3. Approximately 50% of the flows traced by HH objects and jets are bipolar. Of the remainder, it turns out that normally only the blueshifted components are seen, presumably because the redshifted outflow is directed into the parent cloud and obscured.
4. The full projected opening angles of the most highly collimated flows (e.g., the HH 30 jet) are as small as 1° with aspect (length-to-diameter) ratios of more than 30. Usually, however the opening angles traced by HH objects and jets range from 5 to 20° although in a few cases larger values are known, e.g., V645 Cyg, (Goodrich 1986; Zou and Solf, in preparation).
5. Typically the lengths, velocities and number densities of jets are in the range 0.01 to 1 pc, 200 to 600 km s $^{-1}$, and 10 to 200 cm $^{-3}$, respectively. As their diameter can often be resolved, jet mass fluxes in the range 10^{-10} to 3×10^{-6} M $_{\odot}$ yr $^{-1}$ and mechanical luminosities of 10^{-3} to 50 L $_{\odot}$ have been derived.

The rather complex morphologies of jets and the collimated flows traced by HH objects (e.g., HH 84 or HH 85, Reipurth 1989*b*) and even that of the HH objects themselves may arise in part from the inhomogeneous environment with which the flow interacts. However, factors such as temporal variability of the flow and various parameters (e.g., opening angle) are also certainly very important. Finally, it should be kept in mind that HH objects and jets may not trace all of the outflow from a YSO, because they *only* mark those locations where the *normally neutral* (but highly supersonic) flow becomes ionized via shock waves. The reasons why such shock waves arise are discussed below.

C. The Nature of the Emission from HH Objects/Jets and Their Kinematics

The individual spectra of HH objects show a broad range in the degree of their excitation. Those of high-excitation have spectra characterized by strong [O III] λ 5007 emission but comparatively weak [S II] $\lambda\lambda$ 6716, 6731 lines. The reverse is true for low-excitation HH objects and in many of the latter [O III] is not even detectable. Both high- and low-excitation HH objects show the [O I] $\lambda\lambda$ 6300, 6363 lines but this doublet is much stronger in the low-excitation case.

Böhm (1956), Haro and Minkowski (1960) and other pioneers in the field of HH object spectroscopy quickly realized that the large number of low-excitation lines (e.g., Ca II, [Fe II], [O I] and [S II]) seen in many HH objects cannot be due to photoionization as in a H II region. In the latter, atoms like oxygen, which have a first ionization potential similar to hydrogen, exist almost exclusively in an ionized state; hence [O I] emission is always

Figure 6. A [S II] image of the HH 34 jet and the bow shock-shaped HH object HH 34S from Bührke et al. (1988). Note the extensive wings of HH 34S and its knotty appearance near the apex. At least 12 quasi-periodically spaced knots are visible in the jet within $26''$ from the source and roughly halfway between the source and the apex another bow-shaped knot is seen. The latter observation supports the idea that episodic outbursts are common among optical outflow sources.

relatively weak. The origin of their line emission was to remain a mystery until Schwartz (1975) noted the resemblance of the spectra of HH objects to supernova remnants like the Cygnus Loop and this in turn led him to suggest

Figure 7. A contour plot of the HH 110 jet in $H\alpha$ from Reipurth (1989*b*). Here the positions of the knots seem random and the jet oscillates markedly from side to side giving the jet an overall turbulent or chaotic appearance.

Figure 8. The RNO 43N jet and bow shock in [S II] which again, as in the case of HH 110, shows a very chaotic jet, but somewhat surprisingly, a well-defined bow shock. The projected size of this system is at least 0.3 pc although its source has not been clearly identified.

that HH emission was also due to radiative shocks. The precise geometrical form of such shocks was unclear and still is in some cases. Early models assumed the shocks to be plane parallel (see, e.g., Raymond 1979; Dopita 1978) but, although qualitatively it was possible to reproduce many of the spectral characteristics of HH objects, it turned out to be extremely difficult to fit the wide range of line profiles and ionization species found.

Given the spectral resemblance of HH objects and jets, it is clear that the emission from jets is also due to shocks. Here, however, the shocks cannot be perpendicular to the direction of the flow but instead must be oblique. Otherwise it is extremely difficult to explain why for example high-excitation

lines like [O III] λ 5007 have rarely been observed in a jet, (except perhaps at its terminus) despite some jets having velocities of up to 600 km s^{-1} . Instead, only low-excitation lines are seen implying the presence of oblique shocks with normal velocities of around 30 to 70 km s^{-1} (Mundt et al. 1987; Bührke et al. 1988). Such shocks have been seen not only in laboratory jets but in numerically modeled ones as well (see Norman et al. 1982; Norman 1986; Falle et al. 1987 and references therein). Despite the attractiveness of this model, it should be emphasized that, presumably because of seeing limitations, oblique shocks have never been observed in a jet. The jet emission, which comes from the recombination zone behind the shock, originates in a very thin region; typical values are around 10^{15} cm or 0.4 at the distance of Taurus Auriga (see, e.g., Raymond 1979). The radiative zones of HH objects are of similar size and this accounts for the low filling factors for HH objects (and jets) of around 10^{-2} to 10^{-1} (see, e.g., Böhm 1983). Obviously spatial stratification in the ionized species (Raga 1989) is even harder to observe but it may have been seen in the case of HH 34S (Bührke et al. 1988).

Dyson (1987) has emphasized that if HH emission comes from radiative shocks, then HH objects can be produced in a variety of ways. If this is the case then a unified theory for their origin is not possible. Certainly, HH objects come in several forms. Some, which were first identified photographically, turned out upon deeper inspection with CCDs, to be bright knots within jets. Examples include HH 33/40 (Mundt et al. 1984) and the RNO 43N jet (Ray 1987). Others, such as HH 28/29 (Strom et al. 1974) and GGD 37 (Hartigan et al. 1986; Lenzen 1988), appear to be due to the interaction of a poorly collimated YSO wind with its ambient medium. Perhaps, however, the class of HH objects which have attracted the greatest amount of attention recently from a theoretical standpoint are those resembling bow shocks. This group includes HH 1 (Raga et al. 1988), HH 32 (Raga et al. 1986), HH 34N and HH 34S (Bührke et al. 1988), HH 39 (Mundt et al. 1987), HH 83 (Reipurth 1989*b*) and RNO 43N (Ray 1987). Other examples of HH objects for which a bow shock model seems to be appropriate include HH 47 (Hartigan 1989) and HH 101 (Hartigan and Graham 1987) although applying such a model may be difficult for HH 101 (Hartigan 1989). All of these objects appear to mark the end of outflows and are presumably the regions where the jet flows into the surrounding medium. The bow shock itself is where ambient material is accelerated in the direction of the jet while at an inner (jet) shock, the jet material is decelerated. Work is done on the ambient medium as the shock system moves outward, so the latter is often referred to as the "working surface."

Spectroscopically bow shock-like HH objects and jets differ in two major respects: first, as mentioned previously, mostly low excitation lines are seen in jets whereas bow shock-shaped HH objects display high-excitation lines, at least at their apex. Second, while the oblique shocks within jets produce very narrow emission lines ($\text{FWHM} \sim 10 \text{ km s}^{-1}$), much broader lines (with $\text{FWHM} \sim 100$ to 200 km s^{-1}) are found within bow shock-shaped HH objects.

Both of these differences can be adequately explained by simple bow-shock models (Hartigan et al. 1987; Raga et al. 1986). According to such models, the thermal energy in the post-shock zone is approximately equal to the kinetic energy associated with the component of velocity normal to the shock. Thus the apex of the bow shock is expected to be at a much higher temperature, and hence excitation, than the wings. Moreover it can be easily shown that the maximum width of the emission-line profile from a bow shock has a FWZI (full width zero intensity) $\sim V_{bs}$ where V_{bs} is the velocity of the bow shock (see, e.g., Hartigan et al. 1987). Given the large values of the latter, the broad line widths are not surprising.

Bow shock-shaped HH objects often appear clumpy although the cause of their clumpiness is unknown. It may, for example, be due to thermal instabilities (Innes et al. 1987; Raga and Böhm 1987) or inhomogeneities in the ambient medium. Blondin et al. (1989) have shown that dynamical instabilities could also play a role. According to bow-shock models for HH objects, the highest excitation lines appear near the apex of the shock and this is supported by the observations (Ray and Mundt 1988). Moreover, a property of bow shocks is that, although the shock velocity at the apex may be as high as 250 km s^{-1} , that of the wings is much less. Thus, using lines like the [S II] $\lambda\lambda 6716, 6731$ doublet, which are excited when $V_{\text{shock}} \geq 40 \text{ km s}^{-1}$, one can trace the actual wings out to large distances from the apex. Aside from the bow shock, the inner jet shock, which is in the form of a Mach disk, should be observable in some cases. Hartigan (1989) has shown that the surface brightness of both shocks may be comparable if the contrast in densities of the jet and surrounding medium is not more than 1 or 2 orders of magnitude. This agrees with the spectroscopic observations by Bührke et al. (1988) who found that the terminal shock in the HH 34 jet may contribute significantly to the emission from HH 34S. Moreover the location of the terminal shock appears to have been identified by Reipurth (1989b).

While optical emission lines characterize the spectra of moderate-to high-velocity shocks (40 to 300 km s^{-1}), lower-velocity shocks can be detected using the near-infrared lines of molecular hydrogen (see Lane 1989). Historically, the association between shocked molecular H_2 and HH objects has been known for at least a decade (Elias 1980). However, early studies suffered from low resolution (typical beams had apertures ≥ 5 to $10''$) often making it impossible to locate accurately the position of the H_2 emission with respect to the optical. This situation changed with the availability of infrared array detectors making it possible, for the first time, to map large areas very efficiently. These maps showed (Lane 1989) that the shocked H_2 and optical emission are spatially closely related and that the optical and H_2 line intensities are correlated. Moreover it has been established using high resolution spectroscopy that the velocity structure in the H_2 lines is similar to that of the optical lines but the actual widths and velocities are usually much smaller by at least a factor of 2 (Zinnecker et al. 1989).

In the case of bow shocked-shaped HH objects, one expects the H_2

emission to arise far back in the bow-shock wings where the velocities are small enough ($V_{\text{shock}} \leq 30 \text{ km s}^{-1}$) not to dissociate hydrogen. Somewhat higher velocities may be allowed ($V_{\text{shock}} \sim 50 \text{ km s}^{-1}$) if one assumes the shock is not a classical jump (J) shock but instead is a softer MHD continuous (C) shock (Draine 1980; Draine et al. 1983; Smith and Brand 1990). It is then surprising to see, for example, in the case of RNO 43N (Lane 1989), that some of the H_2 emission comes from the vicinity of the bow-shock apex. One explanation for this might be that the jet contains molecular hydrogen (perhaps due to entrainment) and that this hydrogen passes through the jet's terminal shock without significantly being decelerated as is consistent with the high proper motion of RNO 43N. Moreover a possibly related puzzle is that in some outflow sources, e.g., OMC-1 (Brand et al. 1989) and DR21 (Garden 1987), the H_2 line widths reach nearly 140 km s^{-1} . Certainly such broad profiles are difficult to explain using shocks having simple flow geometries without dissociating molecular hydrogen. In principle, however, these broad profiles can be understood in terms of more complex flow patterns with oblique internal shocks. One way around both problems (see Smith et al. 1991) may be C shocks with high Alfvénic velocities ($\sim 50 \text{ km s}^{-1}$). Whether such values are realistic at large distances from the YSO is a matter of debate; certainly this problem requires further investigation.

H_2 emission from jets has been detected in relatively few cases, e.g., HH 7–11 (Garden et al. 1990), HH 40 (Zinnecker et al. 1989; Lane 1989) and possibly the HH 1/2 VLA 1 jet (Zealey et al. 1989). In addition, a few well collimated H_2 flows have been found with no known optical counterparts (see, e.g., Garden et al. 1990). The origin of the emission, like that of the optical, is presumably due to oblique shocks but whether these might, for example, be due to entrainment (Zinnecker et al. 1989) at the jet boundaries or shocks driven into the ambient medium by the passage of the jet itself (see Cohn 1983) is not known.

As HH objects and jets are at least partially ionized, they are also sources of thermal free-free radio emission. At radio flux, however, scales with the $\text{H}\alpha$ surface brightness, and this is very low, the observed fluxes are very small. Pravdo et al. (1985) detected radio continuum emission from HH 1/2 and from the source of these HH objects (HH 1/2 VLA 1). Tentative marginal detections of HH 12 (Snell and Bally 1986) and HH 101 (Brown 1987) have been reported but the faintness of most HH objects make such observations extremely difficult. Recently, Rodríguez (1989) has claimed that the HH objects associated with high-luminosity stars are easier to detect in the radio continuum because of their high intrinsic luminosity and in spite of their large distances. Examples include HH 80/81 (Rodríguez and Reipurth 1989), and the Orion “Streamers” in L1641 (Yusef-Zadeh et al. 1990). However, only in the case of HH 80/81 is the HH nature of these objects beyond question.

The radio continuum images of the sources of HH 1/2 (HH 1/2 VLA 1) and HH 80/81 (IRAS 18162-2048) are interesting in that they display an elongated jet-like morphology with the major axis directed along the outflow

direction. DG Tau, L1551 and Z CMa (Bieging and Cohen 1985) also show a similar shape, and as argued, for example, by Natta (1989), the spatial coincidence of this radio emission with the observed optical jets suggests that the jet contributes significantly to the radio emission from these YSO. This hypothesis is also supported by the observation that those T Tauri stars which show evidence for optical outflows are much more likely to be radio sources than ordinary T Tauri stars (Bieging and Cohen 1985). Thus in some cases the observed radio emission from T Tauri stars may be due to spatially unresolved jets or some other shock-excited gas associated with outflow.

Both HH objects and flows are sources of ultraviolet line and continuum emission. All observations in this case have come from the IUE satellite and the reader is referred to Brugel (1989) for an excellent review of this topic; here only some salient points are made. From an examination of the ultraviolet line spectrum, it is seen that the optical spectroscopic division of HH objects into low- and high-excitation classes carries over. Objects which are classified *optically* to be of low excitation have only weak ultraviolet lines although fluorescent H_2 emission may also be present at short wavelengths. By comparison, high-excitation objects display C IV λ 1549, [C III] λ 1909 and [C II] λ 2326 in emission. An interesting feature of the ultraviolet spectra of HH objects is the presence of a "strong blue continuum," the existence of which was already known from optical studies (Brugel et al. 1981) although it was not suspected that it would extend so far into the ultraviolet (Brugel 1989). It has been proposed that its origin is two photon H I emission (Dopita et al. 1982) although this mechanism cannot explain the energy distribution of the continuum at short ultraviolet wavelengths (see, e.g., Böhm et al. 1987; Cameron and Liseau 1990). Here Böhm et al. (1987) suggest the destruction of H_2 may play a role.

D. Proper Motions

Determining proper motions is important for two main reasons. First they can be combined with spectroscopic radial measurements as an aid to establishing the true, as opposed to the projected, outflow direction. Second, in the many cases where there is confusion, one can determine the source of the HH emission by tracing its proper motion vector backwards. Of course, because HH objects were discovered approximately three decades before jets, large amounts of proper motion data is available for HH objects but has only recently become available for jets. Studies (see, e.g., Schwartz 1986) show that most HH objects have relatively small tangential velocities (~ 0 to 200 km s^{-1}) but higher velocities are known; for example, the knots within HH 1 reach at least 350 km s^{-1} (Herbig and Jones 1981). Moreover, given the recently discovered very high radial velocities of HH objects and jets associated with high-luminosity YSO (see below), it is clear that much higher tangential velocities remain to be uncovered.

In the case of stellar jets, measurements are confined to determining the proper motions of their bright knots. Although this gives a handle on the

jet velocity (when combined with the known radial velocity), it should be emphasized that the tangential velocities of the knots may often not reflect the jet's true tangential velocity. The knots may, for example, be instabilities and hence move with a velocity that is less than the bulk velocity of the jet (see below). Typical proper motions for these knots are in the range (100 to 300 km s⁻¹) and again we expect the upper limit to increase when data becomes available for higher-mass stars. Examples of jets for which proper motions have been measured include the L1551-IRS 5 jet (Neckel and Staude 1987), the HH 34 system (Eisloffel et al. 1989; Reipurth 1989c), and several of the jets of the XZ/HL Tau region (Mundt et al. 1990). As discussed below, such large tangential velocities rule out steady shocks as the origin of the knots.

E. Dependence of Optical Outflow Characteristics on Source Luminosity

Until recently, most known optical outflows were associated with low-luminosity YSO ($L_* \leq 100 L_\odot$), including both embedded infrared sources and optically visible CTTS. However, given that molecular outflows are common across a wide range of pre-main-sequence stars, it is not surprising that HH objects and jets also occur at the higher-mass end of the YSO spectrum as well. Examples where HH objects have been found associated with high-luminosity sources include M42 (Axon and Taylor 1984), Cep A (Hartigan et al. 1986; Lenzen 1988), V645 Cyg (Goodrich 1986; Hamann and Persson 1989; Zou and Solf, in preparation), AFGL 2591 (Poetzel et al., in preparation), HH 80/81 (Rodríguez and Reipurth 1989; Reipurth 1989c) and the Herbig Be stars LkH α 198 and MWC 1080 (Poetzel 1990). Jets have been reported from LkH α 234 (see Fig. 9), AFGL 4029 (Ray et al. 1990) and Z CMa (Poetzel et al. 1989).

While emphasizing that we are dealing with a statistically small sample, several important points can be made:

1. The optical outflows from high-luminosity stars are in general faster than those from low-luminosity stars. Line profiles of the former may extend from 450 to 700 km s⁻¹ in the wings. In addition, mass loss rates and mechanical luminosities are, as one would expect, larger, scaling roughly with $L_{\text{bol}}^{0.6}$ (see Fig. 10).
2. In some cases, e.g., Cep A and V645 Cyg, the HH emission does not seem to be confined to a well-defined central axis but is instead scattered over a broader range of angles. Such scattered emission could be construed as evidence for a poorly collimated high-velocity wind.

Although several of the high-luminosity YSO with optical outflows are embedded sources, of those that are optically visible (LkH α 198, LkH α 234, MWC 1080, Z CMa and V645 Cyg), virtually all show a Herbig Ae/Be spectrum (Herbig 1960; Finkenzeller and Mundt 1984; Goodrich 1986). Z CMa is the exception as it appears to be an FU Orionis star (Hartmann et al. 1989) deriving most of its luminosity from an accretion disk (see Chapter by Hartmann et al.).

Figure 9. An example of a jet from a high-luminosity pre-main-sequence star LkH α 234. This image of the core of NGC 7129, taken in [S II], also shows the edge of a reflection nebula that has been seen as a cavity in CO. The jet is directed along the axis of this cavity.

Most of the optically visible YSO which do have jets and HH objects are also associated with molecular outflows as well. This is true both for the higher-luminosity Ae/Be stars and the lower-luminosity CTTS (Levreault 1988a; Cantó et al. 1984; Schwartz 1983; Edwards and Snell 1982). In both cases, the fraction of the known population of optically visible sources which display these spatially resolved outflow phenomena is small, indicating that they may be transition objects between the embedded and optically visible phases.

Figure 10. A log-log plot of jet mass flux vs bolometric luminosity of the parent source. The same power-law dependence on L_{bol} is seen as for the mass flux required to drive molecular outflows shown in Fig. 5.

F. The Formation and Propagation of Jets

Although various models have been proposed as to how jets form, there is no consensus on their origin. Raga and Cantó (1989), for example, basing their scenario on the earlier models of Cantó (1980) and Königl (1982), suggest that jets form when an initially isotropic YSO wind is collimated by pressure gradients in its surrounding medium. However, we will argue in Sec. IV.G that the jets come directly from the disks and if this is so then the wind will from the start be bipolar (Pudritz 1988) perhaps leaving the innermost regions of the disk in a poorly collimated form. Subsequent focusing by the magnetic field (see, e.g., Uchida and Shibata 1985; Uchida 1989) or the thermal pressure of the ambient medium may then play a role. With regard to the question as to where the jet is focussed the observations of Raga et al. (1991) and Mundt et al. (1991) are interesting. They have mapped, for some jets, the variation in diameter with distance from the source and found that significant collimation

is often achieved within several hundred AU. Recollimation may even occur on larger scales of several thousand AU. Initial opening angles appear to be quite wide before being reduced to a few degrees by external forces over the range of 10^2 to 10^3 AU.

Early numerical models for jets (see, e.g., Norman et al. 1982) all assumed the jet to be adiabatic. This is strictly only true for extragalactic jets because in YSO jets radiative losses, especially in the region where they form and at their working surfaces, can be significant. En route to the working surface, however, the adiabatic approximation appears to be a good one, as radiative losses at the oblique shocks scales with $(V_{\text{shock}}/V_{\text{jet}})^2$ and thus HH jets can propagate over a large portion of their length without significant energy losses. Nonadiabatic propagating (i.e., time-dependent) jets have been studied by Tenorio-Tagle et al. (1988) and Raga (1988), while the detailed behavior of the head of the jet has been explored by Blondin et al. (1989). As pointed out by Raga (1989), far away from the head, and upstream, a pattern of stationary biconical shocks develops and it has been proposed (Falle et al. 1987) that these be identified with the quasi-periodic knots seen in many jets. Obviously if this were the case one could study these shocks in detail by numerically modeling the flow using steady-state equations; this is essentially the approach taken by Falle et al. (1987). However, it appears that such shocks are not the origin of the knots observed, for example, in the HH34 jet. In the first place, such shocks are predicted to be spaced around $M_j D_j$ apart where D_j and M_j are the jet's diameter and Mach number, respectively. As typical Mach numbers and diameters are about 30 and $1''$, the observed spacings are nearly an order of magnitude smaller than predicted by the stationary shock model. Second, as shown, for example, by the proper motion studies of Mundt et al. (1990), Eislöffel et al. (1989) and Reipurth (1989c), knots within YSO jets move outwards with tangential velocities comparable to their observed radial velocities (i.e., a few hundred km s^{-1}). Thus the shocks certainly cannot be regarded as stationary. A third problem (see Raga 1989) concerns the shock velocities predicted by such models. As we are dealing with crossing shocks, the angle they make with the jet's central axis $\theta \sim \sin^{-1}(1/M_j)$. The shock velocities will then be approximately $V_j/M_j = c_s$ where V_j is the jet's velocity and c_s is the sound speed. Assuming a jet temperature of $\sim 10^4$ K, c_s will have a value of 10 to 20 km s^{-1} and the shock velocity is hardly enough to dissociate molecular hydrogen. At best one could use such models to explain very low-excitation jets.

What then is the origin of the quasi-periodic knots seen, for example, in the HH 34 (Bührke et al. 1988), HH 83 and HH 111 jets (Reipurth 1989c)? Bührke et al. (1988) proposed Kelvin-Helmholtz (K-H) pinching instabilities (see, e.g., Ray 1981) as one possible explanation for the knots but to achieve the correct spacing one required a hot tenuous medium outside the jet. As there is no evidence for the latter, an alternative suggestion is an external medium of similar density that travels at a velocity comparable to the jet. As the knot spacing is determined by the *relative velocity* of the jet and its

ambient medium, the spacing in this case can be much smaller than that for the steady-shock models. Moreover, a K–H model can not only explain why the knots move (as pinching instabilities) but also can explain the wiggles seen in some jets, e.g., HH 30 (Ray et al. 1991) and HH 83 (Reipurth 1989c), through the growth of the K–H helical mode. An alternative proposal (Uchida 1989) is that such wiggles are due to the helical instability of a twisted magnetic field. Here the twist is due to the rotation of the star itself. Whatever the origin of the wiggles, it seems unlikely that they are due to precession (see Uchida 1989, and references therein).

Aside from pronounced wiggles, bipolar jets have also been seen to bend gradually in an S-shaped pattern (Mundt et al. 1990) centered on their source. One explanation for the bends might be a misalignment between the ambient magnetic field and the direction of the jet (Mundt et al. 1990). For this mechanism to work the jet has to have a magnetic field of its own. Although magnetic fields in jets and HH objects seem likely, if only because of their ubiquitousness, firm evidence for their presence is lacking. However, the recent observations by Yusef-Zadeh et al. (1990) of nonthermal emission from an HH-like object automatically implies the presence of magnetic fields in at least one case.

G. Relationship of Optical Outflows to Other Outflow Phenomena

While a coherent picture of the role of energetic winds in the star formation process is beginning to emerge, the origin of the optical parts of the outflows, the jets and HH objects, remains the most enigmatic. Although they do not dominate the energetics of the winds, their compelling morphology, with regularly spaced knots delineating collimated structures extending up to a parsec from their source, and their alignment along the axes of the bipolar molecular outflows, pose important questions to those seeking to understand energetic winds from young stars. In particular, study of these optical outflows may hold the key to understanding the timing of accretion events in the disks which ultimately power the outflows, and to identifying the mechanism which powers energetic YSO winds.

In spite of the fact that the optical outflows possess only a trace of the energy and momentum carried by the energetic winds, it is clear that they must both ultimately derive from the same energy source. Not only are the optical outflows found along the axes of bipolar outflows (and presumably the driving winds) from YSO of all luminosities, but their energetics are seen to scale with the bolometric luminosity of the source in precisely the same way as found for the driving winds. The correlations between wind mechanical luminosities and momentum flux of the molecular flows with the bolometric luminosity of the parent YSO was shown in Fig. 5. Leveault (1988b) has shown that the mass loss rates in the driving wind scale with the source bolometric luminosity roughly as $L_{\text{bol}}^{0.6}$. The same scaling law is also found for the mass loss rates from jets with source luminosity, as shown in Fig. 10 (see also Ray 1991), although the magnitude of the jet mass loss rate for a given L_{bol} is down by a

factor of 30 from that for the driving winds. The fact that such a correlation exists at least over the range 0.1 to $2 \times 10^4 L_{\odot}$ argues strongly for a universal mechanism for powering jets and molecular outflows. (It is interesting to note that one of the jet sources in Fig. 10, Z CMa, is best modeled as deriving most of its luminosity from an accretion disk [see Chapter by Hartmann et al.], further suggesting that jets originate from processes related to disk accretion.)

A puzzle which must be explained by any model of energetic winds from young stars is why the outflows have a dual nature (see Stocke et al. 1988). The evidence suggests that neutral atomic winds surround shock-ionized jets in all outflows from embedded sources. Although the atomic winds have only been directly detected from a limited number of outflow sources, the requirement for them on energetic grounds is compelling (Sec. III). Furthermore, images of many outflow regions seem to require their presence as well. For instance, jets are often seen to emerge from conical nebulae, e.g., HH 34 (Bührke et al. 1988), 1548C27 (Mundt et al. 1984), Z CMa (Poetzel et al. 1989) and L1551 IRS-5 (Stocke et al. 1988) where the morphology of the nebula suggests it has also been blown by such a wind. These “cavities” appear much too large (e.g., LkH α 234; see Ray et al. 1990) to have been cleared by the jets themselves.

There is preliminary evidence that the energetic winds from optically visible CTTS may have a dual nature as well. Interpretation of the velocity structure of the forbidden-line profiles in CTTS has suggested that many of these stars have sub-arcsecond, and therefore as yet spatially unresolved jets, similar in velocity and excitation to those which have been imaged (Edwards et al. 1989; Solf 1989; Mundt et al. 1990). Additionally, Mundt (1988) has pointed out that strong emission line CTTS often show narrow blueshifted sodium doublet (Na D) absorption with modest velocities ($\sim 70 \text{ km s}^{-1}$). This, he proposes, is due to a second, less collimated, wind component.

A comparison of the average dynamical time scales $\bar{\tau}_D$ for the optical and molecular outflows provides strong evidence that episodes of mass loss leading to the formation of jets and HH objects may be intermittent during the time interval when a source is in a molecular outflow phase (Mundt et al. 1990). Values for $\bar{\tau}_D$ are derived by simply dividing the length scale of the observed outflows by their characteristic velocities and then averaging. The average dynamical times for molecular outflows $\bar{\tau}_{DM}$ is found to be larger by at least an order of magnitude than the corresponding value $\bar{\tau}_{DO}$ for optical outflows. Rough estimates of $\bar{\tau}_{DO}$ and $\bar{\tau}_{DM}$ are 10^3 and $2\text{--}5 \times 10^4$ yr, respectively (Mundt et al. 1990). If one accepts that the dynamical time of the molecular outflow is indicative of the total time that the source has been in the outflow phase, then this suggests that optical outflows may be an intermittent phenomenon, perhaps caused by multiple outbursts from the parent YSO, and lasting for about a time $\bar{\tau}_{DO}$.

An alternative approach to this comparison is to measure the number of known optical outflow sources in, for example, Taurus Auriga (Mundt et al. 1987), and to compare this with the total number of known CTTS in this

cloud. If the fraction is multiplied by the typical age of CTTS (see Stahler 1983*a*), i.e., $\sim 3 \times 10^5$ yr, one can obtain a statistically estimated total time scale τ_{SO} during which optical outflows are detectable. Mundt et al. (1987) deduced the latter to be $\sim 2 \times 10^4$ yr which again when compared with $\bar{\tau}_{DO}$ suggests optical outflows switch themselves “on and off” within a period of a few hundred to a thousand years. Note, however, the time scale τ_{SO} may be longer for YSO in a closely knit group (Mundt et al. 1988).

Obviously if jet/HH outflows are intermittent, there should exist a class of CTTS which are potential jet/HH sources but where none are present. Mundt et al. (1990) list several candidate members of this class. Intermittency is also indicated by the observations of Reipurth (1989*c*) and Hartigan et al. (1990) who describe several objects (e.g., HH 46/46 and HH 111) with suggestions of velocity variations in their outflows on time scales of 10^2 to 10^3 yr. These objects show not only a leading bow-shock but a second bow shock structure closer to the source. Such a secondary working surface is also seen in the HH 34 system (Bührke et al. 1988; Fig. 6).

V. SUMMARY AND FUTURE PROSPECTS

The role that energetic winds play in the star formation process is beginning to be understood. Theoretical arguments suggest that stars of all masses form largely by accretion of material through circumstellar disks and that the forming stars cannot accept this high angular momentum disk material unless angular momentum is shed via winds from the inner disk/near stellar regions (Chapter by Shu et al.). Observational evidence presented here suggests that energetic winds, with mechanical luminosities which are a significant fraction of the bolometric luminosity of the source, emerge from embedded, forming stars of all luminosities. We have argued on empirical grounds that these energetic winds must derive their energy from a process related to disk accretion and must originate in the near-stellar regions of the star/disk system. We see that the phase of disk accretion/energetic winds can persist after a star has become optically visible, when it will appear as a CTTS or a Herbig Ae/Be star.

The duration of the disk accretion/energetic wind phase appears to vary among stars of a given mass. This is best seen in the low-mass optically visible stars of ages $< 10^7$ yr, where some objects (CTTS) persist in a disk accretion/energetic wind phase for longer than several times 10^6 yr, while some others (WTTS) have apparently cleared their inner disks, terminating, at least temporarily, the disk accretion/energetic wind phase on time scales as short as 10^6 yr (Strom et al. 1989*d*). By 10^7 yr, apparently all low-mass stars have finished the phase in which disk-related activity is a dominant energy source (see Chapter by Strom et al. for a full discussion of the time scales for disk clearing). Presumably initial conditions in the molecular cloud core, such as angular momentum, or gravitational interactions with close neighbors

in the same star-forming complex are responsible for the observed range of disk-clearing time scales (Pringle 1989*b*).

If the above scenario is the correct one, and much work remains to be done to verify it, then there are some important implications for star and planetary system formation:

1. The energetic winds may be agents for carrying away the significant angular momentum which resides in the disk. This would apply even during the optically visible CTTS phase, in order to account for the identical distribution of $v \sin i$ found for the CTTS, presumed to be accreting material from their inner disks rotating with Keplerian velocities, and for the WTTS, in which disk accretion and energetic winds have halted (Hartmann et al. 1986; Walter et al. 1988).
2. If all stars form largely via accumulation of material through circumstellar accretion disks, they may also have the potential to form planetary systems such as our own. If a planetary system is formed from a circumstellar disk, it is unlikely that energetic winds from a T Tauri star can play a major role in the final debris clearing. This follows from the fact that once the inner disk has become optically thin, energetic winds no longer exist.
3. One must look to the properties of the WTTS to evaluate the impact that a young star will have on forming planets, asteroids and comets. These stars are still very active by the solar/stellar standards of old main-sequence stars, and much work remains to be done to characterize their chromospheric/coronal activity.

The optical outflow phenomena associated with the phase of disk accretion/energetic winds from YSO probably hold important clues regarding the mechanism driving the energetic winds and the timing of accretion events in the disks. These shock-ionized jets and HH objects, while not dominating the wind energetics, can possess remarkable degrees of collimation and extend up to a parsec from their source. In at least a few well-studied cases, these jets emerge perpendicular to the disk planes. The dual nature of energetic winds from YSO is not well understood, but the evidence that shock-ionized jets are surrounded by neutral atomic winds from embedded sources is strong. A similar dual-nature wind may persist during the CTTS phase as well, if the majority of these systems are also characterized by spatially unresolved, but highly collimated jets, as suggested by their forbidden-line structure. The degree to which these neutral winds interact with the circumstellar accretion disks, and thus their direct impact on forming planetary systems before the time of disk clearing, remains to be established.

The dynamical time scale for the optical outflow phenomena and the occurrence of sequential, multiple jets and bow shocks from the same source, provide evidence that large, intermittent increases in mass outflow rates, and possibly disk accretion rates as well, may occur. The largest-scale inter-

mittent accretion/outflow events are probably associated with the FU Ori phenomenon, where a disk characterized by extremely high accretion rates appears to dominate the spectrum of a YSO and corresponding very high wind mass loss rates are also inferred (see Chapter by Hartmann et al.). The recent discovery of a very high-velocity and spatially extended jet from an optically visible YSO that appears to be a Fuori object, Z CMa, supports this interpretation (Poetzel et al. 1989).

High spatial resolution imaging of optical outflow phenomena, either from space or with adaptive optics on groundbased telescopes, should clarify some of the uncertainties associated with the formation and propagation of jets. Ascertaining the degree of collimation of jets on spatial scales of several AU will help constrain models for generating energetic winds from YSO and observing the proper motion of fine structure in the jets might, for example, reveal evidence for angular momentum in these outflows.

Acknowledgments. We wish to thank S. Strom for a critical reading of the manuscript, G. Basri and S. Kenyon for valuable comments and suggestions, and C. Andrusis, L. Ghandour and L. Hillenbrand for assistance in preparation of figures. S. Edwards wishes to acknowledge partial support from the NASA Planetary Program. T. Ray acknowledges support from EOLAS, the Irish Science and Technology Agency.

MOLECULAR OUTFLOWS

We review observations of molecular outflows which mark the earliest phase of stellar evolution. Millimeter-wave observations are compared with optical and near-infrared data, and a general description of molecular outflows is given. In addition, a few sources of both low- and high-mass star formation are discussed in detail. The statistical properties of molecular outflows suggest that this phase corresponds to the main accretion phase of protostellar objects. Models of outflow collimation and acceleration, as well as the contribution of outflows to the mechanical support of molecular clouds against gravitational collapse, are discussed in light of the most recent radio data.

I INTRODUCTION

As stars form inside molecular clouds, the first observational manifestation of the star-forming event is usually the production of an energetic mass outflow. Detectable by its broad mm-wave emission lines, especially CO, the outflowing gas is typically observed to move with velocities of order 10 km s^{-1} , but in some flows, this motion exceeds 100 km s^{-1} . Because the mm-wave emission lines are easily excited by collisions with atoms and molecules at the ambient cloud temperature, these lines can be used to trace the total mass, momentum, and energy contained in cold, accelerated molecular gas. Outflows are frequently associated with other observational signatures of dynamical interaction between high-velocity and ambient gas. Shock-excited optical emission in the form of Herbig-Haro (HH) objects and stellar jets, shock-excited near-infrared emission produced by molecular hydrogen, and mid- and far-infrared cooling line radiation such as that from [O I], [C II], OH, and CO can be used to study gas which has been heated to thousands of degrees Kelvin in outflows and to trace the cooling postshock layers. Since the cool-

ing time for the hot component of molecular outflows is short, typically 1 to 100 yr, the infrared and optical lines trace the present location of shocks and energy dissipation in the flow.

In this chapter, we focus on phenomena which are most likely related to the earliest phase of stellar formation. We use a sample of ~ 150 molecular outflows to describe the characteristics of the outflow phase of pre-main-sequence evolution. In analyzing these phenomena, we rely heavily on CO data, which do not suffer from the effects of extinction. In addition, we use a sample of ~ 230 HH objects which have been discovered so far to infer the characteristics of the shocked material in molecular outflows.

In this analysis, we must be cautious about possible differences between the outflows produced by high-mass and low-mass objects. As noted by Shu et al. (1987a), high-mass stars may reach the main sequence while they are still deeply embedded in molecular clouds because of their short evolutionary time scale. This makes it difficult to discern evolutionary status of high-mass protostars precisely from observations. On the other hand, the longer Kelvin-Helmholtz contraction times associated with low-mass protostars imply that they may end their accretion phase without having reached the main sequence, making it easier to recognize their evolutionary status. Although many of the best-known outflows are produced by high-mass objects, it is outflows associated with low-mass, solar-type stars which are most relevant to the study of solar system formation.

We also discuss the current status of our understanding of three outstanding issues concerning molecular outflows: the acceleration and collimation mechanism, the relation of the outflow phase to the evolutionary status of protostars, and the role that outflows play in cloud support, especially in regions of low-mass star formation.

II RADIO OBSERVATIONS OF CARBON MONOXIDE

A. Searches for CO Outflows

Although various signatures of outflow activity from young stellar objects were recognized during the 1960s, it was the discovery of the widespread occurrence of bipolar CO outflows during the late 1970s and early 1980s which led to the realization that outflows are a fundamental feature of the star-formation process. Between 1976 and 1985, searches for broad millimeter CO emission lines were made toward selected optical or near-infrared objects (Bally and Lada 1983; Levreault 1985); HH objects (Snell and Edwards 1981, 1982; Edwards and Snell 1983, 1984); T Tauri stars (Kutner et al. 1982; Edwards and Snell 1982; Calvet et al. 1983); Ae and Be stars (Cantó et al. 1984); and dark clouds (Frerking and Langer 1982; Goldsmith et al. 1984). These works led to the discovery of ~ 60 outflows as listed by Lada (1985).

Since 1985, unbiased surveys of entire molecular clouds have been carried out by two groups using small millimeter telescopes having relatively large beam sizes ($2'$ to $3'$). These surveys were conducted with the Nagoya 4 m

telescope for Orion, Monoceros, Cepheus and Ophiuchus (Fukui 1988,1989; Fukui et al. 1986,1989,1992, in preparation; Sugitani and Fukui 1988; Sugitani et al. 1989; Nozawa et al. 1991), and with the Texas 4.9 m telescope for Monoceros (Margulis and Lada 1986; Margulis et al. 1988). The Orion-Monoceros region has been most intensively surveyed in an unbiased way. Four clouds have been searched with the Nagoya 4 m telescope, including the Orion A or south cloud (containing L1641 and the Orion Nebula), the Orion B or north cloud (containing L1630 and NGC2023, NGC2024, NGC2068 and NGC2071), Mon R2, and S287, and a fifth cloud, Mon OB1 (containing NGC2264), with the Texas 4.9 m telescope. Figure 1 shows the locations of 36 outflows, including 23 that were discovered by unbiased searches. A new unbiased survey has been made for L1641 with the Bell Laboratories 7 m telescope (Morgan and Bally 1991; Morgan et al. 1991).

Figure 1. Locations of 36 molecular outflows shown as circles superposed on a contour map of ^{12}CO ($J=1-0$) total intensity of the Orion-Monoceros region obtained with the Columbia mm-wave telescope (Maddalena et al. 1986). Hatched areas denote the regions where the outflow sources, newly found by the unbiased survey with the Nagoya 4 m telescope (see, e.g., Fukui et al., in preparation), are located. A dashed rectangle denotes the region of the L1641 dark cloud.

The IRAS satellite opened new opportunities for searches for molecular outflows by identifying embedded young stellar objects by their infrared emission. Several surveys of IRAS infrared sources have been carried out (Casoli et al. 1986; Heyer et al. 1987; Snell et al. 1988; P. R. Schwartz et

al. 1988; Parker et al. 1988; Fukui 1989; Wouterloot et al. 1989; Snell et al. 1990; Wilking et al. 1990; Fukui et al. 1992, in preparation; Morgan and Bally 1991). These, unbiased and IRAS-based surveys in the late 1980s, have discovered another 90 flows, of which 52 were found with the Nagoya survey as listed by Fukui (1989).

In Table I, we summarized mapped or confirmed molecular outflows. It includes 163 outflows published in the literature until June 1991 and/or discovered in the Nagoya CO survey. Out of the 163 presently known outflows, ~ 100 are located within 1 kpc of the Sun. This is about twice the number listed by Lada (1985) to lie within 1 kpc. A typical lifetime of 5×10^4 yr, inferred from Table III in Fukui (1989), implies that the outflow formation frequency is $\sim 6 \times 10^{-4} \text{ kpc}^{-2} \text{ yr}^{-1}$, a value comparable to the formation rate of $1 M_{\odot}$ stars (see, e.g., Miller and Scalo 1979). The total number of outflows expected to lie within 1 kpc of the Sun can be estimated from the data shown in Fig. 1, coupled with extensive mapping of the molecular clouds in which they reside. For three clouds, including the Orion south, S287 and Mon OB1 clouds, the ratio of total cloud mass to the number of outflows found in the cloud is 1700, 3000, and 3000 M_{\odot} /outflow, respectively. If we take 2000 as an average value for this ratio, and a total molecular mass of $6 \times 10^5 M_{\odot}$ lying within 1 kpc of the Sun, the total number of outflows associated with this gas is estimated to be 300. As ~ 100 have been detected so far, 200 remain to be discovered within 1 kpc of the Sun.

B. Physical Properties of CO Outflows

Roughly 85% of CO outflows are bipolar, and almost all are associated with infrared sources. The physical characteristics of the outflows discovered after 1985 are similar to the ones listed by Lada (1985) in his Table III, except that they tend to have lower kinetic energy and lower mechanical luminosity. Of the 52 outflows discovered at Nagoya, 90% have stellar luminosities fainter than $1000 L_{\odot}$, while of the sources listed by Lada (1985), $\sim 60\%$ have $L_{*} \geq 1000 L_{\odot}$, showing that the recent searches have resulted in greater numbers of outflows from low-luminosity objects.

Various physical parameters for CO outflows have ranges as follows: $R_{\text{max}} = 0.04$ to 4 pc; $V_{\text{max}} = 3$ to 150 km s^{-1} ; dynamical age = 1×10^3 to 2×10^5 yr; molecular mass = 0.1 to 170 M_{\odot} ; outflow momentum = 0.1 to 1000 $M_{\odot} \text{ km s}^{-1}$; kinetic energy = 10^{43} to 10^{47} erg; and mechanical luminosity = 0.001 to 2600 L_{\odot} . The large outflow mass indicates that most of the accelerated mass has been swept up from the molecular cloud surrounding the central star rather than originating in mass ejected from the protostar.

The bulk of the mass in molecular outflows is cold. Margulis and Lada (1985) and Snell et al. (1984) used observations of the $J=2-1$ and $J=1-0$ transitions of ^{12}CO and ^{13}CO to demonstrate that in a sample of 7 typical outflow sources, the excitation temperature of ^{13}CO is in the range 10 to 90 K, and is on average colder than the surrounding quiescent gas. Another estimate of gas temperature by using the $\text{NH}_3(1,1)$ and $(2,2)$ transitions indicates gas

^a This table is an extension of that published in Fukui (1989), and includes only mapped outflows published in the literature until June 1991 or discovered in the Nagoya CO survey. 51 of them appear in the list of Lada (1985). The remaining 17 sources in Lada's table (1985) are not included here because they are not confirmed to be outflow by mapping observations. Two sources in Fukui (1989), i.e., IRAS 16442-0930 and L1036, were not confirmed to be outflows and were not included in this table. This catalog was edited by T. Iwata, A. Mizuno and Y. Fukui in June 1991.

^b Positions of IRAS point sources.

^c These sources may consist of several outflows.

^d These are possible candidates for driving sources, and should be confirmed by further observations.

temperature of 50 ± 10 K for NH_3 clumps in the NGC2071 outflow (Takano et al. 1985). However, infrared observations of vibration-rotation lines of H_2 and far-infrared/submillimeter observations of [OI], [C II], [Si II], and high- J CO indicate that outflows contain some warm and hot gas at various temperatures up to ~ 3000 K (Gautier et al. 1976; Watson et al. 1985; Lane and Bally 1986; Jaffe et al. 1987; Jaffe et al. 1989, Boreiko and Betz 1989; Lane et al. 1990). Although the amount of gas traced by these excited species decrease with increasing energy above the ground state, the warm and hot components of outflows may be energetically important because they tend to have larger linewidth than the low- J CO transitions (see, e.g., Persson et al. 1981; Crawford et al. 1986; Stacey et al. 1987). While the warm (≥ 200 K) component of outflows may constitute from $\sim 10\%$ to $>50\%$ of the high-velocity molecular material in at least some sources (e.g., Orion/IRc 2: Storey et al. 1981; Cepheus A: Stacey et al. 1987; DR 21: Jaffe et al. 1989), it seems likely that cold gas is dominant in most molecular outflows.

The high-velocity molecular gas does not fill the volume or projected surface area of outflows. Bally and Lada (1983) and Snell et al. (1984) estimate that the mean projected area filling factor ranges from about 0.01 to 0.8, suggesting that the high-velocity molecular gas is concentrated into clumps, filaments, or sheets. Furthermore, the filling factor appears to decrease with increasing velocity away from the rest velocity of the host cloud.

C. Morphology of Molecular Outflows

1. Degree of Collimation. CO mapping of dozens of outflows with small beams ($10''$ to $30''$ resolution) indicates that the majority are bipolar with a moderate degree of collimation (e.g., L1641-North: Fukui et al. 1988). The ratio of major to minor axis reaches values as high as ~ 10 for the best collimated CO flows such as the recently discovered ρ Oph A flow (André et al. 1990a), and the L1448 flow (Bachiller et al. 1990b). On average, CO outflows subtend a relatively large opening angle as seen from the source ($\sim 10^\circ$ to 50°).

2. CO Lobe Symmetry and Structure. Detailed structural information has been derived from mapping of large angular diameter outflows. Most flows exhibit considerable overlap between red- and blue-shifted lobes. Each flow exhibits unique traits, indicating large variations in both the flow properties and in the structure of the cloud into which it is propagating. The prototypical L1551 flow is neatly bipolar with comparable flux and spatial extent in the red and blue lobes. On the other hand, the flow in Mon R2 is asymmetric with large-scale bends and small-scale wiggles. In some sources, multiple outflow axes or flow reversals with alternating pairs of redshifted and blueshifted lobes are seen (e.g., ρ Oph-East and Cep A, see Sec. IV).

In some outflows, high-velocity CO emission is confined to shells or to the walls of evacuated cavities. In L1551, the accelerated CO is concentrated along the walls of a relatively empty cavity and shows evidence of rotation about the outflow axis (Uchida et al. 1987b; Moriarty-Schieven et al. 1987).

Direct evidence for evacuated cavities has been found in optically thin tracers such as ^{13}CO which show holes in the parent cloud in maps of the integrated emission at the position of the high-velocity lobes (Hayashi et al., in preparation). At a velocity a few km s^{-1} different from the cloud rest velocity, the ^{13}CO emission is concentrated into swept-up shells surrounding the cavities; the highest-velocity ^{12}CO is observed to lie just inside the ^{13}CO shells. In other cases, such as Mon R2, the outflow lobes appear to be filled with accelerated gas, while in Cep A, CO emission is confined to cavity rims in one portion of the flow but appears to fill in the flow volume in other regions. In this way, the CO observational data show considerable variety, making it difficult to model the CO emitting region in detail.

III. OPTICAL AND NEAR-INFRARED OBSERVATION OF OUTFLOWS

High-velocity CO emission, HH objects and shock-excited near-infrared lines of H_2 are complimentary tracers of outflow activity. As shown below, there exists a relatively high correlation among these three tracers in spite of the effects of extinction in the optical and near-infrared lines. While the CO lines trace the bulk of the accelerated gas, the average velocity of this component is low (1 to 20 km s^{-1}). The H_2 lines tend to have linewidths of order 20 to 100 km s^{-1} . The optical lines in HH objects tend to exhibit the highest velocities, with values ranging from less than 100 to over 600 km s^{-1} . Much work still remains to be done in order to understand the relationships among optical, near-infrared, far-infrared and mm-wave emission lines. In the following section, we discuss coincidence of the three tracers on the basis of the most recent catalogs for them, and discuss some aspects relevant to our understanding of molecular outflows.

A. Statistics of Radio, Optical and Near-Infrared Outflow Phenomena

Herbig-Haro (HH) objects are small shock-excited nebulae frequently found in regions of active star formation (see reviews by R. D. Schwartz 1983 and Raga 1989). A catalog of 184 HH objects has recently been presented by von Hippel et al. (1988) and about 45 new HH objects have been reported by Reipurth and Graham (1988), Reipurth (1989*a, c*), Ogura (1990) and Ogura and Walsh (1991). The majority of HH objects occur in groups, with each group probably associated with a specific outflow source. About 230 individual HH objects are catalogued which can be assigned to about 90 individual outflow sources.

Lists of HH objects and CO outflows are necessarily incomplete, making statistical comparisons of these two manifestations of mass loss difficult. Most of the recently discovered HH objects have not yet been searched for CO outflows and, conversely, most of the outflows listed by Fukui (1989) have not been searched for HH objects. Nonetheless, despite the incompleteness of the searches, the overlap of these tracers is already striking. About 26

CO outflows, out of about 40 that have been searched, are known to contain HH objects within their boundaries. On the other hand, out of 31 HH object complexes which have been observed with high sensitivity (≤ 1 K) in CO, 26 have associated CO outflows. The frequent occurrence of HH objects among the sample of *well-studied* CO outflow regions suggests that HH objects are an important feature of outflow activity.

The nearest CO outflows tend to be the ones associated with HH objects. Good examples include L1551/IRS5 and HL/XZ Tau, the HH 7–11 complex, and the NGC1999 region in Orion. In most cases (although not all), the visible HH objects are located within the blue (approaching) lobe of the CO outflow which usually suffers less extinction than the red (receding) lobe.

Although about 80% of the HH objects have been found in regions of low-mass star formation, this probably reflects a selection effect because low-mass star-forming regions are more numerous, are found closer to the Sun, and tend to be located in smaller cloud cores suffering less extinction than high-mass star-forming regions. Indeed, a number of HH objects (5 to 10% of the known sources) are associated with high-luminosity sources such as the Orion/IRc2 outflow (M42-HHs: Axon and Taylor 1984) and Cepheus A (GGD37 and HH-NE: Lenzen 1988).

Figure 2. An ESO Schmidt telescope plate showing a 20' by 30' field illustrating the locations and orientation of 9 optical outflows (Herbig-Haro objects) in the northern part of the L1641 cloud. The HH 1/2 region near NGC1999 is near the bottom left of the plate (figure from Reipurth 1989a).

About 42 molecular outflows are associated with shock-excited H_2 emission at near-infrared wavelengths. So far, at least 60 regions have been searched for H_2 emission: out of 42 detections, 32 are CO outflows, and 29 are HH objects, with 19 being both HH objects and CO outflows. Several H_2 sources (such as RU Lupi) are not listed as either HH objects or CO outflows.

Nearly 20 of the HH objects associated with low-luminosity young stellar objects (YSO) in the Orion region occur in portions of the L1641 and L1630 clouds which have been mapped in ^{12}CO with the Nagoya and Bell telescopes. Of these HH objects, only a few have been detected as CO outflows. This may be due to another selection effect resulting from the difficulty in distinguishing low-velocity accelerated CO against the turbulent background emission of a typical molecular cloud. Because the CO linewidth of outflows correlates with the luminosity of the driving star, fainter sources having lower-velocity CO flows are harder to distinguish against the background emission. Alternatively, these optical objects may be more evolved than typical CO outflows, having much less molecular gas around them to supply outflow with CO gas. This interpretation is consistent with apparent low luminosities of the driving sources of optical jets, showing no sign of vigorous mass accretion producing thereby large luminosity excess. The ubiquity of optical outflows and HH objects is dramatically illustrated by the recent work of Reipurth (1989a) who shows that at least 11 distinct optical flows from YSO's are present in a $30' \times 30'$ field in the northern part of the L1641 region of Orion (see Fig. 2). Only three CO outflows have so far been detected in this region [HH 1-2 and HH 35 (Levreault 1985), HH 83 (Bally et al. in preparation.)].

B. Models for Shocks in Herbig-Haro Objects

HH objects are the optical manifestation of luminous shocks formed when two fluids collide with a relative velocity in the range 10 to $>300 \text{ km s}^{-1}$. These shocks can arise in four general circumstances:

1. Internal shocks in a moving fluid such as a wind or jet (Raga 1989);
2. A shock formed where a wind or jet rams denser quiescent gas in a bow shock (Reipurth et al. 1986);
3. In a bow shock resulting from a wind blowing past an obstacle (Schwartz 1978);
4. In a bow shock formed when a fast-moving knot of dense gas rams into lower-density gas at rest ("an interstellar bullet"; Norman and Silk 1979).

Models (2) and (4) are similar except that the density ratio of the moving and stationary gas is inverted. Although all four kinds of shocks have been seen in HH objects, many HH objects remain difficult to classify.

Internal shocks in a moving fluid (type 1 HH object) are seen in about a dozen stellar jets such as those associated with HH 33/40 (Lane 1989) and HH 34 in Orion (Reipurth et al. 1986). The HH 34 jet emerges from a $0.5 L_{\odot}$ source at a velocity of $>100 \text{ km s}^{-1}$, yet mostly excites low-excitation species

such as [S II]. A bow shock (type 2 HH object) is seen about $90''$ south of the jet where it slams into denser gas in the surrounding cloud. Shock-excited H_2 emission has been seen from the HH 33/40 jet (Lane 1989) but not from the HH 34 region, possibly because either the cloud has too low a density, or is mostly atomic. This interpretation is supported by the low average extinction towards this object, and may explain the absence of a CO outflow there, as well.

The objects HH 7–11 may contain examples of bow shocks formed by a wind blowing past stationary obstacles (type 3 HH object). Although the optical velocities are large, mm-wave interferometric observations show stationary knots of dense molecular gas near the positions of the HH objects (Rudolph and Welch 1988). Even without detection of the dense knot, the flow past an obstacle can be identified by the relative spatial position of high- and low-excitation emission. Such an analysis has indicated that HH 43 in Orion also is a type 3 HH object (R. D. Schwartz et al. 1988).

Some HH objects form when a rapidly moving object moves through a stationary medium as an “interstellar bullet.” The high proper motion and spatial and velocity structure of regions such as HH 1–2 and GGD37 in Cep A, as well as the relative location of the high- and low-excitation lines, suggest that these may be type 4 HH objects.

C. Near-Infrared Observations of Shock-Excited Molecular Hydrogen from Outflows

Many molecular outflows are associated with bright, shock-excited H_2 emission at near-infrared wavelengths. The most prominent line is usually the $v=1-0$ S(1) line at $2.122\ \mu\text{m}$ which is frequently bright in HH objects and outflows located in relatively obscured molecular clouds. HH objects lying in regions of low obscuration or towards which background star fields are readily visible tend not to produce detectable H_2 lines. This property of H_2 emission can be understood in terms of environmental factors: only shocks propagating into relatively dense molecular gas can produce H_2 emission. Those propagating into low-density or mostly atomic gas cannot produce these lines since H_2 is not present in the medium and the H_2 formation time scale in the post-shock medium is longer than the shock dynamic time scale.

Although molecular hydrogen emission is usually found in the same vicinity as the optical line emission which defines HH objects, the H_2 emission region frequently exhibits different morphology (Lane and Bally 1986; Harvey et al. 1986; Lane 1989; Garden et al. 1990). These structural differences can be understood as a consequence of the shock temperature and density structure, and the mechanism of line excitation (Lane and Bally, in preparation).

The most luminous sources of shock-excited H_2 emission tend to be associated with energetic, luminous molecular outflows such as Orion/IRc2, NGC2071, DR21 and Cep A (see Lane 1989, and references therein). The close association between HH objects near low luminosity outflows and shock-excited molecular hydrogen emission gives us some confidence that the exci-

tation conditions in the high luminosity outflow sources are similar in nature to those found in the HH objects. Therefore, the $2\ \mu\text{m}$ lines of H_2 can be used to infer the presence of extensive shock-excited gas in these sources which is similar in nature to HH objects. The highly energetic outflows such as DR21 and Orion/IRc2 clearly contain extensive regions of shock-excited gas. On the other hand, some massive flows such as Mon R2, which are very old as inferred from the dynamic age of the CO emission, have only fluorescent rather than shock-excited H_2 emission (Aspin et al., in preparation). There may be no active radiative shocks in these old flows, and the high-velocity CO may be coasting without active acceleration. In highly obscured sources, it may be possible to use the near-infrared lines to identify knots of H_2 emission as invisible, near-infrared “HH objects.”

IV. DETAILED DISCUSSION OF SELECTED OUTFLOWS

The most extensively studied outflows are those associated with the low-luminosity sources L1551/IRS5 and HH 7–11/SVS13 and the high luminosity sources Orion/IRc2 and NGC 2071. Recent references and/or summaries of the extensive work on these outflows may be found in Stocke et al. (1988) and Moriarty-Schieven and Snell (1988) for L1551; Masson et al. (1990) and Liseau et al. (1988) for HH 7–11; Masson et al. (1987), Lane (1989), and Lane and Bally (in preparation) for the Orion outflow; Moriarty-Schieven et al. (1989) and Garden et al. (1990) for NGC 2071. We have selected two sources for detailed discussion for which recent high-resolution observations have revealed particularly interesting features.

A. ρ Oph-East (IRAS 16293–2422): Low-Luminosity Multiple Outflow Lobes

Rho Oph-East (IRAS 16293–2422) is one of the molecular outflows discovered in the Nagoya CO survey of star-formation regions (Fukui et al. 1986), and was independently discovered by Wootten and Loren (1987) and Walker et al. (1988). It is located $\sim 1.5^\circ$ east of the ρ Oph main cloud at a distance of 160 pc, and is associated with an IRAS point source (IRAS 16293–2422) whose luminosity is $\sim 27\ L_\odot$ (Mundy et al. 1986b). The IRAS source has an unusually cold infrared spectrum, which can be fitted by a single $\sim 40\ \text{K}$ blackbody spectrum. Such a very cold dust temperature strongly suggests that IRAS 16293–2422 is one of the best candidates for a solar-type protostar.

The high-velocity ^{12}CO ($J=1-0$) emission has been resolved into four separate compact lobes, suggesting two coincident bipolar outflows, in addition to an extended monopolar blueshifted lobe (Mizuno et al. 1990). Figure 3 shows a map of the two compact bipolar flows obtained with the Nobeyama 45 m telescope. Although the spatial extent of the four compact lobes is smaller than $4'$ ($\sim 0.2\ \text{pc}$), the additional extended blue lobe extends $\sim 10'$ east from the IRAS source. Physical properties of the four compact lobes are similar to each other but differ from those of the additional extended

Figure 3. Distribution of the high-velocity ^{12}CO ($J=1-0$) emission in ρ Oph-East obtained with the Nobeyama 45 m telescope (Mizuno et al. 1990). The integrated intensity of the redshifted wing is shown by solid contours and that of the blueshifted wing is shown by dashed contours. Contours are every 5.4 K km s^{-1} from 10.8 K km s^{-1} . The position of an IRAS point source (IRAS 16293–2422) is denoted by a cross.

monopolar lobe. The typical velocity of the high-velocity CO gas and the dynamical time scale of the four compact lobes are $\sim 14 \text{ km s}^{-1}$ and $\sim 1 \times 10^4$ yr, respectively. The extended blue lobe with lower velocity, $\sim 6 \text{ km s}^{-1}$, has a dynamical time scale of $\sim 1 \times 10^5$ yr, an order of magnitude longer than that of the compact bipolar outflows. We find no candidate for the driving source other than IRAS 16293–2422 within the sensitivity limits of the IRAS point source catalog and POSS (Palomar Observatory Sky Survey) plate in the outflow lobes, suggesting that five outflow lobes are emanating from the common driving source IRAS 16293–2422.

It is important to understand what is the origin of such a multiplicity of outflow lobes. The simplest model is multiple driving sources clustered in a small region which is unresolved by the IRAS beam. Interferometry in the 2.7 mm continuum and in ^{13}CO ($J=1-0$) by Mundy et al. (1986b) revealed a compact and rapidly rotating dust disk with a projected size of $\sim 1800 \text{ AU}$ by less than 800 AU toward IRAS 16293–2422. VLA maps of 6 cm and 2 cm continuum emission by Wootten (1989) reveal two continuum peaks separated by $\sim 750 \text{ AU}$ in the NW-SE direction of the dust disk, suggesting that IRAS 16293–2422 may contain a binary system.

Two driving engines with stationary axes in the E-W and NE-SW directions, respectively, may explain the four compact lobes. In this case, the extended monopolar outflow and the E-W compact bipolar outflow are both supposed to be driven by a common E-W oriented engine. An order-of-magnitude difference of time scales and mechanical luminosities between the extended monopolar outflow and the compact outflow implies that the outflow activity driven by the E-W oriented engine may have been enhanced drastically in the last $\sim 10^4$ yr.

A third possible model is a precessing jet. If one of the stars in this binary has a disk tilted to the orbital plane, the disk should undergo precession due to the gravitational quadrupole interaction with the companion. If the molecular outflow is driven by a circumstellar disk, as predicted in magnetohydrodynamical models (see, e.g., Uchida and Shibata 1985), the outflow can undergo precession. Details of the ^{12}CO map, showing that the four compact lobes appear well separated from each other, however, are not well explained by the precession model.

Figure 4. Interferometric ^{12}CO map of ρ Oph-East taken with the Nobeyama Millimeter Array is superposed on the 2.7 mm continuum interferometric map of Mundy et al. (1986b). The velocity intervals are -0.4 to -3.6 km s^{-1} (low-velocity blue wing) and 8.5 to 12.5 km s^{-1} (high-velocity red wing). The contours extend from 2σ rms noise with a 1σ step. The 1σ rms noise level is 70 mJy beam^{-1} .

A high resolution ^{12}CO ($J=1-0$) map (Fig. 4) made with the Nobeyama Millimeter Array (Mizuno et al., in preparation) reveals the distribution of the high-velocity gas near the driving source. The blueshifted gas is located on the east side and the redshifted gas on the west side, suggesting that the

axis of bipolar outflow is originally oriented in the E-W direction. In the vicinity of the IRAS source, the NE-SW bipolar flow is not seen. Taking this result into consideration, it may be most likely that the NE-SW bipolar flow is formed by some secondary effect such as a dynamical interaction between the high-velocity outflow and the dense ambient cloud. In fact, there is a clear indication for dynamical interaction of the outflow with the nearby NH_3 dense core which is located $\sim 80''$ east of the IRAS source (Mizuno et al. 1990). The NH_3 core is located just toward the eastern edge of the eastern blue lobe. At the interface of the outflow and the dense core, the velocity of the NH_3 core is abruptly blueshifted from the rest velocity of the NH_3 cloud. The calculated momentum of the CO outflow is large enough to accelerate the NH_3 core and to cause such an abrupt velocity shift. The outflow pressure is so large that the NH_3 core is not in equilibrium. It is likely that the north-south-elongated structure of the NH_3 core may be formed by the outflow.

Dynamical interaction of outflow with ambient material has been noted in some cases, e.g., L1641-North (Fukui et al. 1988), NGC2071-North (Iwata et al. 1988) and NGC2071 (Takano et al. 1986). Rho Oph-East provides an even clearer example of such interaction. The distribution of the northeastern red lobe shows a remarkable anticorrelation with the NH_3 dense core (Fig. 9 in Mizuno et al. 1990). It suggests that the CO lobe morphology may be influenced by the existence of ambient dense gas; i.e., the outflow gas may be excluded from a volume with higher density than its surroundings. Although this dynamical interaction model can explain the compact lobes' morphology on the east side of the IRAS source, it is still obscure how the extended blue lobe, which is by an order of magnitude older, is formed and how the interaction occurs on the west side. The puzzle of the multiplicity of ρ Oph-East is not resolved completely.

B. Cepheus A: Multiple Outflow Lobes and Time Variable Wind

Cepheus A is a region of massive star formation with a total luminosity of $2 \times 10^4 L_\odot$. The driving source of a molecular outflow and associated Herbig-Haro objects is buried in a region of high extinction (visual extinction $A_V \geq 75$ mag) and is marked by a strong H_2O maser and a cluster of compact radio continuum sources, one of which has the radio spectral index of an optically thick outflow source (Hughes 1988, and references therein). A bright far-infrared source and a near-infrared reflection nebula mark the general vicinity of the driving source, which is invisible even at $2 \mu\text{m}$. The region has been imaged at $\sim 1''$ resolution in the $2.122 \mu\text{m}$ line of H_2 (Lane 1989; Bally and Lane 1990) and mapped with $15''$ resolution in the ^{12}CO ($J=1-0$) line (Bally et al. 1991). Figure 5 shows a superposition of the H_2 and high-velocity CO maps, with the location of the outflow driving source marked by a cross.

Cep A contains one of the brightest and highest velocity HH objects known. It is a clear example of a source where CO emission, optical emission, and infrared emission arise from the same outflow region. The GGD37 cluster of HH objects is located ~ 1.5 to $2'$ west of the driving source and appears

Figure 5. A gray-scale image of the $2.122\text{ }\mu\text{m}$ $v = 1 - 0$ S(1) line of the molecular hydrogen toward Cep A superposed on a contour map of high-velocity ^{12}CO ($J=1-0$) emission. Solid contours indicate blueshifted CO, integrated from -26 to -16 km s^{-1} . Dashed contours indicate redshifted CO, integrated from -3 to 7 km s^{-1} . Contour levels are set at 3 , 6 and 12 K km s^{-1} . The GGD37 HH object lies $\sim 2'$ west of the bright infrared reflection nebula, while HH-NE lies $\sim 1'$ to the northeast. The location of the driving source for the molecular outflow is denoted by a cross.

as a complex of arcs, bubbles, and twisted filaments in H_2 line emission (see Figs. 2 and 4 in Lane 1989). A second HH object (Cep A HH-NE; Lenzen 1988), also prominent in H_2 emission, lies $\sim 1'$ to the northeast of the bright infrared reflection nebula.

The highest velocity CO extends mostly E-W of the core over a $3' \times 7'$ region, corresponding to $\sim 0.6 \times 1.5\text{ pc}$ at a distance of 730 pc . Although the CO outflow is bipolar within $\sim 1'$ of the driving source (with redshifted gas to the west and blueshifted gas to the east), the flow structure is more complex away from the center. To the west, the redshifted lobe is followed by a blueshifted one starting in the vicinity of GGD37 and continuing with a slight bend to the north for several arcminutes. A second west lobe of redshifted gas is also found about $100''$ west of the core, indicating that the CO lines are broader in the vicinity of GGD37.

Only the infrared core contains luminous embedded sources. There are no bright objects between the extra-blue and redshifted lobes found to the west. Polarization measurements of the scattered $2\text{ }\mu\text{m}$ continuum radiation

in the east and the west indicate that the illumination for both regions comes from the central infrared source (Lenzen et al. 1984). This suggests that the entire extent of the CO outflow is energized by the activity of young stars embedded in the infrared core.

The optical/infrared reflection nebula in the east and the optical reflection nebula near GGD37 in the west form a bipolar structure in reflected light which confirms the nearly E-W orientation of the high-velocity outflow and flow channel near the source. Optical proper motions of knots of emission in GGD37 and HH-NE are consistent with this flow axis (Lenzen 1988) but suggest that, away from the infrared source, there is a deflection of the outflow towards the north which is also seen in the large-scale CO morphology.

To the east, only blueshifted gas is seen. However, in addition to the (alternating) E-W lobes, a second pair of bipolar lobes having a lower velocity range extends out from the core along a NE-SW axis. The coincidence of the E and NE blue lobes with the edges of the infrared reflection nebula suggests that they mark the walls of a cavity through which a blueshifted wind emerges. The shock-excited HH object, HH-NE, lies squarely between the two blueshifted CO lobes. At low relative velocities, the W and SW redshifted lobes form a second pair of ridges oriented opposite to the blueshifted lobes. However, the reflected light is associated only with the eastern lobe near GGD37. The low-velocity S-W redshifted lobe may be recoiling from the deflection of the higher-velocity western flow to the north. Alternatively, it is possible that this component represents either an unrelated, lower energy flow superimposed on the main flow, or is the debris left over from an earlier epoch when the Cep A wind directed energy in another direction.

There are some interesting correlations between the CO, optical, and infrared properties of Cep A. The CO outflow appears to reverse polarity in the vicinity of the HH object GGD37. Near the shocks, a second blueshifted lobe of emission appears, and extends 3 arcminutes to the west. The transverse width of the optical emission region and the CO lobe are similar, indicating that much of the interior region of the CO lobe is filled with ultra-high-velocity gas having a velocity of order 300 to 600 km s⁻¹ as determined from optical proper motions, radio proper motions (Hughes and Moriarty-Schieven 1990) and the highest observed optical radial velocities.

The optical emission from the GGD37 shocks consists of filled cones of emission suggesting that the low-excitation tracers must be excited throughout the volume of the bow-shock structures. Turbulence in the postshock gas lying behind the reverse shock through which the wind passes provides a viable mechanism for the excitation of ionic and atomic lines in this region. The H₂ line emission forms a series of arcs surrounding the H α and [S II] structures. Their morphology and location are consistent with excitation in the bow-shock skirts where pre-existing H₂ can survive passage through the shock (Lane 1989; Bally and Lane 1990). The observed brightness of the S(1) line places a constraint of $n \geq 10^4$ cm⁻³ on the density of the radiating medium.

The CO lines broaden downwind from GGD37 (away from the central source) where the western lobe of blueshifted emission first appears. This suggests that the fast wind responsible for GGD37 may also accelerate CO in the lobes of Cep A by a few km s^{-1} . A possible model for the accelerated CO in this (and other outflows) is that all of the CO has been accelerated by shocks similar in nature to the GGD37 shocks. Like H_2 , CO is a robust molecule which can survive accelerations of several tens of km s^{-1} which would be produced in the skirts of a bow shock such as GGD37. In this picture, the radiating shocks seen as HH objects or as near-infrared luminous regions of shock-excited H_2 emission are *the sites of CO acceleration*. The localization of the shocks to a region much smaller than the projected area of the outflow can be interpreted as one indication of time-variable winds (Bally and Lane 1990).

We have discussed our recent knowledge on ρ Oph-East and Cep A as examples of low- and high-mass molecular outflows with multilobes. At present, we do not have a general consensus about the driving mechanism of such multilobe outflows. Further detailed observations at radio, infrared and optical wavelengths are necessary to elucidate the mechanism.

V. ACCELERATION AND COLLIMATION

A. Background

Molecular outflows are collimated and accelerated to velocities of order 3 to 30 km s^{-1} and sometimes to more than 100 km s^{-1} . The molecular component requires some acceleration mechanism other than stellar radiation to provide the observed momentum. The mechanical luminosity of molecular outflows L_{mech} is defined as the total kinetic energy of the high-velocity molecular gas divided by the dynamical time scale of the outflow. In all molecular flows, the ratio L_{mech}/L_* is less than unity, with a value in the range 0.002 to 0.2. However, the average force needed to accelerate outflows, defined as the momentum in the high-velocity gas divided by the dynamical age, is greater than the force of stellar radiation pressure L_*/c . The force required to accelerate molecular flows typically exceeds that produced by radiation pressure by a factor of 100 to 1000, indicating that radiation pressure cannot drive outflows unless the photon scattering optical depth is of order of 100 to 1000 at the wavelength where the radiation field is in thermal equilibrium with the gas temperature (i.e., the mid- to far-infrared). This is the basic reason why some nonradiative acceleration mechanism is needed (Bally and Lada 1983).

A second problem is the physical nature of the collimating agent. Early studies suggested that large-scale “interstellar” ($\sim 10^{17} \text{ cm}$) toroids of dense gas constrained the CO outflows (see, e.g., Torrelles et al. 1983). However, recent interferometric imaging has shown that some CO outflows are already collimated on scales much smaller than this (e.g., ρ Oph-East: Mizuno et al., in preparation, see Sec. IV.A). This is consistent with the suggestion that

collimation is made very close to the central star, $\lesssim 10^{16}$ cm, on the basis of observations of the compact dense gas clouds associated with the central stars (Takano et al. 1984; Fukui et al. 1988). On the other hand, optical jets appear to be collimated within a few arcsec of the source (see, e.g., Mundt et al. 1987), indicating that for at least some sources, collimation of the highest velocity ($V \gtrsim 200 \text{ km s}^{-1}$) outflow occurs closer than 1000 AU, the size scale of a protoplanetary disk.

Models of outflows can be grouped into two categories: (1) magnetohydrodynamic (MHD) models, in which the wind is primarily accelerated by magnetic fields which thread the protostellar disk; and (2) stellar-wind models, in which the wind is produced in the immediate vicinity of the star.

B. Magnetohydrodynamic Models

The basic idea of magnetohydrodynamic (MHD) models such as discussed by Uchida and Shibata (1985) and by Pudritz and Norman (1986) is that a compact, rotating, circumstellar disk of $\sim 10^{15}$ to 10^{16} cm radius forces corotation of the surrounding interstellar magnetic field by magnetic tension. The distorted magnetic field has a radial component as illustrated in Fig. 6, which accelerates ions frozen to the magnetic field. The ions are coupled to the neutral molecular gas by collisions and accelerate this component. The predicted velocities in these models are 30 to 40 km s^{-1} , depending on the adopted disk parameters. A further prediction of these models is that the wind velocity increases with decreasing radius, which can result in the formation of a high-speed inner jet at a radius of $\sim 10^{11}$ to 10^{12} cm. The inner jet may have velocities up to $\sim 300 \text{ km s}^{-1}$. MHD models naturally produce cold flows without any shock heating of the gas and therefore can explain the outflow component observed in the low- J CO transitions having temperatures of 10 to 100 K. This low temperature, however, may not be unique to the MHD models; the cooling time of gas at temperatures of order a few times 10^3 K with densities above a few hundred cm^{-3} is a few years, so even in models in which the entire CO flow is accelerated by shocks, most of the mass is expected to be near the temperature determined by collisional and thermal equilibrium.

The basic observed characteristics of CO outflows, e.g., a typical flow velocity of $\sim 10 \text{ km s}^{-1}$ and bipolar symmetry, are readily explained by the MHD models. On the other hand, direct evidence for massive and magnetized disks is still lacking, in part due to current limitations of resolution and sensitivity. Future submillimeter and far-infrared line studies and polarimetry (see, e.g., Dragovan 1986; Novak et al. 1989) may provide crucial tests of MHD models by probing magnetic field orientation and grain alignment and by searching for velocity differences between ions and neutral species on arcsecond angular scales.

MHD models make two testable predictions (Uchida and Shibata 1985). The CO lobes are expected to rotate about the symmetry axis, and the molecular gas is expected to be accelerated gradually over a linear scale of order

0.1 pc. Uchida et al. (1987*b*) present high angular resolution CO observations of the L1551 outflow with $\sim 20''$ resolution obtained with the Nobeyama 45 m telescope. Their data indicate rotation of the lobes about the outflow axis with a velocity of order 1 km s^{-1} . Furthermore, the CO radial velocity vector is seen to increase gradually to its maximum amplitude over a distance of order 0.1 pc, as predicted by the model. Moriarty-Schieven and Snell (1988) confirm these results. Unfortunately, as only the radial velocity component of the flow vector is observed, it is difficult to distinguish true acceleration from projection effects. L1551 is so far the only source with a clear indication of rotation in the CO lobes. Although it is not entirely clear why L1551 IRS5 is unique in this respect, its strong ^{12}CO emission in the outflow and relatively quiescent ambient cloud (^{12}CO linewidth of $\sim 2 \text{ km s}^{-1}$) may favor the detection. Several other sources exhibit radial velocity fields consistent with gradual acceleration over a 0.1 pc scale.

Figure 6. A schematic drawing of the magnetohydrodynamical model.

C. Stellar-Wind Models

In this class of models, most of the high-velocity CO has been swept up from the molecular cloud surrounding the YSO by a faster primary wind which is hard to detect directly as it may be mostly atomic. Radio continuum observations (see, e.g., Snell and Bally 1986) have revealed that many outflow-exciting sources have compact components with a spectrum rising as ν^α where α is in the range 0 to 2. Models indicate that $\alpha \approx 0.6$ for a fully ionized wind with an r^{-2} electron-density profile (Wright and Barlow 1975; Panagia and Felli 1975). For a collimated (or partially collimated) flow, the spectral index α can lie in the range 0 to 2 (Reynolds 1986). Under the assumption of steady state and full ionization, the mass-loss rates inferred from the radio continuum parameters typically fail by 2 orders of magnitude to provide the observed momentum in the CO flow. However, the winds may be mostly atomic with only a trace of plasma which is responsible for the radio continuum emission. Several outflows have been found which exhibit broad 21-cm H I lines, consistent with models in which the primary wind is mostly atomic (Bally and Stark 1983; Lizano et al. 1988). Very faint "extremely high-velocity" CO emission with velocities up to $\sim 155 \text{ km s}^{-1}$ from line center has been observed towards a few sources (Lizano et al. 1988; Koo 1989; Margulis and Snell 1989). This component of the flow may trace a wind in which hydrogen is in atomic form but carbon has been partially converted into CO (Glassgold et al. 1989).

The primary wind rams into the quiescent cloud surrounding the YSO, accelerating the swept-up gas to the velocity observed in the CO outflow. The primary wind may be accelerated and collimated by a magnetized disk, and in one recent model, the "X-celerator" model of Shu et al. (1988), the wind originates from the inner edge of the disk where gas passes through an accretion shock and decelerates from a Keplerian velocity to the rotation velocity of the young star.

Several outflows (e.g., L1551: Uchida et al. 1987*b*; Moriarty-Schieven and Snell 1988), exhibit a hollow shell morphology which is consistent with acceleration of the molecular gas in a snowplow shock produced by the ram pressure of the primary wind. High-velocity HH objects are frequently found near low-mass stars, indicating that fast winds occur in these sources. Lane and Bally (in preparation) and Bally and Lane (1990) argue that HH objects and H₂ emission regions mark the locations where the primary wind drives shocks into the ambient cloud, accelerating the CO seen in the outflows. Both lobes of the L1551 outflow contain extensive amounts of shock-excited gas in the form of HH objects (Rodríguez et al. 1989*a*). The total momentum in the visible shocks appears to be too small to produce the extended massive CO lobes. However, the momentum in the fast-wind may have been greater in the past, and the optical shocks may provide only a lower limit to the fast-wind momentum.

D. Discussion: A Comparison of the Models

The hollow-shell morphology of the CO lobes in L1551 is consistent with both models discussed above. Such a hollow cavity will be created by acceleration of the CO in a snowplow shock produced by the ram pressure of the primary wind, while MHD models equally well explain the hollow distribution, as demonstrated by the numerical simulations by Uchida and Shibata (1985). Flow morphology may not give a clue to discriminate between these models.

The extremely high-velocity (EHV) CO lines seen towards some sources pose constraints on source models. Six outflows are now known to exhibit faint CO components with linewidths ranging from 100 to over 300 km s⁻¹. Most outflows have not been searched with sufficient sensitivity to detect these faint high-velocity features. While three of the EHV CO flows are associated with luminous sources: NGC2071, CRL490 and S140 with $L \approx 10^3$ to $10^4 L_\odot$ (Margulis and Snell 1989). Three others driven by low-luminosity sources exhibit EHV CO components: the HH 7-11 outflow 90 L_☉ (Koo 1990; Bachiller and Cernicharo 1990; Masson et al. 1990), the flow in L1448 with $L < 11 L_\odot$ (Bachiller et al. 1990a), and the flow in L723 (Margulis and Snell 1989). Recent observation (Masson et al. 1990; Bachiller and Cernicharo 1990) show that the EHV gas in HH 7-11 in CO ($J=2-1$, and $J=3-2$) is confined to two knots of emission extending over a 60'' region and located in the vicinity of the shocks traced by H₂ and the stationary HCO⁺ clumps observed by Rudolph and Welch (1988). Unlike the classical CO line wings, the EHV CO is seen as high-velocity CO cloudlets with a velocity of about 100 km s⁻¹ or greater with respect to the molecular cloud, and linewidths of about 20 km s⁻¹. The spatial extent of the EHV CO is somewhat smaller than the lower-velocity "classical" CO flow as mapped by Liseau et al. (1988) and Bachiller and Cernicharo (1990) who find that the spatial extent of the CO flow is about 30'' by 120''. The velocity of the EHV CO is comparable to that of the optical HH object in this region. The total mass in the EHV CO component is estimated to be about 0.03 M_☉, about 1% of the total outflow mass. Although the momentum in the EHV component is about an order of magnitude less than that in the classical flow (2.2 vs 11 M_☉ km s⁻¹), the mechanical power is about 2 orders of magnitude larger (450 vs 3.3 L_☉). The EHV CO may be part of a fast wind emerging from SVS13, possibly clumped into "bullets," or may represent gas swept from the surrounding cloud and accelerated to the observed velocities by momentum transfer from an even faster wind. In the former model, the CO may form by ion-molecule reactions within a mostly atomic wind, in which H is atomic, but some of the carbon is converted to molecules. CO may have a much lower relative abundance with respect to hydrogen than is typical of molecular clouds (Glassgold et al. 1989), leading to an underestimate of the mass and momentum in the EHV CO flow.

The MHD models cannot produce velocities as high as those observed in the EHV CO component, at least from the outer parts of disks. However,

in some versions of the MHD models, the inner portion of the disk give rise to high-velocity jets (Uchida and Shibata 1984; Pudritz and Norman 1986) with velocities similar to the EHV CO. It remains to be seen if the EHV CO is collimated into a jet or if the models can produce the amount of gas seen in this component.

A question recently raised concerning MHD models is the balance between the angular momentum involved in the CO lobe vs that of the driving disk. The study by Moriarty-Schieven and Snell (1988) indicates that the total molecular mass contained in the outflowing gas in L1551 may be a factor of 3 to 10 greater than previously supposed, suggesting that the total molecular mass in the CO lobes may be $\approx 3.6 M_{\odot}$. The rotation speed observed in the CO lobes is $\sim 1 \text{ km s}^{-1}$. Assuming that we are looking at the outflow nearly from the direction normal to the outflow axis, the total angular momentum in the flow is as large as $\sim 3 M_{\odot} \text{ km s}^{-1}$. On the other hand, the assumed circumstellar disk has much smaller angular momentum, maybe < 0.1 of the above value. However, this may not be a difficulty. First, the disk sitting near the central star should have already released angular momentum to the CO lobes, thus having much less angular momentum at present than before the CO lobe acceleration. Second, it is likely that not all the molecular gas is rotating as indicated by the ^{12}CO velocity maps. The ^{12}CO maps show rotation is obvious only at a distance $\lesssim 0.1 \text{ pc}$ from the center. Third, we should also take account of the angular momentum of the ambient molecular gas. Most molecular mass in outflows is not from the central small volume near the driving source, but from the ambient molecular gas distributed over the interstellar scale. This interstellar gas should have a certain amount of angular momentum before the acceleration. Alfvén waves act to wrap up the ambient gas, thereby bringing it to a smaller radius via the pinching effect, as has been demonstrated by the numerical simulations by Uchida et al. (in preparation). This suggests that there may be additional spin-up from the velocity of the ambient gas, so that the apparent CO lobe rotation may be a combined effect of the angular momentum of the driving disk and that of the ambient gas. In order to account for such an effect properly, theoretical models which incorporate the effect of the ambient material in CO lobe formation are needed.

It is premature to conclude which model is correct. However, the two models share some common characteristics. In particular, the coupling of the magnetic field with rotation of the circumstellar disk or the star itself may be playing an essential role in acceleration and collimation. A point of controversy is the scale of the accelerator. We may accept a general argument that material having velocities $\geq 100 \text{ km s}^{-1}$ comes from close to the stellar surface, and that lower-velocity material, with speeds $\leq 30 \text{ km s}^{-1}$, may come from the outer regions as a manifestation of the deepness of the gravitational potential well (see, e.g., Shu et al. 1988). Another question which may be raised is whether the acceleration mechanism is common among stars having different masses. At the present time, the highest-velocity outflows are found

mostly toward high-mass stars, suggesting the possibility that high-mass stars may have a more efficient acceleration mechanism than low-mass stars.

VI. THE ORION SOUTH GIANT MOLECULAR CLOUD: TESTS FOR EVOLUTIONARY STATUS AND CLOUD SUPPORT

The giant molecular cloud, Orion south, is one of the most active sites of star formation and has been intensively studied in mm-wave molecular spectra (see, e.g., Fukui et al. 1986, 1989; Bally et al. 1987). A new ^{13}CO ($J=1-0$) map of the cloud is shown in Fig. 7 (Fukui et al., in preparation). The total molecular mass estimated from ^{13}CO data is $3 \times 10^4 M_{\odot}$. In Fig. 7, the Orion KL region and the H II region M42 are located at $l = 210^{\circ}$, and the dark cloud L1641 lies at $l = 212^{\circ}-213^{\circ}$. The Orion KL region is a site of massive star formation, while the L1641 region is a site of low- to intermediate-mass star formation. In addition to many T Tauri stars, HH objects and reflection nebulae, there are 12 molecular outflows in this cloud. We also note the molecular cloud is highly filamentary showing a trend of smaller widths in latitude toward smaller longitudes. In this section, we use the new molecular data on this cloud to illustrate our current understanding of the evolutionary status of molecular outflows and the role outflows may play in supporting giant molecular clouds against gravitational collapse.

A. Evolutionary Status of Molecular Outflows in L1641

Comparison of the outflow detection rates for visible and embedded objects suggests that molecular outflows correspond to an evolutionary state earlier than T Tauri stars (Lada 1985). A study of molecular outflows in dark cloud cores (Myers et al. 1988) suggested a trend of higher bolometric luminosities in CO outflow sources, although samples of outflows used by these authors were not statistically complete.

Other studies providing some information on the evolutionary status of molecular outflows include optically selected pre-main-sequence objects (Levereault 1988a) and IRAS/ H_2O maser sources (Wouterloot et al. 1989; Snell et al. 1990). A study of published data on outflows in various star-forming regions (Berilli et al. 1989), as well as the above previous studies, did not find an evolutionary trend of molecular outflows. These studies are not statistically complete, however, being biased toward luminous and perhaps therefore more massive objects.

Most recently, two unbiased surveys have been used to study the evolutionary status of flows. One is the survey of the Mon OB1 cloud by Margulis et al. (1988). The distance to the cloud (760 pc was adopted by the authors), however, sets a lower limit for the infrared luminosity measured by IRAS of $\sim 3 L_{\odot}$, too large for studying low mass protostars, and source confusion within the IRAS beam makes it difficult to identify individual sources. The other is an unbiased survey of the L1641 cloud by Fukui et al. (1989); we discuss their results below.

Lynds 1641 ^{13}CO (J=1-0)

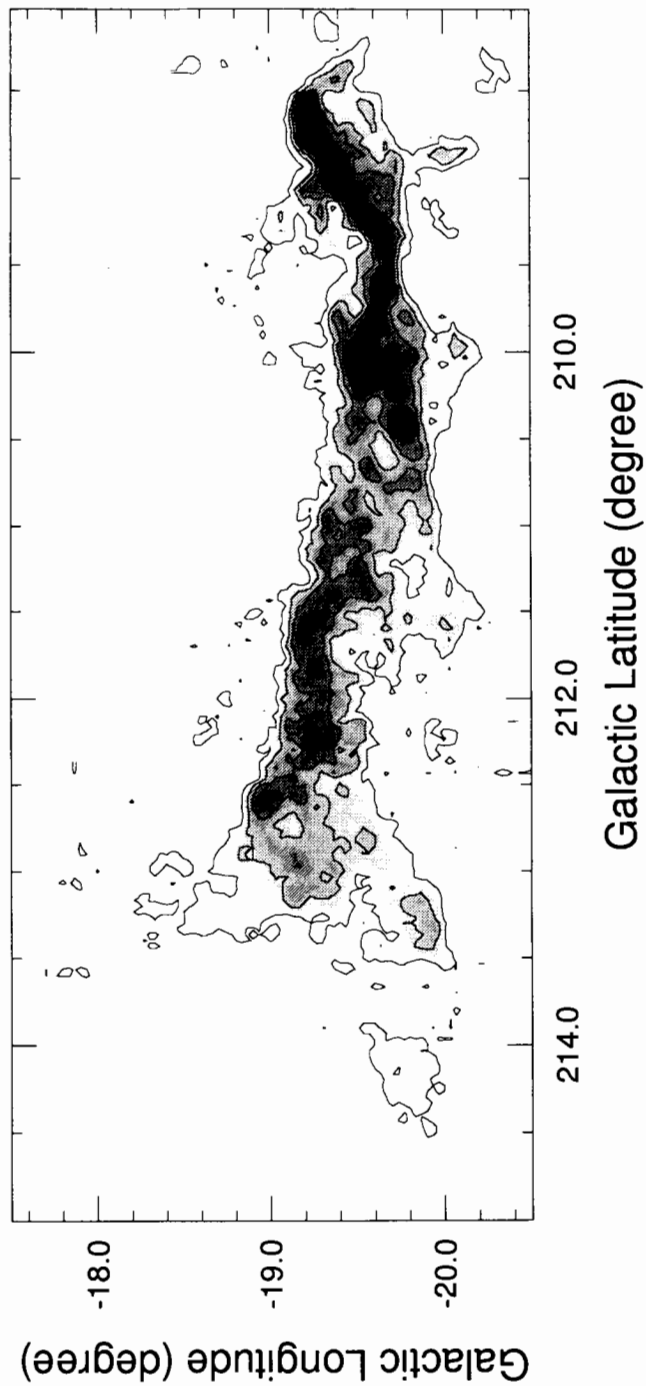

Figure 7. ^{13}CO total intensity map of the Orion south cloud (Fukui et al., in preparation). Contours are every 5 K km s^{-1} from 5 K km s^{-1} .

In order to characterize outflow sources, Fukui et al. (1989) used a complete sample of molecular outflows in L1641 (part of the Orion south cloud). Below declination $\leq 7^\circ$, there are six molecular outflows (see Table 1 in Fukui et al. 1989). All of them have been mapped in CO with three different beam sizes from 2.7 to $20''$, and their driving sources are identified in the IRAS point source catalog. The sensitivity limit of the sample corresponds to $L_{\text{mech}} \sim 0.001 L_\odot$, 2 orders of magnitude smaller than the L1551 outflow. There is a possibility that outflows having much smaller mechanical luminosities than currently known remain undetected in the unbiased survey, and the broad CO emission having a velocity range of $\leq 8 \text{ km s}^{-1}$ from the quiescent gas in L1641 may mask outflows having line widths smaller than that. The IRAS point sources in the L1641 region have been studied by Strom et al. (1989c). The authors selected 48 sources detected at 12, 25 and $60 \mu\text{m}$ from the list of Strom et al. and located them in the ^{13}CO total intensity map (Fig. 8).

The L1641 region contains a sufficiently large number of sources for statistical studies, and its proximity to the Sun ($\sim 500 \text{ pc}$) allows one to obtain reasonably high sensitivity both for outflows and IRAS sources. In L1641, it is shown that optical emission-line stars are mostly T Tauri stars having masses around $1 M_\odot$ (Cohen and Kuhi 1979; Herbig and Bell 1988). Thus, solar-type low-mass stars are the main stellar component in the L1641 cloud. A 12/25/60 μm two-color diagram of the 48 sources (Fig. 9) shows that all the outflows are located in the lower left part of the diagram. This indicates that the outflows are characterized by a significantly cooler dust color temperature than T Tauri stars, which are marked by a box in Fig. 9. Most of the other 42 sources without outflows are likely T Tauri stars, as suggested from their color shown in Fig. 9. About 1/5 of the 42 sources are in fact identified as T Tauri stars catalogued by Herbig and Bell (1988). The appreciable increase in the 25 μm flux is the cause of the cooler color temperature of the outflow sources. The outflow sources have ~ 10 times more massive dust envelopes than the T Tauri stars, suggesting that the outflow sources are embedded more heavily in the dust envelope than the T Tauri stars according to a spectral fitting by a two-temperature model (Fukui 1988). This is consistent with the idea that outflow is a signature of an evolutionary stage earlier than pre-main-sequence stars represented by T Tauri stars, i.e., a dynamical phase in which the protostellar matter has not yet established quasi-static equilibrium.

Figure 10 shows a bolometric luminosity-color diagram for the IRAS sources. The detection limit is $\sim 1 L_\odot$. Most of the sources located in or near the T Tauri box in Fig. 9 have luminosities in the range 2 to $20 L_\odot$. On the other hand, all the outflows have considerably larger luminosities of 20 to $300 L_\odot$. The molecular outflow sources are distinguished from the majority by their luminosity excess. Fukui et al. (1989) attributed the large luminosity of the outflow sources to gravitational energy released in the dynamical mass accretion onto the protostellar core. The accretion luminosity is calculated by using the equation $L_{\text{acc}} = GM_*\dot{M}/R_*$, where \dot{M} is a mass accretion rate

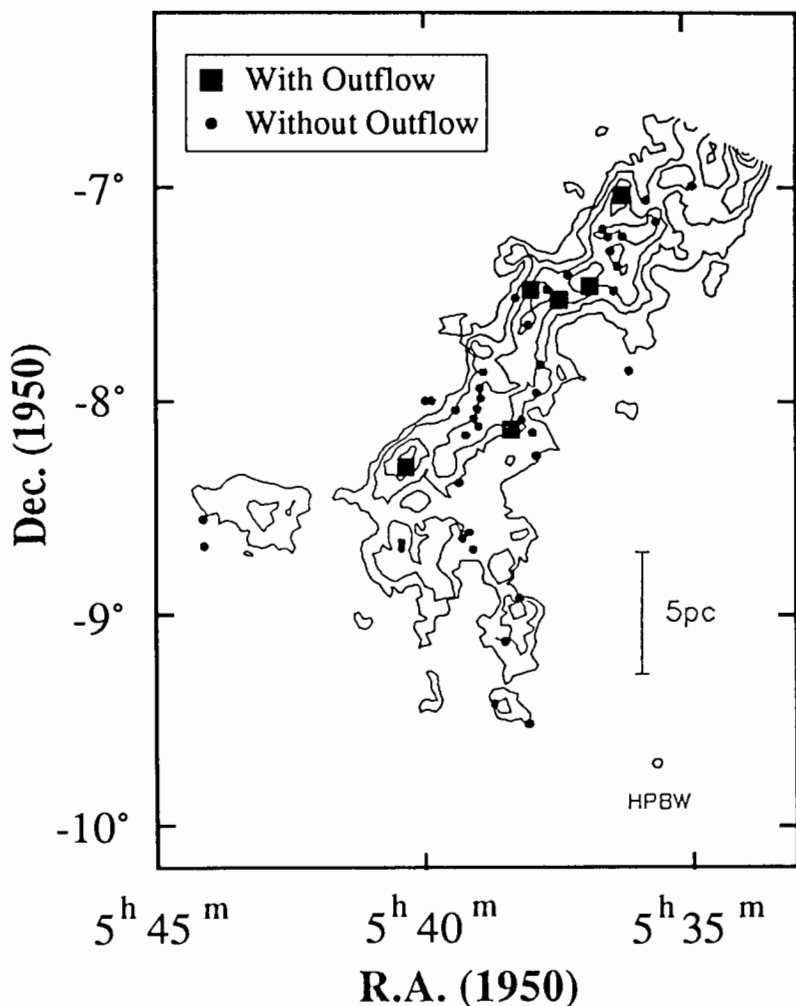

Figure 8. Contour map of ^{13}CO ($J=1-0$) total intensity of the L1641 molecular cloud at Decl. (1950) $\leq -7^\circ$ obtained with the Nagoya 4 m telescope. IRAS point sources associated with and not associated with molecular outflow are denoted by filled squares and small circles, respectively (Fukui et al. 1989).

(Stahler et al. 1980). For a typical mass accretion rate in a giant molecular cloud of $10^{-5} M_\odot \text{ yr}^{-1}$, and a typical radius for a $1 M_\odot$ protostar of $\sim 4 R_\odot$, the maximum accretion luminosity of a $1 M_\odot$ star is estimated to be $\sim 70 L_\odot$. This value may explain the large luminosity of the outflow sources.

The completeness of the sample allows us to estimate the ratio of the outflow time scale to the T Tauri lifetime to be $\sim 1/7$. The actual number of T Tauri stars may be even larger than that shown in Fig. 10 because the IRAS

Figure 9. 12/25/60 μm color-color diagram for 48 IRAS point sources from Strom et al. (1989c) in L1641 (Fukui et al. 1989). A rectangular area corresponds to the T Tauri box (Beichman et al. 1986). Filled circles denote IRAS point sources associated with molecular outflow.

detected only T Tauri stars with a dust envelope. The above ratio is then likely $< 1/10$ if we correct for T Tauri stars not detected by the IRAS. This is consistent with the typical dynamical time scale for outflows of $\sim 10^5$ yr, less than $1/10$ of a T Tauri star age of $\sim 3 \times 10^6$ yr (Cohen and Kuhl 1979). On the other hand, the accretion time scale is 1×10^5 yr for the above mass accretion rate. This suggests that for low-mass stars in L1641, outflow lasts for almost the entire main accretion phase.

If we accept this interpretation, molecular outflows may correspond to the main accretion phase of solar-type low-mass protostars. It is then likely that accretion takes place inside a flattened circumstellar disk around a protostellar core, and that outflow occurs along the poles (see, e.g., Fig. 11 in Uchida and Shibata 1985). If the outflow is ultimately powered by the energy released by accretion (see, e.g., Strom et al. 1988), the mechanical luminosity of outflow should be smaller than the bolometric luminosity. We find this is actually the case for all known outflows.

The work on L1641 has provided the first observational evidence for the extremely young evolutionary status of molecular outflows. The conclusion

Figure 10. Bolometric luminosity vs $12/25\text{ }\mu\text{m}$ color for 48 IRAS point sources selected from Strom et al. (1989c) in L1641 (Fukui et al. 1989). Upper horizontal scale is the dust color temperature derived from $12\text{ }\mu\text{m}$ and $25\text{ }\mu\text{m}$ flux densities on the assumption of a λ^{-1} emissivity law. Filled circles denote IRAS point sources associated with molecular outflow.

reached by Fukui et al. (1989) is basically consistent with a scenario of protostellar evolution in which molecular outflow coincides with the main accretion phase of protostars (Shu et al. 1987a). We note that the trend of higher luminosities of outflows is also found in other regions studied by unbiased surveys, S287 and Mon R2 (Fukui et al., in preparation).

The time scale of outflows is several times 10^4 yr, nearly comparable to, or a little smaller than, that of the main accretion phase of a protostar. We should learn this more exactly when outflow is ignited and how it grows in time. This probably corresponds to understanding the time evolution of the main accretion phase. In this connection, it is interesting to note a recent discovery of a compact outflow in Ophiuchus (IRAS 16285–2356). IRAS 16285–2356 is detected only in the $100\text{ }\mu\text{m}$ band, is invisible on the POSS plate, and has a total luminosity $\leq 2 L_{\odot}$ (Mizuno et al., in preparation). Its dynamical time scale is $\sim 1 \times 10^4$ yr. If we assume the luminosity is solely supplied by mass

accretion and take a typical mass accretion rate of $\sim 5 \times 10^{-6} M_{\odot} \text{ yr}^{-1}$ in a dark cloud, the protostellar core mass is estimated to be $\sim 5 \times 10^{-2} M_{\odot}$. This gives an age of the protostellar core of $\leq 1 \times 10^4$ yr, nearly equal to the outflow age. Then, this outflow may truly be ignited at the beginning of the main accretion phase. Further more-sensitive unbiased surveys for compact outflows should be extremely important in shedding more light on these questions.

Another way to infer the time of ignition of CO outflow may be provided by observations of CO outflows formed in small bright rimmed globules in H II regions. Including the three outflows (IC1396-North, Ori-I-2 and L1206), eight CO outflows have so far been detected and mapped in bright rimmed globules having cloud masses of 3 to $150 M_{\odot}$ (Sugitani et al. 1989, 1991). Dynamical evolution of such globules has been extensively studied theoretically, and the starting time of cloud collapse is estimated to be \sim a few times 10^4 yr in most cases. This time scale is comparable to the dynamical time scales of CO outflows, suggesting again that the ignition of CO outflows is very early in star formation.

If CO outflow is powered by mass accretion, as is suggested by magneto-hydrodynamical models, termination of outflow must correspond to the end of mass accretion. Dispersal of the protostellar cloud core is likely accomplished both by mass accretion and by outflow, with similar mass flow rates, $\sim 10^{-5}$ to $10^{-6} M_{\odot} \text{ yr}^{-1}$, leading to the end of mass accretion (Shu et al. 1988). These luminosity excesses are mostly emitted at infrared wavelengths longer than $25 \mu\text{m}$. If this far-infrared excess is characteristic of mass accretion from interstellar gas, gas density toward infrared sources should be correlated with the far-infrared excess, or with the luminosity excess. The correlation between luminosity and molecular gas column density $N(\text{H}_2)$ derived from ^{13}CO does indicate that this is actually the case for IRAS sources in L1641 (Chen et al. 1991).

B. Cloud Support by Outflows

It has been a long-standing question how a giant molecular cloud is prevented from free-fall collapse. Supersonic turbulent motion in molecular gas may be supporting a cloud against gravity. In fact, molecular linewidths in giant molecular clouds are commonly supersonic, ~ 2 to 3 km s^{-1} , representing random motion needed for cloud support. It is, however, not obvious how such supersonic turbulent motion is generated and maintained because such turbulence must quickly dissipate via interstellar shocks. The highly filamentary and clumpy structure seen in large-scale maps of clouds suggests that the area filling factor of gas is in the range $f = 0.05$ to 0.3 , so a cloud fragment may survive for approximately $1/f$ crossing times. For a typical cloud like Orion south, this implies that the total internal turbulent energy, $M_{\text{cloud}} V_{\text{turb}}^2 / 2 = \text{several times } 10^{47} \text{ erg}$ (for $M_{\text{cloud}} = \text{several times } 10^4 M_{\odot}$ and $V_{\text{turb}} = 1 \text{ km s}^{-1}$), would be dissipated over a period of 10 Myr. To maintain this turbulence in a steady state, kinetic energy and momentum must be supplied to the cloud. Molecular clouds must be supported against gravi-

tational collapse as the star formation rate averaged over the Galaxy is about $3 \text{ M}_{\odot} \text{ yr}^{-1}$ from a total molecular mass of $\sim 3 \times 10^9 \text{ M}_{\odot}$, implying that the steady-state clouds collapse at a rate $\sim 10^{-3} \tau_{ff}$. Two general mechanisms may inhibit rapid gravitational collapse: a strong magnetic field and a supply of kinetic energy. There is evidence that magnetic fields play an important role in regulating cloud collapse and may contribute to cloud support. However, fields are "slippery" in that gas can readily move along the field lines, permitting collapse of the gas into flattened disks, although Alfvén waves may inhibit this mode. When a cloud becomes sufficiently large that the fractional ionization drops below about 10^{-8} , ambipolar diffusion sets in, making the magnetic field ineffective in supporting the cloud. Even in the presence of B magnetic fields, energy injection is required in order to maintain star formation at the observed rate.

Several distinct mechanisms may inject kinetic energy into molecular clouds, which can be categorized into external and internal energy sources. Large-scale external energy injection includes processes such as cloud-cloud collisions, while on smaller scales, CO outflows and optical and near-infrared shocks may provide an internal source of energy input. In particular, molecular outflows involving large momenta may be a major source of turbulent motion if they are generated nearly constantly and uniformly in a cloud over the cloud lifetime (Bally and Lada 1983; Fukui et al. 1986). The results of the unbiased surveys may well serve as a test of the importance of outflows in cloud support.

Figure 1 shows that molecular outflows are fairly evenly distributed in each molecular cloud of 10 to 40 pc length. In the case of the Orion south and S287 clouds, the mean separation of outflows is roughly 5 pc. Such uniform distribution is favorable for cloud support, as a single molecular outflow can cover a radius not larger than a few pc. A more quantitative test is made by estimating the time scale needed to feed the turbulence momentum by molecular outflows (see, e.g., Margulis et al. 1988).

The number of generations of molecular outflows required may be calculated by dividing $M_{\text{cloud}} \times V_{\text{turb}}$ by the sum of the outflow momenta observed at the present epoch. The time scale needed to feed the turbulence momentum is then obtained by multiplying the number of generations by the mean lifetime of outflows. If this time scale is smaller than the cloud collapse time scale, molecular outflows are able to maintain the turbulence. From the results of unbiased surveys toward the three giant molecular clouds, Orion south, S287 (Fukui 1989), and Mon OB1 (Margulis et al. 1988), typical total momentum of outflows in a single cloud and a single generation is estimated to be 200 to $300 \text{ M}_{\odot} \text{ km s}^{-1}$ (Table II). On the other hand, the total cloud mass and turbulent velocity for them are several times 10^4 M_{\odot} and $\sim 1 \text{ km s}^{-1}$, respectively. The 50 to 160 generations of molecular outflows are needed for cloud support, and it takes ~ 3 to $9 \times 10^6 \text{ yr}$ to feed the turbulent momentum with the mean outflow lifetime of 3 to $17 \times 10^4 \text{ yr}$. This time scale is similar to the cloud free-fall time scale estimated from typical ^{13}CO linewidths ($\sim 2 \text{ km s}^{-1}$) and

TABLE II
Momentum Injection by Outflows in Giant Molecular Clouds

	Orion South ^e	S287 ^e	Mon OB1 ^e
Number of Outflows ^a	12	5	5
Outflow Momentum ^b ($M_{\odot} \text{ km s}^{-1}$)	320	270	190
Turbulent Momentum ($M_{\odot} \text{ km s}^{-1}$)	2×10^4	1.4×10^4	3×10^4
Generations	60	50	160
τ_{outflow}^c (yr)	5×10^4	1.7×10^5	3×10^4
τ_{support}^d (yr)	3×10^6	9×10^6	5×10^6

^a Number of outflows observed at the present epoch; this is assumed as the number of outflows in a single generation.

^b Total momentum of outflows in a single cloud in a single generation.

^c Mean outflow lifetime.

^d Time scale required to feed the turbulent momentum by molecular outflows.

typical cloud sizes (20 pc). It is therefore suggested that molecular outflows play an important role in cloud support.

VII. CONCLUSION

Recent progress in both high-resolution mm-wave observations and infrared imaging has provided a wealth of information on the mass outflow phenomenon from protostars. Systematic searches for molecular outflows have begun to provide the unbiased samples needed for statistical studies of outflow properties. Such studies have shown that molecular outflow sources are characterized by significantly larger luminosity than T Tauri stars in L1641. This suggests that molecular outflows correspond to the main accretion phase of protostellar evolution, with significant luminosity excess resulting from gravitational energy released by mass accretion. There is also increasing evidence for the role of molecular outflows in cloud support, and for dynamical interaction between individual outflows and their ambient gas. It is important to make even more systematic efforts in unbiased surveys, as our coverage of the sky in high-resolution CO surveys is still extremely small. These surveys and high-resolution observations with millimeter interferometers and large-format infrared cameras will provide deeper understanding of the role and evolutionary status of molecular outflows in star formation.

ORIGIN OF OUTFLOWS AND WINDS

ARIEH KÖNIGL

University of Chicago

and

STEVEN P. RUDEN

University of California, Irvine

A successful interpretation of the energetic bipolar outflows in young stellar objects should account for their ubiquity and for their inferred association with circumstellar accretion disks. The theory also has to explain the apparent presence of two distinct outflow components: an extended, neutral wind which has sufficient momentum to drive the large-scale molecular lobes, and a pair of collimated, ionized jets which emerge along the symmetry axis at high velocities but with a comparatively small momentum discharge. It is argued that the weakly ionized wind most likely represents an MHD outflow driven centrifugally from the disk surfaces or from the boundary between the disk and the star. Specific wind models for each of these alternatives are presented, and it is noted that both provide a natural explanation of the observed correlation between accretion and outflow. The kinematic, thermal and chemical wind properties predicted by these models are described and their observational implications are considered. In particular, it is pointed out that the wind characteristics may be reflected in the observed forbidden line and infrared continuum emission of T Tauri stars and in the measured abundances of various molecular species. The origin of the high-velocity jets is at present less well established. The jets may represent the ionized inner regions of a disk-driven wind or else could correspond to an isotropic, MHD wave-driven stellar wind that has been collimated by the ambient neutral outflow. Yet another possibility is that the jets are powered by the energy released in a shear boundary layer between the disk and the star. Episodic accretion events associated, perhaps, with FU Orionis outbursts might account for the nonsteady mass ejection indicated in certain jets.

The existence of high-velocity winds in T Tauri stars has been known for some thirty years now (see Herbig 1962*b*). However, only during the last decade, following the discovery of bipolar molecular flows and highly collimated optical jets (see Lada 1985 and Mundt 1985 for reviews), has it become apparent that energetic outflows are a ubiquitous phenomenon in young stellar objects (YSOs) ranging from deeply embedded infrared sources (DEIS) to classical T Tauri stars (CTTS). It is now recognized that the mechanical energy injected by YSOs into their parent molecular clouds could have a strong impact on the evolution of the clouds in that it may provide the required support against gravitational collapse (see, e.g., McKee 1989). It has also

been suggested (Shu and Terebey 1984) that these energetic outflows are responsible for terminating the YSO accretion phase by reversing the infall of the surrounding gas toward the star, which would have direct implications to the distribution of YSO masses and to the clearing of protoplanetary disks. Understanding the origin of YSO outflows is thus of fundamental importance to the theory of star and planet formation.

An important recent development has been the emergence of evidence that the outflow activity is strongly linked to the presence of circumstellar accretion disks and that many of the radiative properties of YSOs are direct manifestations of the accretion and outflow processes. However, despite the substantial observational progress, there is still no firm theoretical understanding of the origin of the outflows and of their role in the evolution of YSOs. Ordinary stellar wind mechanisms have proved inadequate to account for the large momentum discharges that are needed to drive the bipolar flows, so other mechanisms have been explored. In particular, the possibilities of tapping the liberated gravitational energy of the accreted material or the rotational kinetic energy of the star have been investigated. One of the most promising ideas has been that of a centrifugally driven wind (CDW), wherein magnetic fields anchored in a rotating disk or star accelerate the outflowing gas by means of the centrifugal force. This mechanism can readily account for the inferred momentum discharges and is consistent with the growing evidence for the presence of strong magnetic fields in YSOs and their environments. CDWs generally also carry large angular momentum discharges and can exert strong braking torques on the driving disks or stars. In fact, such winds could dominate the angular momentum transport in circumstellar disks and may be responsible for the ability of stars that had been spun up to breakup speeds to continue accreting. In this way they could play an essential role in the evolution of YSOs, which might account for their ubiquity.

Our review focuses on the recent developments concerning the accretion-outflow connection and the role of magnetic fields. In Sec. I we summarize the observational evidence for the two main outflow components, namely the ionized jets and the neutral (atomic and molecular) winds, as well as evidence for the association of energetic outflows with circumstellar disks and the dynamical importance of magnetic fields. Section II is devoted to the origin of the recently discovered neutral outflows. We concentrate on the theory of CDWs and discuss their kinematic, thermal, and chemical properties and their observational implications. In Sec. III we consider the formation of the less massive but higher velocity ionized jets. In Sec. IV we discuss a simple model that unifies star formation and bipolar flows. Finally, our conclusions are summarized in Sec. V.

I. OBSERVATIONAL BACKGROUND

A. The Two Outflow Components

Since the original discovery of a molecular bipolar flow source in L1551 IRS 5 by Snell et al. (1980), approximately 150 such sources have been identified (see Chapter by Fukui et al.). The most striking property of these flows is their bipolarity. Although they are often rather poorly collimated (see Lada 1985), these flows nevertheless almost always exhibit a two-lobe morphology, with molecular gas moving in two opposite directions away from a central YSO. The characteristic scales and dynamical ages of the flows are ~ 0.1 to 1 pc and $\gtrsim 10^4$ yr, respectively, and their momentum discharges F_{lobe} are of the order of 10^{-6} to $10^{-2} M_{\odot} \text{ yr}^{-1} \text{ km s}^{-1}$. Both the momentum discharge and the kinetic power L_{lobe} appear to be correlated with the bolometric luminosity L_{bol} of the central source, but the force F_{lobe} acting on the lobes is typically 100 to 1000 times greater than L_{bol}/c (where c is the speed of light), indicating that, with the possible exception of high-luminosity YSOs, they are not driven by radiation pressure.

It is now generally accepted that the bipolar molecular lobes, whose velocities V_{lobe} are $\lesssim 25 \text{ km s}^{-1}$, consist mostly of ambient gas that has been swept up by a much higher velocity wind emanating from the central region. This conclusion is consistent with the comparatively large ($\gtrsim 1 M_{\odot}$) inferred masses of the moving lobes and with the fact that the emission-weighted extent of the flow is often nearly independent of velocity, as expected for an expanding shell (Snell 1987). In the case of the L1551 IRS 5 flow, the presence of a thin, expanding shell has been directly confirmed by high-resolution CO imaging (see, e.g., Moriarty-Schieven et al. 1987). On the assumption that the lobes represent momentum-driven interstellar bubbles (Steigman et al. 1975; see Sec. IV), one can equate the force F_{lobe} on the lobes to the momentum discharge of the wind (i.e., to the product $\dot{M}_w V_w$ of the mass outflow rate and the wind velocity). The wind kinetic powers inferred in this way, $L_w \approx (V_w/V_{\text{lobe}}) L_{\text{lobe}}$, are generally limited to $\lesssim 0.1 L_{\text{bol}}$. In several well-collimated and highly resolved bipolar flow sources, systematic velocity gradients have been observed along the outflow major axis (Snell et al. 1984; Moriarty-Schieven et al. 1987; Fridlund et al. 1989). The line-of-sight velocity v_{\parallel} is seen to increase linearly with the projected distance r_{\perp} along a lobe

$$v_{\parallel} \propto r_{\perp} \quad (1)$$

for projected distances up to (typically) several tenths of a parsec away from the flow center. This ‘‘Hubble’’ law may arise if the outflow consists of clumps of gas with a range of velocities. As time progresses, the clumps naturally sort themselves in such a way that the highest velocity gas has traveled the farthest from the central source (as with freely flying shrapnel from an explosion). We will return to the origin of this linear Hubble relation in Sec. IV.

Recent surveys of outflows in molecular clouds (Fukui et al. 1986; Margulis et al. 1988; Snell et al. 1988; Wouterloot et al. 1989) clearly indicate

that a large fraction ($\sim 50\%$) of embedded young stellar objects go through the outflow phase some time during their evolution. High-resolution interferometric observations (Terebey et al. 1989) have shown that the outflow phase can occur very early in the evolution of a YSO and that outflow (presumably along the poles) can occur coevally with infall (presumably onto an equatorial disk). In the solar neighborhood, the frequency of occurrence of outflows is sufficiently high when compared to the stellar birth rate that this phase may be common to all stars with masses greater than that of the Sun (Margulis et al. 1988). The momentum and energy in a typical outflow are sufficient to disrupt the natal molecular cloud core surrounding a YSO (Mathieu et al. 1988); furthermore, outflows are predominantly associated with deeply embedded sources but only rarely with optically revealed YSOs (Lada 1988*b*; Margulis et al. 1989). On the basis of these facts, it seems likely that outflows are responsible for removing circumstellar material and for driving the evolution of YSOs from DEIS to CTTS. By dispersing the infalling molecular cloud core, outflows are also instrumental in determining the final mass of the combined star-disk system (Shu et al. 1987*a*).

Ionized optical jets are usually associated with DEIS or strong-emission CTTS. In contrast to the molecular flows, they are generally highly collimated (opening angles 3° to 10°), with the collimation lengths inferred to be $\lesssim 100$ AU (see, e.g., Mundt et al. 1987). Their velocities typically lie in the range 200 to 400 km s $^{-1}$, although some luminous sources (with $L_{\text{bol}} \gtrsim 10^3 L_\odot$) have measured radial speeds of 450 to 700 km s $^{-1}$ (see, e.g., Poetzel et al. 1989; Ray et al. 1990). The jet velocities are inferred both from spectroscopy and from proper motion measurements of optical emission knots. For example, the system of knots in the IRS 5 jet in L1551 exhibits maximum radial speeds of 350 km s $^{-1}$ (Stocke et al. 1988) and a transverse velocity of 190 km s $^{-1}$ (Neckel and Staude 1987), which is comparable to the proper motions of 150 and 170 km s $^{-1}$ measured for the associated Herbig-Haro (HH) objects HH 28 and HH 29 (Cudworth and Herbig 1979). The characteristic dynamical ages (~ 200 to 3000 yr) are 1 to 2 orders of magnitude lower than those of the molecular flows, and there is growing evidence for velocity variability and for nonsteady outflow episodes (Reipurth 1989*b*; see also Mitchell et al. 1988*a*; Bachiller et al. 1990*a*; Raga et al. 1990; Reipurth and Heathcote 1991).

The mass outflow rates in the jets have been inferred from optical line emission (in particular, the density sensitive [S II] $\lambda\lambda 6716, 6731$ lines) and radio continuum measurements to be $\dot{M}_j \approx 10^{-9}$ – $10^{-8} M_\odot \text{ yr}^{-1}$, and for the few cases where both jets and molecular flows are detected in the same source, it was found that their kinetic powers are comparable (Mundt et al. 1987). This raises the possibility that the jets could drive the molecular lobes if the latter represent energy-driven (Weaver et al. 1977), rather than momentum-driven, interstellar bubbles. This possibility could in principle be realized if the cooling time t_{cool} of the shocked jet material that, in this picture, fills the bubble, were longer than the age $t_{\text{lobe}} \approx R_{\text{lobe}}/V_{\text{lobe}}$ of the molecular lobes. We defer discussion of this possibility to Sec. III, where we also reexamine the

derivation of \dot{M}_j . It should be noted, however, that many molecular lobes are apparently not powered in this way. For example, in the source L1551 IRS 5, measurements of the far infrared emission from the molecular outflow region directly indicate that the expanding molecular shell is not energy driven (see, e.g., Clark et al. 1986). Furthermore, an analysis of the optically luminous Herbig-Haro objects that are associated with the heads of stellar jets suggests that, at least in some cases, the shocked jet material cools within the jet head and contributes to the observed emission (see, e.g., Hartigan 1989).

One of the most significant developments during the last few years has been the discovery in several DEIS of a *neutral* outflow component that apparently involves a sufficiently large momentum discharge to drive the molecular lobes. This component has been detected in the form of high-velocity ($\sim 150 \text{ km s}^{-1}$) atomic (Lizano et al. 1988) and molecular (see, e.g., Mitchell et al. 1988*b*; Koo 1989,1990; Mitchell et al. 1989; Masson et al. 1990; Mitchell and Hasegawa 1991) winds. It is as yet unclear whether the molecular gas, which appears to be clumpy, represents entrained ambient material or is due to the formation of molecules in the high-velocity atomic outflow (see Sec. II.C). In any case, there are indications that even some of the lower-velocity molecular gas in a source like L1551 IRS 5 originates in the vicinity of the YSO and is not part of the swept-up shell (Fridlund and White 1989). The presence of neutral atomic winds in CTTS has previously been inferred from Na I D line measurements (see, e.g., Mundt 1984), and the corresponding momentum discharges also appear to be large enough to drive the associated molecular flows (see, e.g., Natta and Giovanardi 1990). The existence of two distinct outflow components has been deduced in L1551 IRS 5 from an analysis of the optical emission-line spectra (Stocke et al. 1988). This analysis indicates that the CO lobe is pervaded by a $\sim 160 \text{ km s}^{-1}$ wind whose momentum discharge is an order of magnitude greater than that of the 440 km s^{-1} jet and could account for the expanding molecular lobes.

B. The Disk-Wind Connection

There is growing evidence that low-mass ($\lesssim 2 M_\odot$) YSOs, including both DEIS and CTTS, are surrounded by circumstellar disks with estimated masses ~ 0.01 to $1 M_\odot$ on scales $\sim 10^2$ to 10^3 AU (see Chapters by Beckwith and Sargent and by Basri and Bertout). The most direct evidence has come from molecular line and millimeter continuum interferometric measurements as well as from high-resolution infrared observations. For example, the presence of a rotating, Keplerian disk has been inferred in this way in HL Tau (Sargent and Beckwith 1987) and in T Tau (Weintraub et al. 1989*a*). A compact molecular core (of radius ~ 45 AU) detected around IRS 5 in L1551 (Keene and Masson 1990) is also a likely candidate for a circumstellar disk. Additional evidence has been provided by analyses of infrared and ultraviolet spectra, optical emission line profiles, and optical polarization maps. Furthermore, there are strong indications that Keplerian disks form in a similar fashion around high-mass YSOs (see, e.g., Vogel et al. 1985; Persson et al.

1988; Plambeck et al. 1990).

Evidence is also mounting for the existence of a strong link between circumstellar disks and energetic outflows in YSOs (see Chapter by Edwards et al.). Perhaps the most compelling argument in favor of such an association in low-mass YSOs derives from a comparison of DEIS and CTTS with weak-line T Tauri stars (WTTS; Walter et al. 1988). WTTS are similar to CTTS in all respects except that they do not exhibit infrared excesses and strong linear polarizations (a signature of circumstellar dust) or ultraviolet excesses (commonly attributed to emission from accreted gas that reaches the stellar surface) and that they lack the strong low-ionization and forbidden line emission as well as the P Cygni line profiles which are the hallmark of energetic outflows in CTTS. The simultaneous absence of evidence for substantial disks and strong winds in WTTS points to a likely connection between the accretion and outflow processes in YSOs. The properties of DEIS and CTTS suggest that the basic relationship lies in the outflows being powered by accretion. In particular, the observed correlation between L_w and L_{bol} is then understood from the fact that the luminosity excesses in YSOs can also be attributed to accretion. In a similar vein, the fact that DEIS and CTTS with comparable bolometric luminosities also have similar outflow parameters indicates that the wind-driving mechanism is the same in both types of objects and that it is tied to the presence of an active accretion disk. Additional support for the disk-wind connection comes from observations of CTTS of the YY Ori type, which show evidence for concurrent mass outflow and inflow (manifested, respectively, in P Cygni and inverse P Cygni line profiles) as well as for the existence of an opaque disk (indicated by the absence of redshifted forbidden line emission). The correlation between disk and wind signatures in DEIS and CTTS is apparently present also in higher-mass stars (Strom et al. 1988), which suggests that the accretion-outflow connection is a basic property of all YSOs.

The fact that the inferred wind kinetic powers are not much smaller than the bolometric luminosities ($L_w \lesssim 0.1 L_{bol}$) indicates that the bulk of the energy and momentum of the outflows is injected near the central YSO. Whether the wind emanates from the disk, the star, or the boundary between them is still an open question (see Sec. II). However, there are indications that at least part of the outflow is launched at a finite distance from the YSO, presumably from the surface of the associated disk. For example, several CTTS exhibit a narrow, blueshifted (-30 to -100 km s^{-1}) absorption component in the Na I D lines which is sometimes superposed on a classical P Cygni profile and which is plausibly interpreted as forming in a largely neutral wind on a scale of $\gtrsim 10$ stellar radii (Mundt 1988). In the case of neutral outflows detected in high-luminosity DEIS such as GL 2591 (Mitchell et al. 1989), one can argue that the wind is unlikely to originate at the stellar surface because of the high effective temperature of the YSO.

C. The Dynamical Role of Magnetic Fields

Magnetic fields are believed to play a central role in the evolution of molecular clouds and in the initiation of star formation by cloud core collapse (see Chapter by McKee et al.). Their importance in bipolar flows is suggested by the finding that the axes of the molecular lobes and of the associated jets are aligned within 30° of the ambient field direction (as determined by polarization measurements) in over 70% of the surveyed sources (Strom et al. 1986). In those cases where a flattened circumstellar mass distribution has been imaged, its minor axis is found to be parallel to the bipolar flow direction and is thus also aligned with the local magnetic field. Although dense molecular cores are apparently not magnetic pressure-dominated and hence their contraction is not directly controlled by magnetic stresses, this result suggests that the magnetic field nevertheless influences the orientations of the embedded circumstellar disks. This is presumably achieved through magnetic braking (see, e.g., Mouschovias and Paleologou 1980), which removes the angular momentum component normal to the field more efficiently than the parallel component and thus leads to preferential contraction along the field lines and to an alignment of the minor axis of the cloud core with the local magnetic field. Since a wind that originates in the vicinity of a YSO would be naturally directed along the axis of the associated disk, it is then not surprising that the bipolar flows are found to be aligned with the ambient magnetic field. The field is also expected to contribute to the subsequent collimation of the outflows both directly, through its confining transverse stress, and indirectly, through the anisotropic density distribution that it induces in the molecular cloud (Königl 1982; Shu et al. 1991; see Sec. IV).

Although the collapse of molecular cloud cores that form low-mass protostars is likely triggered by the reduction of the magnetic field support of the cloud by ambipolar diffusion (Lizano and Shu 1989), significant magnetic flux may still be carried in by the inflowing matter (see, e.g., Umebayashi and Nakano 1988). The advected magnetic field would not be strong enough to inhibit the accumulation of mass in the center, but it could play an important role in the removal of the excess angular momentum of the accreted matter, as we discuss in Sec. II.A. It is interesting to note in this connection that meteoritic evidence points to the existence of a ~ 1 gauss field at a distance of ~ 3 AU from the center of the protosolar nebula (Levy and Sonett 1978), which is of the right order of magnitude for this effect. The YSO itself could develop a strong magnetic field by dynamo action when it becomes convective (see, e.g., Shu and Terebey 1984). In fact, T Tauri stars exhibit vigorous magnetic activity that implies a surface field of a few hundred gauss (see Chapter by Montmerle et al.), and although direct Zeeman measurements have proven difficult, there are several cases where even higher values ($\gtrsim 10^3$ gauss) are consistent with the data (see, e.g., Johnstone and Penston 1986). Magnetic fields of this magnitude could lead to efficient braking of the stellar rotation (see Sec. III.B). Furthermore, a kilogauss-strength dipole field could

disrupt a circumstellar accretion disk at a distance of a few stellar radii and thereby alter the nature of the accretion flow onto the YSO. This situation has already been indicated in several objects (see, e.g., Bertout et al. 1988) and could have important implications to the dynamical and radiative properties of CTTS (Königl 1991).

II. ORIGIN OF NEUTRAL OUTFLOWS

As we pointed out in Sec. I.A, the large inferred momentum discharges in the bipolar flows and the comparatively low bolometric luminosities of most YSOs imply that radiation pressure is generally much too weak to drive the molecular lobes. An alternative possibility, that the high-velocity winds which push on the expanding molecular shells are driven by thermal pressure, can be ruled out on the basis of efficiency considerations. To generate the energetic YSO outflows, the temperatures at the base of the wind would be too high and the radiative losses too severe to be consistent with the observations (DeCampli 1981). The only potentially viable mechanisms proposed to date involve tapping the rotational energies of the YSO or its circumstellar disk through the agency of a magnetic field that threads the rotating mass. In these models, the magnetic field lines are wound up at the base of the wind and accelerate the outflowing gas either centrifugally, like beads on a rotating wire, or by axial pressure gradients, like an uncoiling spring. Similar ideas have been considered in connection with jets in active galactic nuclei, and it may therefore be fruitful to study bipolar flows in the context of the general theory of cosmic jets (Königl 1986). We discuss the basic principles of magnetohydrodynamic (MHD) winds from accretion disks and from the central YSOs in Secs. II.A and B, respectively. The thermal and chemical properties of the winds and their observational consequences are considered in Sec. II.C.

A. MHD Winds from Accretion Disks

1. CDW Models. The basic theory of steady-state, axisymmetric MHD outflows from rotating objects was developed in the context of stellar winds and was originally limited to a two-dimensional (equatorial plane) geometry (Weber and Davis 1967). Blandford and Payne (1982) generalized these ideas to a three-dimensional disk geometry using a self-similar model in the zero temperature limit, and Sakurai (1985,1987) further extended the formalism by re-introducing thermal pressure effects and dropping the self-similarity assumption. The theory was first applied to YSOs and circumstellar disks by Hartmann and MacGregor (1982) and Pudritz and Norman (1983,1986), respectively.

The structure of a perfectly conducting CDW from the surface of a Keplerian accretion disk can be described by referring to the three characteristic surfaces that form the loci of the points where the poloidal (meridional plane) component of the flow velocity is equal to that of the slow magnetosonic

(SMS), the Alfvén, and the fast magnetosonic (FMS) wave velocities, respectively. The wind is initially magnetically dominated, in the sense that the magnetic energy density is larger than the thermal, the gravitational, and the kinetic energy densities. In the limit of a cold outflow (speed of sound C_s much smaller than the Alfvén speed $V_A = B/(4\pi\rho)^{1/2}$, where B is the magnetic field amplitude and ρ is the mass density), the SMS speed reduces to C_s and the SMS surface is located very close to the face of the disk. Below the SMS surface, the poloidal acceleration is essentially thermal. However, above this surface the acceleration is centrifugal and is well approximated by the “bead on a rigid wire” picture (Henriksen and Rayburn 1971). Using this mechanical analogy, one can readily derive the condition for a centrifugal launching of the wind (Blandford and Payne 1982). If the wire intersects the disk at a distance r_0 from the center and makes an angle θ to the disk normal, then the balance of gravitational and centrifugal forces along the wire implies that, in equilibrium, the effective potential $\Phi_{\text{eff}}(y)$ satisfies

$$\frac{\partial \Phi_{\text{eff}}}{\partial y} = \frac{y + \sin \theta}{(1 + 2y \sin \theta + y^2)^{3/2}} - y \sin^2 \theta - \sin \theta = 0 \quad (2)$$

where the dimensionless variable $y \equiv s/r_0$ measures the distance s along the wire. The equilibrium is unstable when $\partial^2 \Phi_{\text{eff}}/\partial y^2$ is negative, which at $y = 0$ occurs for $\theta > 30^\circ$. Hence, centrifugal driving sets in if the poloidal component of the field is inclined at an angle of $<60^\circ$ to the outward radius vector.

The magnetic field continues to dominate the outflow up to the Alfvén surface. The inner region of the wind is then effectively force free ($(\nabla \times \mathbf{B}) \times \mathbf{B} = 0$), with the magnetic pressure gradient approximately balancing the magnetic tension. The tension is associated with the bending of the field lines toward the rotation axis (Fig. 1), which provides the initial collimation of the flow. Another consequence of the magnetic field dominance is that the gas along a given magnetic flux tube corotates with the disk material at the foot of the tube (i.e., the azimuthal velocity component satisfies $V_\phi \approx \Omega_K[r_0]r$, where $\Omega_K[r_0]$ is the Keplerian angular velocity at r_0 and r is the distance from the rotation axis). The wind can thus exert a substantial back torque on the disk, with the effective lever arm being of the order of the cylindrical radius r_A of the Alfvén surface. CDWs therefore represent a potentially very effective mechanism for removing angular momentum from the accretion flow. In the limit when virtually all the excess angular momentum of the inflowing matter is transported by the wind, the angular momentum conservation equation and the corotation property imply that \dot{M}_w is related to the mass accretion rate \dot{M}_{in} by

$$\frac{\dot{M}_w}{\dot{M}_{\text{in}}} \approx \left(\frac{r_0}{r_A} \right)^2 \quad (3)$$

which shows that converting only a small fraction of the inflow into an outgoing wind may suffice for this purpose (see Blandford and Payne 1982).

Figure 1. (*top*) The poloidal magnetic field lines in a self-similar, centrifugally driven wind from the surface (*heavy line*) of a Keplerian accretion disk. Under the assumed good coupling conditions, the plotted lines also represent the meridional projections of the wind flow lines. The model used in this plot corresponds to a central mass of $0.5 M_{\odot}$, a mass accretion rate of $3 \times 10^{-6} M_{\odot} \text{ yr}^{-1}$, and a mass outflow rate between 0.1 and 10 AU of $5 \times 10^{-8} M_{\odot} \text{ yr}^{-1}$ (with an equal contribution from each decade in radius). (*bottom*) Contours of constant poloidal velocity (*dashed lines*, labeled in km s^{-1}) and particle density (*solid lines*, labeled in $\log[n/\text{cm}^{-3}]$) for the same wind model. The heavy line on the left indicates the flow line that originates at $r_0 = 0.1 \text{ AU}$.

The wind inertia becomes important beyond the Alfvén surface, causing the field lines to become progressively more toroidal as the azimuthal flow velocity decreases below the corotation value (Fig. 2). The magnetic “hoop” stresses associated with the toroidal field component act to further collimate the flow. This field component is induced by a poloidal current, and it has, in fact, been shown (Heyvaerts and Norman 1989; Eichler 1992) that the magnetic flux surfaces of any MHD wind that encloses a finite poloidal current asymptotically assume a cylindrical or a paraboloidal morphology. The twisting of the field lines also results in the magnetic pressure gradient

replacing the centrifugal force as the main acceleration mechanism in this region.

Figure 2. The distribution of the magnetic field (*top*) and of the velocity (*bottom*) along a flow line for the cold, self-similar, disk-driven wind model shown in Fig. 1. Both B and V are normalized by their values at the base of the wind. The dash-dotted line marks the position of the critical (Alfvén) point of the flow. Note that V_ϕ decreases above the critical point because of inertial effects but that V_z continues to increase because of the magnetic pressure-gradient force.

The acceleration effectively continues up to the FMS surface, whose location depends on the initial temperature of the wind and on the shape of the field lines (Phinney 1983). In the cold flow limit, the FMS speed approaches V_A and the asymptotic poloidal wind velocity can be approximated by

$$V_w \approx \Omega_K(r_0) r_A \quad (4)$$

(see, e.g., Pudritz and Norman 1986). The asymptotic velocity is thus a factor $\sim r_A/r_0$ larger than the Keplerian velocity at the base of the outflow.

The relations (3) and (4) can be used to estimate the kinetic power of the wind. As we noted in Sec. I.B, the observations suggest that most of the energy injection into the wind occurs near the central YSO, and this is also the theoretical expectation for Keplerian disks (Blandford and Payne 1982). In particular, evaluating the kinetic power

$$L_w \approx \dot{M}_w V_w^2 \approx \dot{M}_w [\Omega_K(r_0) r_A]^2 \approx \dot{M}_{in} [\Omega_K(r_0) r_0]^2 \approx G M_* \dot{M}_{in}/r_0 \quad (5)$$

(where G is the gravitational constant) at the inner edge (r_{min}) of the disk and noting that the accretion-dominated bolometric luminosity is

$$L_{bol} \approx \frac{G M_* \dot{M}_{in}}{R_*} \gtrsim \frac{G M_* \dot{M}_{in}}{r_{min}} \quad (6)$$

(where M_* and R_* are the mass and radius of the YSO), one sees that this model provides a natural explanation for the observed correlation between L_w and L_{bol} and for the limit $L_w \lesssim 0.1 L_{bol}$. Most of the momentum injection is also expected to take place near the central star and the predicted momentum discharge can be as high as $\sim L_{bol}/V_w (> > L_{bol}/c)$. In the case of L1551 IRS 5, this value is consistent with the inferred magnitude of F_{lobe} and supports the conclusion that the expanding molecular shell is momentum driven. In the original application to bipolar flows (Pudritz and Norman 1983, 1986), the molecular lobes were identified with large-scale MHD winds from the surfaces of massive disks and most of the momentum and energy injection were assumed to occur at large radii. This interpretation of the lobes has not been substantiated by subsequent observations (see Sec. I.A) and also faces severe theoretical difficulties in view of the large mass accretion rates that it implies (Shu et al. 1987a).

One can express the effective value of r_A/r_0 in terms of observable quantities by using the momentum-driven bubble approximation $F_{lobe} \approx \dot{M}_w V_w$ and the condition $\dot{M}_{in} \gtrsim R_* L_{bol}/G M_*$ in Eq. (1), which gives

$$\frac{r_A}{r_0} \gtrsim \left(\frac{R_* V_w L_{bol}}{G M_* F_{lobe}} \right)^{1/2}. \quad (7)$$

For self-consistency, the right-hand side of Eq. (7) must be greater than 1; if this condition is not satisfied, then both the accretion and the outflow might be nonsteady (see Sec. III). The magnetic field amplitude B_0 at the base of the wind can be estimated in a similar fashion from the assumption that the outflow carries away the excess angular momentum of the accreted matter (see Eq. [11] below), which implies

$$B_0 \gtrsim \frac{L_{bol}^{1/2}}{(G M_* r_0^3)^{1/4}} \left(\frac{R_*}{r_0} \right)^{1/2}. \quad (8)$$

For a low-mass YSO like IRS 5 in L1551, this yields a field strength of a few gauss at $r_0 = 1$ AU, which is consistent with the available evidence for the protosolar nebula (Sec. I.C).

The construction of general wind solutions for a perfectly conducting gas with an adiabatic equation of state was discussed by Sakurai (1985). A steady-state, axisymmetric MHD wind possesses five field-line constants: the specific energy e and angular momentum l , which include both material and magnetic contributions, the field angular velocity ω , the ratio k of the mass flux to the magnetic flux, and the magnitude of the coefficient K in the adiabatic relation $P = K\rho^\Gamma$ (where P is the pressure and Γ is the adiabatic index). These constants uniquely determine the kinematic and thermodynamic structure of the wind. For a given distribution of angular velocity, pressure, and density at the base of the flow, one can solve for e , l , k , and K in terms of the magnetic stream function Ψ (which determines the poloidal field components) by requiring that the wind pass through the SMS and FMS critical points. The distribution of Ψ is, in turn, evolved from the top of the disk by solving the cross-field force balance equation and imposing the regularity condition at the Alfvén surface. Sakurai (1987) obtained solutions for self-gravitating disks with a split-monopole field configuration. Blandford and Payne (1982) assumed self-similarity in the *spherical* radial coordinate (which for a Keplerian disk implies $B_0 \propto r_0^{-5/4}$) and neglected thermal effects (which is a fair approximation for a wind that is driven mainly by centrifugal forces; cf. Belcher and MacGregor 1976). They further assumed that the flow starts with zero poloidal velocity from the equatorial plane. In this case the solutions only need to pass through one critical point and their topology is completely specified by the dimensionless versions of the parameters k and l . Figures 1 and 2 show a representative solution of this type, slightly generalized to include the effects of finite initial poloidal velocity and height above the midplane.

Several investigators have discussed MHD wind models in which centrifugal forces play a secondary role and the magnetic pressure gradient dominates the acceleration from the outset. An early version of such models was constructed by Draine (1983), who considered a YSO threaded by interstellar magnetic field lines and suggested that the rapid winding of the field by the stellar rotation would drive a strong shock wave into the ambient medium and produce an evacuated magnetic bubble. Uchida and Shibata (1985) performed numerical simulations of disks that are initially rotating at sub-Keplerian velocities and showed that the relaxation of the field-line twist induced by the contracting disk pushes out matter in the polar directions. Both of these models are manifestly time dependent. Lovelace et al. (1991) examined a steady-state version of this idea and proposed that the gradient of the zz component of the magnetic stress, $(B_r^2 + B_\phi^2 - B_z^2)/8\pi$, can drive a wind from the disk surface to escape speeds. In this picture, the wind need not carry a net poloidal current and hence may not be collimated by magnetic hoop stresses. However, it is still assumed to transport the excess angular momentum of

the accreted gas. A potential difficulty with these models is that it has not yet been demonstrated that the large z -gradients of B_ϕ that are postulated to exist at the base of the outflow can actually be achieved except as transient events. For one thing, tightly wrapped field configurations (as in Draine's model) are susceptible to field-line reconnection. Furthermore, the azimuthal field generated by differential rotation in a disk that is threaded by open field lines would tend to compress the gas rather than expel it (and similarly for the B_r component induced by the radial inflow), which suggests that the surface boundary conditions envisioned in the Lovelace et al. scenario may be hard to realize. In particular, the transition from inflow to outflow might occur only after the density in the disk had dropped sufficiently to allow the field to control the motion of the gas, in which case the field may be expected to assume the force-free configuration postulated in the CDW model (see Sec. II.A.2 for an illustration of these points).

The preceding discussion of MHD winds has been based on the assumption that the magnetic field is effectively "frozen" into the outflowing gas. In reality, atomic and molecular winds from circumstellar disks would be mostly neutral, so the validity of this assumption must be verified. The charged particles typically consist of free electrons and of positively charged ions. The magnetic flux is transported by the electrons, which are usually well coupled to the positive ions by electrostatic forces. In a weakly ionized medium, it is thus convenient to divide the gas into two components: the neutrals, which provide the dominant contribution to the inertia and thermal pressure; and the ions, which carry the magnetic flux and are subject to the Lorentz force. These two components are coupled by collisions. To an excellent approximation, the steady-state equations of motion of the neutrals and the ions (subscript i) are, respectively,

$$\rho(\mathbf{V} \cdot \nabla)\mathbf{V} + \nabla P + \rho \nabla \Phi = \gamma \rho_i \rho (\mathbf{V}_i - \mathbf{V}) \quad (9)$$

and

$$\frac{1}{4\pi} (\nabla \times \mathbf{B}) \times \mathbf{B} = \gamma \rho_i \rho (\mathbf{V}_i - \mathbf{V}) \quad (10)$$

where Φ is the gravitational potential and $\gamma \approx 3.5 \times 10^{13} \text{ cm}^3 \text{ g}^{-1} \text{ s}^{-1}$ (valid for $|\mathbf{V}_i - \mathbf{V}| \lesssim 2 \times 10^6 \text{ cm s}^{-1}$; Draine et al. 1983) is the collisional coupling coefficient. Equations (9) and (10) show explicitly that the neutrals experience the effect of magnetic stresses only through their collisions with the ions. The wind dynamics can be treated in the single fluid approximation if the magnitude $|\mathbf{V}_i - \mathbf{V}|$ of the ion-neutral drift velocity (calculated from Eq. [10]) is everywhere much smaller than the bulk outflow speed V , which will be the case if the ion-neutral collision time is much shorter than the outflow time. Figure 3 illustrates how the collisional ionization induced by ambipolar diffusion heating (see Sec. II.C) and the radiative ionization of "heavy" atoms (primarily carbon) by the ultraviolet photons from the YSO contribute to the fulfillment of this condition in the wind model presented in Figs. 1 and 2.

Inasmuch as most of the high-energy photons originate in the accretion flow, the radiative ionization represents a feedback mechanism by which the inflow influences the coupling of the magnetic field to the wind and hence the removal of the excess angular momentum of the accreted matter (Pudritz and Norman 1983). It is important to note, however, that even though the outflow can be well represented *dynamically* as a single-component medium, the energy dissipation associated with the ion-neutral drift cannot be neglected in the calculation of the *thermal* properties of the gas (see Sec. II.C).

Figure 3. (top) The normalized ion-neutral drift velocity along two flow lines for the model shown in Figs. 1 and 2. The solid lines represent the effect of collisional ionization alone whereas the dashed lines depict the added effect of the ionization of "heavy" atoms (C, O, Si, and Fe) by the stellar radiation field (assuming a photosphere of radius $3 R_\odot$ and an effective temperature of 4×10^3 K). (bottom) The minimum grain-neutral drift velocity that is required for uplifting dust from the disk. Characteristic values of the grain radius ($0.1 \mu\text{m}$) and density (3 g cm^{-3}) and a normal dust-to-gas ratio have been assumed.

Figure 3 also demonstrates that the neutrals, after being accelerated by neutral-ion collisions, can uplift the dust in the wind formation zone by means of grain-neutral collisions. This has significant implications to the optical and infrared properties of YSOs (Safier and Königl 1992). A direct consequence of the efficient acceleration of grains is that the effective dust photosphere for absorption and reprocessing of stellar radiation is raised above the midplane, which can strongly affect the observed continuum spectrum (see, e.g., Kenyon and Hartmann 1987). In particular, the reprocessed radiation may account for the approximately flat ($\nu F_\nu \approx \text{const}$) near- and mid-infrared spectra measured in some of the CTTS that show evidence for circumstellar disks and energetic outflows (see, e.g., Rucinski 1985). A dusty disk-driven wind could also give rise to the $\sim 10^2$ to 10^3 AU cometary reflection nebulae that have been imaged around several YSOs (including IRS 5 in L1551; see, e.g., Strom et al. 1985; Campbell et al. 1988a). Furthermore, such a wind could lead, through multiple scattering of stellar radiation, to the aligned linear polarization pattern exhibited (in both visible and infrared light) by many bipolar outflow sources (see Bastien 1989).

2. Magnetized Disk Models. One of the key challenges of CDW models is the construction of self-consistent disk-wind configurations in which the global magnetic field geometry and the mass outflow rate are calculated for given inflow parameters. To account for the shearing (by differential rotation) and radial advection of the magnetic field lines, steady-state models of Keplerian accretion disks must include a field dissipation mechanism: either ambipolar diffusion or (for densities $\gtrsim 10^{11} \text{ cm}^{-3}$) Ohmic diffusivity. Königl (1989) studied self-similar models of this type that were matched onto the cold wind solutions of Blandford and Payne (1982). He assumed that the disk is threaded by open field lines whose stresses regulate the angular momentum transport of the inflowing gas and solved explicitly the angular momentum conservation equation

$$\frac{\rho V_r}{r} \frac{\partial}{\partial r} (r V_\phi) = \frac{B_r}{4\pi r} \frac{\partial}{\partial r} (r B_\phi) + \frac{B_z}{4\pi} \frac{\partial B_\phi}{\partial z} \quad (11)$$

(with V_z set equal to zero, appropriate for a geometrically thin disk) and the induction equation, which in the ambipolar diffusion-dominated regime takes the form

$$\nabla \times (\mathbf{V}_i \times \mathbf{B}) = 0 \quad (12)$$

(with \mathbf{V}_i determined from Eq. [1]). The solutions were derived subject to the constraint

$$\nabla \cdot \mathbf{B} = 0. \quad (13)$$

By imposing the continuity of the magnetic field components and of the field-line constant $\omega = [V_{i\phi} - (V_{ir} B_\phi / B_r)]/r$ at the disk-wind interface (which follow from the continuity of the momentum flux density as well as of the tangential electric field and normal magnetic field components at the boundary), the disk solutions (Fig. 4) were joined smoothly onto the corresponding

self-similar wind solutions. The main result of this study was that continuous disk-wind configurations in which the bulk of the excess angular momentum as well as most of the liberated gravitational energy of the accreted matter are carried away by a super-Alfvénic and magnetically collimated CDW can be readily constructed for representative values of the (four) free parameters of the model.

This motivated the suggestion that the ubiquity of energetic outflows in accreting YSOs can be attributed to the fact that the winds are a *necessary* ingredient in the accretion process in that they carry away most of the angular momentum that needs to be removed in order for the accretion to proceed. It was argued that this mechanism should be highly effective because only a small fraction of the accreted mass is typically required to transport away the liberated angular momentum and energy of the inflowing matter (see Eq. [3]), and because this mass can be removed fairly easily on account of the near balance of the gravitational and centrifugal forces acting on it (see also Blandford and Payne 1982). Furthermore, it was noted that the disk may be expected to evolve to a steady state under the action of several feedback mechanisms. For example, an increase in the mass accretion rate over its equilibrium value would lead to a higher density at the base of the wind and hence to a higher outflow rate that would remove the excess energy and angular momentum. Similarly, a sudden increase in the angular momentum inside the disk should result in a larger torque at the base of the wind that would increase the magnitude of B_ϕ and hence the angular momentum carried by the outflow (Blandford and Payne 1982). Finally, any increase in the magnetic-field amplitude in the disk over its equilibrium value should be rapidly smoothed out by the ion-neutral drift, which scales as B^2 (see Eq. [10]).

Figure 4. The poloidal magnetic field geometry in a self-similar, ambipolar diffusion-dominated accretion disk. The heavy lines depict a few of the field lines whereas the dashed line delineates the surface of the disk. The arrows represent the drift velocities of the ions relative to the neutral disk material. Contrast the bending of the field lines away from the symmetry axis with the bending toward the axis in a centrifugally driven wind (top panel of Fig. 1).

The self-similar model employed by Königl did not address the question of whether the derived field configuration can actually be set up in a disk with realistic density and ionization profiles. To make further progress, Wardle and Königl (1992) focused on the vertical structure of a localized region in a thin Keplerian disk and assumed a constant sound speed C_s (with $P = C_s^2 \rho$)

and a uniform ion density ρ_i . (These assumptions may, in fact, apply in real molecular disks in the density regime $\sim 10^8$ to 10^{10} cm $^{-3}$; see Nakano 1984.) They then solved Eqs. (9), (10), (12), (13), and the mass conservation equation

$$\nabla \cdot (\rho \mathbf{V}) = 0 \quad (14)$$

neglecting radial derivatives in comparison with z -derivatives whenever possible. An illustrative example of their calculations is presented in Fig. 5. It is seen that most of the disk material is in quasi-hydrostatic equilibrium, with the vertical compression by the combined magnetic and tidal stresses being balanced by the thermal pressure gradient. The neutral gas is in near-Keplerian rotation, and the frictional torque that it exerts on the ions causes the field lines (which are “frozen” into the ionized component) to move around at a slightly lower azimuthal speed. The resulting transfer of angular momentum from the neutrals to the field allows the neutral gas to move toward the center. Under the assumed steady-state conditions there is, however, no inward transport of magnetic flux, so the field lines remain stationary. The neutrals thus move across the field lines, maintaining sub-Keplerian azimuthal speeds on account of the radial neutral-ion drag. The radial drag on the ions in turn causes the field lines to bend away from the rotation axis (see Eq. [10] and Fig. 4), which, as we discussed in Sec. II.A.1, is a necessary condition for launching a CDW.

The angular-momentum conservation equation (the ϕ component of Eq. [9]) together with the constancy of ω along a field line imply that the difference between the angular velocities of the neutrals and the ions decreases as the field lines bend away from the symmetry axis toward regions of lower V_ϕ/r . Eventually a transition point is reached where the ions overtake the neutrals: above this point the field transfers angular momentum back to the matter (a process which in a fully developed CDW continues all the way up to the Alfvén point). Because V_z is much smaller than V_ϕ in a thin disk, the angular-momentum conservation equation also implies that V_r changes sign near this point. In fact, it can be readily shown that the radial drag vanishes and V_ϕ becomes equal to the Keplerian speed V_K at practically the same location (see Fig. 5). Beyond this point the field pushes on the matter and, if the bending angle is large enough (see Sec. II.A.1), a centrifugally driven outflow is initiated. The locus of these transition points can thus be naturally identified with the boundary between the disk and the wind. In a disk where most of the matter transfers angular momentum and energy to the field and only a small fraction of the accreted mass is expelled, the distance of this boundary from the midplane must exceed a density scale height. Under these conditions the base of the wind is effectively force free and the field is usually strong enough to dominate the vertical compression of the disk.

Much more work remains to be done in establishing the validity and applicability of this scenario. The main task is to construct global disk-wind solutions in which the outflow passes through all the relevant critical points. As part of this effort, the self-similar model would have to be generalized to

Figure 5. The distribution of the magnetic field, the density, and the velocity in an ambipolar diffusion-dominated accretion disk. All the quantities are normalized by their midplane values (subscript 0), with V_K denoting the Keplerian speed. The solutions were derived for an isothermal gas with a constant ion density and assuming a geometrically thin disk (so that $B_z = B_0 = \text{const.}$). Note the large drop in density below the point where the inflow changes into an outflow ($V_r = 0$) and the change in the sign of the gradient of B_r and B_ϕ above that point. The dash-dotted line marks the location of the sonic point. The parameters used in this model correspond to a gas with temperature $T \approx 10$ K, particle density $n \approx 10^9 \text{ cm}^{-3}$, electron density $n_e \approx 0.1 \text{ cm}^{-3}$, and magnetic field amplitude $B \approx 1 \text{ mG}$ at a distance $r_0 \approx 10^2 \text{ AU}$ from a solar-mass star that accretes at a rate $\dot{M}_{\text{in}} \approx 10^{-6} M_\odot \text{ yr}^{-1}$.

take account of the boundary conditions in the inner and outer radii of the disk. It is also important to investigate the magnetic field configurations that are likely to result from the initial collapse of the parent molecular cloud and the magnitude of the magnetic flux that might be subsequently brought in through the disk. Furthermore, in studying the denser regions of the disk, the effects of Ohmic diffusivity would have to be included. There are also interesting questions of stability and of the global current flow in a magnetically self-collimating wind that would need to be addressed in a complete theory.

B. MHD Winds from YSOs: The X-celerator Mechanism

We summarized the evidence for the presence of disks surrounding YSOs in Sec. I.B. It is generally believed that a large fraction of the final protostellar mass must be accreted through a geometrically thin disk (see Chapter by Shu et al.). For this matter to flow inward, it must lose both energy and angular momentum (Lynden-Bell and Pringle 1974). The physical mecha-

nism that governs the loss of angular momentum determines the rate \dot{M}_{in} at which the protostar can gain mass. Processes such as global spiral density waves (Adams et al. 1989), local turbulent convective viscosity (Lin and Papaloizou 1985; Ruden and Lin 1986), and centrifugally driven disk winds (see Sec. II.A) have been invoked as the dominant source of angular momentum loss (see also the chapter by Adams and Lin). No matter which mechanism is operative, as the protostar gains mass from the disk, it also gains angular momentum at the rate $\dot{M}_{\text{in}} j_{\text{in}}$, where j_{in} is the specific angular momentum at the protostellar equator R_e . During the disk accretion phase, the protostar can easily gain sufficient angular momentum to be spun up to equatorial breakup velocities $V_e \approx (GM_*/R_e)^{1/2}$ (Ruden and Pollack 1991). After this critical state is reached, additional matter cannot flow past the centrifugal potential barrier and be added to the protostar unless either the accreting gas can lose angular momentum or the protostar can spin down below breakup. Two recent papers (Paczynski 1991; Popham and Narayan 1991) have investigated the possibility that a rapidly rotating star can remain below the breakup speed by transferring angular momentum to the surrounding disk via extremely strong viscous torques. In this subsection we discuss an alternate means by which a magnetic protostar can continue to accrete while rotating near breakup, namely, the ejection of a powerful wind that carries away a small amount of mass but a large amount of angular momentum.

Before discussing the physical mechanism behind the protostellar wind, we estimate the mass and angular momentum loss rates that are needed in order for the protostar to continue accreting (Shu et al. 1988; hereafter SLRN). We start with a low-mass protostar on the “deuterium birthline,” where nuclear burning of deuterium acts as a thermostat that keeps the central temperature at $\sim 10^6$ K while the star accretes (Stahler 1983a). Such an object is fully convective and can be adequately modeled as an $n = 3/2$ polytrope; it obeys a linear mass–polar radius relation

$$R_* \approx 8 R_\odot \left(\frac{M_*}{M_\odot} \right) \quad (15)$$

(Shu et al. 1987a). For analytical simplicity, we assume that the protostar is rotating uniformly at a rate Ω_* and has total angular momentum $\mathcal{J}_* = b M_* (GM_* R_e)^{1/2}$. For a critically rotating $n = 3/2$ polytrope, James (1964) has shown that $R_e \approx 1.63 R_*$, $\Omega_* \approx (GM_*/R_e^3)^{1/2}$, and $b \approx 0.136$. Using these formulae and Eq. (15), it is easy to show that the equatorial rotation velocity V_e is *constant* along the deuterium birthline,

$$V_e = \Omega_* R_e \approx \left(\frac{GM_*}{R_e} \right)^{1/2} \approx 125 \text{ km s}^{-1} \quad (16a)$$

and that the angular momentum is proportional to the square of the stellar mass,

$$\mathcal{J}_* = b \frac{GM_*^2}{V_e}. \quad (16b)$$

In the presence of both disk accretion and an outflowing wind (but neglecting viscous transport of angular momentum between star and disk), the protostar gains mass and angular momentum at the *net* rates of

$$\dot{M}_* = \dot{M}_{\text{in}} - \dot{M}_w \quad (17a)$$

and

$$\begin{aligned} \dot{J}_* &= \dot{M}_{\text{in}} j_{\text{in}} - \dot{M}_w j_w \\ &= (\dot{M}_{\text{in}} - J \dot{M}_w) \Omega_* R_c^2 \end{aligned} \quad (17b)$$

respectively, where the streamline-averaged specific angular momentum carried by the wind is $j_w \equiv J \Omega_* R_c^2$. To remain on the deuterium birthline, the protostar must gain angular momentum at a rate given by the time derivative of Eq. (16b),

$$\dot{J}_* = 2b \frac{GM_*}{V_e} \dot{M}_*. \quad (18)$$

Equating Eqs. (17b) and (18) and using equations (16a) and (17a), we find that the mass flux in the wind must be related to the mass flux through the disk by

$$\dot{M}_w = \frac{1 - 2b}{J - 2b} \dot{M}_{\text{in}} \quad (19)$$

(SLRN; compare Eq. [3]). For the star to gain more mass from the disk than is lost in the wind, Eqs. (17a) and (19) show that J must exceed unity. In fact, an asymptotic analysis of centrifugally driven winds shows that $J > 3/2$ (Sakurai 1985; SLRN; Heyvaerts and Norman 1989). Furthermore, if the Poynting stress of the magnetic field becomes asymptotically small, J is related to the terminal wind velocity V_∞ by

$$J = \frac{3}{2} + \frac{1}{2} \left(\frac{V_\infty}{V_e} \right)^2. \quad (20)$$

In the case of the outflow associated with HH 7–11, Lizano et al. (1988) measured the terminal wind velocity to be 170 km s^{-1} ($= 1.36 V_e$; see Eq. [16a]), so by Eqs. (19) and (20), $\dot{M}_w/\dot{M}_{\text{in}} \approx 0.3$. The predicted value of this ratio is in encouragingly good agreement with the value found by dividing the outflow rate $\dot{M}_w \approx 3 \times 10^{-6} M_\odot \text{ yr}^{-1}$ inferred by these investigators by the disk accretion rate $\dot{M}_{\text{in}} \approx 10^{-5} M_\odot \text{ yr}^{-1}$ deduced from infrared spectral modeling (F. C. Adams, personal communication). An important test of this theory will be to verify Eq. (19) for sources other than HH 7–11.

The physics of centrifugally driven mass loss from rapidly rotating magnetic protostars has been analyzed in a variety of contexts by Draine (1983), by Hartmann and MacGregor (1982), and by SLRN. The latter group of authors specifically consider the loss of mass from *cool* stars where the isothermal sound speed of the photospheric layers C_s is much less than the equatorial breakup speed (the virial velocity, Eq. [16a]). In low-mass protostars the

dimensionless ratio $\varepsilon \equiv C_s/V_e$ is typically ~ 0.05 . Suppose that a rapidly rotating, *nonmagnetic* protostar attempts to launch a wind using just the thermal pressure of the photosphere. The outflowing gas, which maintains the same specific angular momentum as the stellar surface, does not have sufficient rotation to remain in orbit at a larger radius and, for $\varepsilon < 1$, must settle back onto the star. The presence of a magnetic field is essential for supplying the additional angular momentum that allows the gas to continue moving out (recall the “bead on a rigid wire” analogy discussed in Sec. II.A.1). We can estimate the magnitude of the required magnetic field by demanding that the Alfvén velocity $V_A = B/(4\pi\rho)^{1/2}$ be comparable to the virial velocity V_e in order that magnetic stresses can overcome the gravitational potential barrier. (An analogous estimate of the coronal temperature needed to launch a wind by purely thermal means would imply $C_s \approx V_e$, i.e., $\varepsilon \approx 1$.) A fiducial measure of the density in the wind is $\rho \approx \dot{M}_w/4\pi R_*^2 V_e$, which can be substituted into the criterion $V_A \approx V_e$ to yield

$$B_* \approx \left(\frac{\dot{M}_w V_e}{R_*^2} \right)^{1/2}. \quad (21)$$

Because the bolometric luminosity satisfies $L_{\text{bol}} \approx GM_* \dot{M}_{\text{in}}/R_*$ and because $\dot{M}_{\text{in}} \approx \dot{M}_w$ by Eq. (19), we can rewrite this last equation as

$$B_* \approx \frac{L_{\text{bol}}^{1/2}}{(GM_* R_*^3)^{1/4}} \quad (22)$$

which may be compared with the earlier estimate (Eq. [8]) for B in disk-driven winds. For typical protostellar parameters ($M_* \approx 0.5 M_\odot$, $R_* \approx 4 R_\odot$), Eq. (21) shows that magnetic fields of order 100 gauss (averaged over the stellar surface) are required to launch winds with mass-loss rates of order $10^{-6} M_\odot \text{ yr}^{-1}$. Such field strengths are consistent with the values commonly inferred in YSOs (see Sec. I.C).

Mechanistically, we may think of the wind mass-loss rate as determined at the sonic point and the wind angular momentum loss rate as determined at the Alfvén point (Weber and Davis 1967). For outflow velocities and mass loss rates of the order inferred in HH 7–11, the density at the base of the wind, where the sonic transition is made, must be high—comparable to photospheric values. To make analytic calculations tractable, SLRN assumed that the magnetic field lines at the sonic point rotate at the breakup speed. Because the field is anchored deep in the protostar, this assumption requires the protostar to rotate at breakup as well. In this particular case, the wind is best analyzed in the rotating frame of the star, where an effective gravitational potential Φ_{eff} that includes the centrifugal effects of rotation can be rigorously defined. In the rotating frame, ideal MHD requires the magnetic field to be exactly parallel to the flow velocity, which means that there is no Lorentz force

along the streamlines of the outflowing wind. Bernoulli's equation requires that the outflow velocity satisfy

$$\frac{1}{2} |\mathbf{V} - \Omega_* \hat{\mathbf{z}} \times \mathbf{r}|^2 + h(\rho) + \Phi_{\text{eff}} = e(\Psi) \quad (23)$$

where $h(\rho)$ is the enthalpy of the gas and $e(\Psi)$ is the (conserved) energy on the streamline labeled by the stream function Ψ . The density and the poloidal velocity are related to the stream function through $\rho \mathbf{V}_{\text{pol}} = \nabla \times [\Psi(r, z) \hat{\phi}]$, which means that the equation of continuity (Eq. [14]) is automatically satisfied. Force balance *across* different streamlines is governed by the analog of the Grad-Shafranov equation from plasma fusion, which describes axisymmetric, steady-state fluid configurations in tokomaks (Shafranov 1966; Heinemann and Olbert 1978). In the outflow problem, the transfield force balance equation takes the form

$$\nabla \cdot (\mathcal{A} \nabla \Psi) = \mathcal{Q} \quad (24)$$

where \mathcal{A} is an Alfvén discriminant that changes sign across the Alfvén surface and \mathcal{Q} is a sum of terms involving the derivative *across* streamlines of each of the five functions that are constant *along* streamlines (energy, angular momentum, angular velocity, ratio of magnetic flux to mass flux, and entropy; see Sec. II.A.1). Equation (24) has the (apparent) form of a steady-state heat conduction equation in which force imbalance across streamlines (detailed in \mathcal{Q}) leads to the spreading of the flow streamlines (rather than to the diffusion of heat). The solution of the coupled Eqs. (23) and (24) determines the density and velocity structure in the wind.

At the base of the outflow, pressure forces are required to accelerate the wind to sonic speeds. For a smooth transition from subsonic to supersonic flow to be made (no shocks), SLRN have shown that the sonic transition must occur within a distance $\sim \varepsilon R_*$ from the “X-point” of the effective potential (defined to be where $\nabla \Phi_{\text{eff}} = 0$). For a star rotating at the breakup speed, this “point” is actually a narrow ring at the stellar equator where the centrifugal force balances gravity. Although thermal pressure forces initially are important in launching the wind, well downstream of the sonic point, they are negligibly small compared to magnetic forces, and the wind can be treated as dynamically cold. Once the gas has made the sonic transition, magnetocentrifugal acceleration takes over and enforces approximate corotation of the wind at the angular velocity Ω_* out to the Alfvén radius. If the sonically outflowing gas from the X-point is to pass smoothly through the Alfvén point, the magnetic field strength near the X-point must be $\sim \varepsilon^{-1}$ larger than the estimate above (Eq. [21]) and the gas density must be $\sim \varepsilon^{-2}$ larger than $\dot{M}_w / 4\pi R_*^2 V_e$. This large value of the density at the X-point can be understood from the fact that the gas which moves with a speed $C_s = \varepsilon V_e$ through two narrow bands just above and below the stellar equator, each with area $2\pi R_* \cdot \varepsilon R_*$, must carry the full mass discharge \dot{M}_w . The concentration of the stellar magnetic field near

the locus of the X-points in the equatorial plane is crucial in several ways. First, the magnitude of \mathbf{B} is sufficiently large to ensure that the gas flowing from the sonic point can be torqued up to super-Alfvénic speeds. Second, the poloidal field component has the correct topology to launch a centrifugally driven wind, i.e., it is inclined by less than 60° to the equatorial plane (see Sec. II.A.1). Third, the high magnetic field strengths mean that the region inside the Alfvén surface is nearly force free. The strong magnetic pressure pushes the streamlines poleward and is responsible for the initial collimation of the outflow. Outside the Alfvén surface, the inertia of the gas dominates the magnetic field, and the “hoop” stress associated with the azimuthal component of \mathbf{B} focuses the outflow on a global scale (Nerney and Suess 1975; see Sec. II.A.1).

Figure 6. The geometry of the X-celerator protostellar wind model. Material enters the star from a thin disk, and the wind leaves from two narrow equatorial bands lying above and below the inflowing matter. The gas makes a sonic transition near the X-point of the effective gravitational potential. The primary acceleration of the wind occurs magnetocentrifugally between the X-point and the Alfvén surface. The location and shape of the Alfvén surface depend on the magnitude of the magnetic field and the distribution of mass on field lines. The material in the “dead zone” is on closed field lines and is static. In some protostars, a fraction of these closed field lines may be blown open and may give rise to the ionized jets seen in some CTTS. Any wind that emanates from the “dead zone” is confined and focused by the more massive wind from the X-point.

In Fig. 6 we schematically diagram this outflow mechanism, which SLRN have dubbed the “X-celerator” because of the crucial role played by the X-point (see also Chapter by Shu et al.). The wind begins in a band of height $\sim \varepsilon R_*$ in the high-density photospheric regions at the protostellar equator. The magnetic field, with magnitude $\sim \varepsilon^{-1} (\dot{M}_w \Omega_* / R_*)^{1/2}$, forces the gas to corotate at the protostellar angular velocity Ω_* until the Alfvén transition is made, after which the gas flows out to infinity while undergoing more gradual collimation by the toroidal magnetic field. Our estimate of the ratio \dot{M}_w / \dot{M}_{in} in Eq. (19) was based on the assumption that the protostellar wind can carry off *whatever* angular momentum flux is necessary for the protostar to remain on the deuterium birthline. We expect the X-celerator mechanism to be able to regulate its mass-loss rate to this equilibrium value because of the sensitivity of \dot{M}_w to the value of the mass density at the sonic point. For example, if the wind carries away too little angular momentum (\dot{M}_w smaller than required by Eq. [19]), the outer layers of the star will spin up as they accrete fresh mass and angular momentum from the disk, the increased centrifugal support will cause the stellar surface to rise relative to the location of the X-point, and the density at the base of the wind will increase. The higher-density material making the sonic transition will then tend to restore \dot{M}_w to its equilibrium value. Conversely, if the wind carries away too much angular momentum (\dot{M}_w larger than required by Eq. [19]), the equatorial regions of the star will spin down, the stellar surface will fall relative to the X-point, and the density at the base of the wind will decrease, which will again tend to restore the equilibrium value of \dot{M}_w .

For analytical convenience and mathematical tractability, SLRN adopted a magnetic field anchored into a protostar uniformly rotating at exactly the critical rate required for centrifugal balance. The magnetic field topology and the focusing of the gas streamlines in the outflow are then determined from Eqs. (23) and (24). Numerical solutions that smoothly pass through the Alfvén surface (where $\mathcal{A} = 0$) are currently being calculated. For protostars rotating at less than the breakup speed, the analytic development of SLRN does not strictly apply. However, Galli and Shu (in preparation) have recently shown that the equatorial accretion of mass and angular momentum from a disk induces a global circulation pattern in the outermost layers of a protostar that rotates below breakup. They find that newly accreted material flows from the equator towards the poles of the star; in a steady state, a return current at the stellar surface completes the loop by carrying matter from the poles back towards the equator. It is tempting to speculate that this surface circulation could transport stellar magnetic flux into the rapidly rotating and sheared equatorial regions, where a modified form of the X-celerator process would give rise to an outflow. Clearly, much more work remains to be done in analyzing such scenarios that involve more complicated field topologies and possibly time-dependent effects.

C. The Thermal and Chemical Properties of the Winds

The predicted distributions of the kinetic temperature T and degree of ionization $f_e \equiv n_e/n$ (where n_e and n are the electron and total number densities, respectively) of the outflow as well as of the chemical composition of the wind lead to important observational diagnostics which may be used to test the CDW models that we have discussed. In particular, the thermal structure of the winds turns out to depend sensitively on their driving mechanism and on their geometry and could thus be useful for identifying the relevant models. In a similar vein, the freeze-out abundances of various molecular species may provide a unique probe of the physical conditions in the observationally inaccessible wind acceleration region.

The thermal balance of the outflowing gas, treated as a single-phase medium characterized by the temperature T , is governed by the first law of thermodynamics,

$$\frac{3}{2}nk_B \frac{dT}{dt} = k_B T \frac{dn}{dt} + \Gamma - \Lambda \quad (25)$$

where n is the local number density of particles and d/dt is the convective derivative along a flow line. The first term on the right-hand side represents the adiabatic cooling of the gas due to expansion ($dn/dt < 0$). The next two terms represent the total heating and cooling rates per unit volume for the translational degrees of freedom of the gas. Energy sources or sinks due to the interconversion of chemical species (such as dissociation of molecular hydrogen) must also be included in Γ and Λ . In the absence of net sources or sinks of energy ($\Gamma - \Lambda = 0$), Eq. (25) indicates that the gas temperature becomes proportional to $n^{2/3}$. For a constant-velocity wind expanding into a cone with a constant opening angle, the temperature decreases away from the source as $T \propto r^{-4/3}$. This adiabatic-expansion cooling is typically the dominant energy loss mechanism and represents a severe constraint on potential heat sources in the wind.

The dominant heating mechanism of neutral MHD winds in YSOs is the ambipolar diffusion heating induced by the relative drift between ions and neutrals that underlies the wind acceleration process (Ruden et al. 1990; Safier and Königl 1992). This is just the Joule heating that accompanies the electromagnetic driving of the outflow. The net collisional force per unit volume acting on the neutrals (which transfers the magnetic stress from the ions) is

$$\mathbf{f} = \gamma \rho_i \rho (\mathbf{V}_i - \mathbf{V}) \quad (26)$$

(see Eqs. [9] and [10]). The rate at which this force does work on the neutral component is the ambipolar diffusion heating rate (per unit volume)

$$\begin{aligned} \Gamma &= \mathbf{f} \cdot (\mathbf{V}_i - \mathbf{V}) \\ &= \frac{|\mathbf{f}|^2}{\gamma \rho_i \rho} \end{aligned} \quad (27)$$

Equation (27) plays a central role in the ensuing discussion. As noted above, the main energy-loss mechanism is the adiabatic cooling induced by the expansion of the gas, although radiative and photochemical cooling can also play a role.

1. *Thermal Structure of Disk-Driven Winds.* Safier and Königl (1992) calculated the thermodynamic properties of a self-similar atomic CDW from the surface of a Keplerian disk (see Sec. II.A.1). Using Eq. (10) to substitute for \mathbf{f} in Eq. (27), the ambipolar diffusion heating rate becomes

$$\Gamma = \frac{|\nabla \times \mathbf{B}|^2}{16\pi^2 \gamma m_{\text{H}}^2 n^2 f_e (1 - 2f_e)} \quad (28)$$

where a pure-hydrogen composition has been adopted for simplicity. Because the large-scale structure of the wind is not affected by the thermal pressure, the distribution of the density and magnetic field in the wind is effectively fixed, and the only unknown quantities in Eqs. (25) and (28) are T and f_e . They can be determined with the help of the ionization balance equation

$$\frac{df_e}{dt} = \{I(T)f_e[1 - 2f_e] - R(T)f_e^2\}n \quad (29)$$

where

$$I(T) = 7.8 \times 10^{-11} T^{1/2} \exp(-1.6 \times 10^5/T) \text{ cm}^3 \text{ s}^{-1} \quad (30a)$$

and

$$R(T) = 4.8 \times 10^{-11} T^{-1/2} \text{ cm}^3 \text{ s}^{-1} \quad (30b)$$

are the ground-state collisional ionization and recombination coefficients, respectively.

Figure 7 exhibits the behavior of T and f_e along two representative flow lines for the disk-wind model of Figs. 1–3. The striking property of these solutions is the rapid rise of the temperature to a value of $\sim 10^4$ K that is maintained over three decades in distance irrespective of the initial radius, and the correspondingly high values attained by f_e . This behavior is a manifestation of a feedback effect involving T and f_e : a low degree of ionization leads to an increase in the temperature (since the heating rate scales as $\sim f_e^{-1}$), which in turn increases the collisional ionization rate (through the exponential term in $I(T)$) and hence the value of f_e . The coupling between the temperature and the degree of ionization is terminated when the drop in n brought about by the expansion of the flow quenches the growth of f_e (see Eq. [29]). A necessary condition for this behavior is that the adiabatic cooling, which causes the eventual drop in T , should not dominate the heating near the base of the flow. This condition is not fulfilled for the YSO wind model discussed in Sec. II.B, in which the rapid radial expansion reduces

Figure 7. The distribution of the temperature (*top*) and the degree of ionization (*bottom*) along two flow lines for the self-similar wind model shown in Figs. 1–3. The effects of ambipolar-diffusion heating, adiabatic and radiative cooling, as well as collisional and radiative ionization have been included.

the temperature from its initial photospheric value to $\lesssim 50$ K at a distance of $\lesssim 10^3$ AU from the center (see Fig. 8).

The high values of T and f_e that are obtained in the disk-driven wind model at large distances from the origin provide a natural explanation of some of the characteristic radiative properties of YSOs (Safier and Königl 1992). In particular, they may account for the forbidden line emission (typically [O I] $\lambda 6300$ and [S II] $\lambda 6716$, $\lambda 6731$) that has been measured in a number of CTTS on scales of $\sim 10^2$ AU (see Chapter by Edwards et al.). The inferred temperatures ($\sim 10^4$ K) and electron densities ($\gtrsim 10^4$ cm $^{-3}$) in the emission region are, in fact, in good agreement with the predicted values, and the double-peaked line profiles often exhibited by these sources are consistent with the latitude-dependent velocity distribution that characterizes the CDW model (Edwards et al. 1987; see Fig. 1). The predicted rapid rise of T above the disk surface could also explain the unique temperature inversion

pattern inferred from Ca II triplet line measurements in several YSOs (Hamann and Persson 1989). Furthermore, the high- f_e regions might account for the extended ($\gtrsim 10^2$ AU) thermal radio emission detected in several CTTS (see, e.g., Bieging et al. 1984). However, the radio emission as well as the blueshifted component of the forbidden line emission could, in principle, also originate in the high-velocity ionized jets (see Kwan and Tademaru 1988). High-resolution observations as well as detailed calculations of the expected forbidden line profiles and radio intensity maps would be required to discriminate between these two possibilities.

2. *Chemistry of protostellar winds.* Motivated by the detection of CO and atomic hydrogen in a neutral wind from HH 7–11 (Lizano et al. 1988), Ruden et al. (1990) have analyzed the thermal and chemical structure of winds from cool protostars. They considered the quasi-spherical steady flow of gas with velocity $V_w(r)$ into an effective area $A(r)$; the local gas number density follows from mass conservation as

$$n(r) = \frac{\dot{M}_w}{mV_w(r)A(r)} \quad (31)$$

where m is the mean molecular mass per gas particle. To mimic steady acceleration from the sound speed near the protostellar photosphere to the terminal velocity at large radii, the wind velocity was taken to be $V_w(r) = V_\infty (1 - R_*/r)$. For this velocity profile the wind makes the sonic transition at $r_s \approx R_* (1 + C_s/V_\infty)$, which serves as the radial starting point for their thermal structure calculations. The geometry of the outflow is parameterized by $A(r)$. For spherically symmetric winds $A(r) = 4\pi r^2$, while for the X-celerator mechanism $A(r) \approx 4\pi r^2 (1 - R_*/r)$, reflecting the fact that the flow emanates from a narrow cylindrical ring at the stellar equator rather than from the entire stellar surface. Ruden et al. concentrated on the detailed hydrogen chemistry, taking into account the ground ($n = 1$) and first excited ($n = 2$) states of hydrogen, the negative and positive hydrogen ions H^- and H^+ , as well as molecular hydrogen H_2 and its ion H_2^+ . In view of its low ionization potential and small photoionization cross section, sodium was included in the models to represent the level of ionization due to singly ionized metals. As sodium remains ionized in all wind models, it sets the minimum electron fraction at $f_e \gtrsim 2.3 \times 10^{-6}$. Because of the strong radiative trapping of Lyman α photons in the wind (line optical depths exceeding 10^{10}), a population of $n = 2$ excited hydrogen that greatly exceeds the LTE level can be built up. Photoionization of hydrogen from this excited state by the Balmer continuum of the protostellar photosphere is the dominant mechanism for increasing the electron fraction above the minimum set by sodium. At the base of the wind, the gas temperature is set equal to the photospheric temperature, and the hydrogen is atomic and predominantly neutral ($f_e \ll 1$). This is in contrast to winds from disks where the hydrogen starts out in molecular form except for the innermost disk regions near the protostar.

Figure 8. The thermal structure of protostellar wind models. The physical properties of the models are listed in Table I. The models are labeled “W” followed by the (negative) logarithm of the mass-loss rate in $M_{\odot} \text{ yr}^{-1}$. The solid curves show the gas kinetic temperature, the dashed curves show the gas temperature in the absence of net sources of heat (adiabatic expansion), and the dash-dotted curves show the equilibrium dust grain temperature. The latter curves begin where dust grains are first formed.

The most important source of energy in the wind is ambipolar diffusion heating. In the case of cool, quasi-spherical outflows, Eq. (9) can be used to write the ion-neutral frictional force as

$$|\mathbf{f}| \approx \rho \left(V_w \frac{dV_w}{dr} + \frac{GM_*}{r^2} \right) \quad (32)$$

which can be substituted into Eq. (27) to determine the magnitude of the ambipolar diffusion heating rate. This expression assumes that the Lorentz force (Eq. [10]) provides the necessary thrust for producing the postulated velocity profile. Equation (32) is useful because only the wind velocity $V_w(r)$ but not the exact topology and strength of the magnetic field must be specified in any given model. Najita (1991, personal communication) has shown that this simple formula leads to a surprisingly accurate estimate of the ambipolar diffusion heating rate near the star for the X-celerator wind geometry. Near the photosphere of the protostar the wind density is high (for large mass-loss rates), and three-body reactions among hydrogen atoms can produce molecular hydrogen. The H_2 formation energy ($\approx 4.5 \text{ eV}$) is liberated as heat and can be an additional source of energy for large values of \dot{M}_w . As the wind expands and cools, dust grains can form at $r \gtrsim 10 R_*$. The grains are heated by absorption of protostellar radiation and in turn can heat the gas through direct

Figure 9. The chemistry in the protostellar wind model W5 depicted in Fig. 8. The ordinate is the number abundance (relative to hydrogen nuclei). Solid curves depict electron and neutral hydrogen species: e , $H(n=1)$, $H(n=2)$, and H_2 ; dash-dotted curves depict ionized hydrogen species: H^+ , H^- , and H_2^+ ; and the dashed curve depicts once-ionized sodium: Na^+ .

collisions. However, this heating mechanism is of secondary importance in comparison with ambipolar diffusion.

The temperature distribution in the wind is found by integrating Eq. (25) for T using Eqs. (27) and (32) for the ambipolar diffusion heating rate and Eq. (31) for the density. Additional heating and cooling terms are added to describe the energy gain or loss accompanying chemical reactions (such as H_2 formation) or dust formation. These equations are solved simultaneously with ones that describe the production and destruction of each of the species in the chemical network. The ion fraction is of particular importance because of the role it plays in the ambipolar diffusion heating rate (Eq. [27]). Figure 8 shows the thermal structure of a sequence of wind models designed to mimic the simultaneous change of physical parameters in going from high-luminosity

Figure 10. Same as Fig. 9 but for Model W6.

sources with high mass-loss rates (DEIS) to their low-luminosity, low-mass-loss-rate counterparts (CTTS). Figures 9–12 show the chemical structure along this representative sequence. In all cases, the geometry of the flow was taken to be that of the X-celerator, and the terminal wind speed was $V_\infty = 150 \text{ km s}^{-1}$. Because the wind kinetic luminosity and force vary roughly linearly with the bolometric luminosity (see Sec. I.A), the protostellar luminosity L_* was chosen in each case so as to make the ratios $\dot{M}_w V_\infty^2 / 2L_*$ and $\dot{M}_w V_\infty c / L_*$ equal to 0.02 and 80, respectively. The photospheric temperature T_* was lowered from 6500 K to 3500 K as the mass-loss rate decreased from 10^{-5} to $10^{-8} M_\odot \text{ yr}^{-1}$ along the sequence. The physical properties of the central protostar are listed in Table I for the cases shown. The calculations have revealed that the thermal structure and wind chemistry are primarily sensitive to the density and the flow crossing time $r/V_w(r)$ rather than to the protostellar luminosity or the photospheric temperature. In all of the cases, there is an adiabatic drop in the gas temperature as the wind expands away from the stellar equator. The high wind densities and cool temperatures are

Figure 11. Same as Fig. 9 but for Model W7.

conductive to the formation of molecular hydrogen, which reheats the gas by liberating the formation energy. The gas temperature reaches a plateau ranging from 2600 K (for $\dot{M}_w = 10^{-5} M_\odot \text{ yr}^{-1}$) to 5400 K (for $\dot{M}_w = 10^{-8} M_\odot \text{ yr}^{-1}$), which is high enough to dissociate the newly formed H_2 (the formation and destruction of H_2 near the protostar is clearly evident in Fig. 10). In all the models, ambipolar-diffusion heating dominates in the wind for radii greater than $5 R_*$. It can be shown that ambipolar diffusion heating leads asymptotically to a gas temperature profile

$$T(r) \approx 32\pi \frac{m^2}{k_B \langle \sigma v \rangle} V_\infty^4 \frac{R_*}{f_c \dot{M}_w} \left(\frac{R_*}{r} \right) \quad (33)$$

(Ruden et al. 1990), where m is the mean molecular weight of the gas and $\langle \sigma v \rangle \approx 2.4 \times 10^{-9} \text{ cm}^3 \text{ s}^{-1}$ is the cross section for collisions between ions and neutral hydrogen atoms (Draine et al. 1983). Equation (33) indicates that the gas temperature falls off inversely with distance from the protostar and is

Figure 12. Same as Fig. 9 but for Model W8.

inversely proportional to the ionization fraction and mass-loss rate (see also Eq. [27]). These findings are in accord with the numerical results shown in Fig. 8. Dust grains may form in the outflowing wind but do not provide a significant heat input; their temperature distribution is also shown in Fig. 8.

For mass-loss rates $\gtrsim 10^{-6} M_{\odot} \text{ yr}^{-1}$ the wind density is so high that hydrogen is almost entirely neutral and singly ionized sodium donates the electrons (see Figs. 9–12). For lower values of \dot{M}_w , the wind density is lower and hydrogen is the dominant ionized species. In all the cases presented in Figs. 9–12, however, the wind remains predominantly neutral. It is also important to note that, although molecular hydrogen may be formed near the protostar, it is usually destroyed as the wind flows outward and heats up. The exception is model W5, with $\dot{M}_w = 10^{-5} M_{\odot} \text{ yr}^{-1}$ (see Fig. 9). In this case, the density is high enough and the temperature low enough for a significant amount of molecular hydrogen to remain in the wind at large radii ($n_{\text{H}_2}/n \approx 0.05$). For mass-loss rates greatly exceeding $10^{-5} M_{\odot} \text{ yr}^{-1}$, the hydrogen in the wind becomes predominantly molecular.

TABLE I
Protostellar Wind Parameters

Model	L_* [L_\odot]	T_* [K]	R_* [R_\odot]	\dot{M}_w [$M_\odot \text{ yr}^{-1}$]
W5	1000	6500	25.0	10^{-5}
W6	100	5500	11.0	10^{-6}
W7	10	4500	5.2	10^{-7}
W8	1	3500	2.7	10^{-8}

Although Ruden et al. (1990) did not specifically calculate the carbon chemistry in their models, Glassgold et al. (1989,1991) have shown that in similar wind environments there is significant production of CO even though the wind remains atomic as a whole, which fits the observations in HH 7–11. Recent high-resolution millimeter-wave observations of this source have indicated that the outflowing gas may be clumpy and that some of the CO may not originate in the wind but rather as entrained ambient cloud material (Koo 1990; Masson et al. 1990). Further observations and theoretical diagnostics are clearly called for to determine how much of the CO is produced in the wind itself, to identify the physical mechanism causing the clumping (e.g., thermal or interfacial shear instabilities), and to differentiate between the chemical signatures of YSO and disk-driven outflows.

III. ORIGIN OF IONIZED JETS

Although several promising mechanisms have been proposed to explain the collimated ionized outflows, only a few quantitative models have appeared in the literature and there is still no consensus on the origin of the jets. The construction of viable models is hindered by the existing uncertainty over the physical parameters of the jets, notably the mass-loss rate \dot{M}_j . The values $\sim 10^{-9}$ to $10^{-8} M_\odot \text{ yr}^{-1}$ quoted in Sec. I.A were derived on the assumption that the electron densities inferred from the measured [S II] $\lambda 6716/\lambda 6731$ line ratios represent the *postshock* densities behind weak, oblique shocks in the jets, and that the mean (preshock) densities are significantly lower (see, e.g., Mundt et al. 1987). These estimates appear to be consistent with those obtained from radio continuum measurements (see, e.g., Rodríguez et al. 1990) after taking into account the nonspherical geometry of the emission region (Reynolds 1986), and imply that the jets could in principle originate as stellar winds (see, e.g., DeCampli 1981). However, at least part of the optical radiation in certain jets has been attributed to low-level collisional excitation that acts throughout the emission region and is probably associated with the growth of a mixing layer near the boundary of the jet (see, e.g., Solf 1987; Meaburn and Dyson 1987; Cantó and Raga 1991). In this picture, the measured [S II] line ratios are interpreted as corresponding to the actual mean electron densities in the jets. This raises the estimates of \dot{M}_j by over an order of magnitude to values as high as a few times $10^{-7} M_\odot \text{ yr}^{-1}$ (see, e.g.,

Hartigan 1989). Even higher values are inferred by noting that the observed low-excitation gas is only partially ionized (with a degree of ionization as low as $\sim 10\%$), in which case the implied momentum discharges in the jets would be large enough to drive the typical molecular lobes (Raga 1991). Such energetic outflows are unlikely to originate as stellar winds and one possible interpretation of the jets is then that they represent the ionized inner regions of disk-driven winds.

An explicit constraint on \dot{M}_j can be obtained in jets whose heads are associated with bow-shaped Herbig-Haro objects. The observed morphology suggests that the leading bow shock (which propagates into the ambient medium) is radiative, which in turn implies that the postshock cooling length

$$d_{\text{cool}} \approx 4.5 \times 10^{16} n_a^{-1} V_{\text{bs},7}^4 \text{ cm} \quad (34)$$

(where n_a is the ambient particle density and $V_{\text{bs},7}$ is the bowshock speed in units of 10^7 cm s^{-1}) is smaller than the radius $r_h = 10^{16} r_{h,16} \text{ cm}$ of the jet head (see, e.g., Blondin et al. 1989). The jet (mass) density ρ_j is related to the corresponding ambient density ρ_a through the force balance equation

$$\rho_j (V_j - V_{\text{bs}})^2 \mathcal{A}_j = \rho_a V_{\text{bs}}^2 \mathcal{A}_h \quad (35)$$

where V_j is the jet speed, $\mathcal{A}_h = \pi r_h^2$ is the transverse area of the jet head, and \mathcal{A}_j is the instantaneous cross-sectional area of the jet (which in principle could be smaller than \mathcal{A}_h ; see, e.g., Hardee and Norman 1990). Combining the above relations gives a lower limit on $\dot{M}_j = \rho_j V_j \mathcal{A}_j$,

$$\dot{M}_j \gtrsim 4.8 \times 10^{-10} V_{\text{bs},7}^6 V_{j,7}^{-1} (1 - V_{\text{bs}}/V_j)^{-2} r_{h,16} \text{ M}_{\odot} \text{ yr}^{-1}. \quad (36)$$

Although the value of V_j is generally not directly measurable, it is safe to assume that it does not exceed $\sim 500 \text{ km s}^{-1}$ in low-mass YSOs (see, e.g., Hartigan 1989). Equation (36) then leads to a lower bound on \dot{M}_j that effectively depends only on the observable quantities r_h (obtained from high-resolution imaging) and V_{bs} (inferred from proper motion measurements). For example, in the case of the archetypal object HH 1, this equation implies $\dot{M}_j \gtrsim 7 \times 10^{-8} r_{h,16} \text{ M}_{\odot} \text{ yr}^{-1}$ (with $r_{h,16} \gtrsim 1$) if one identifies the bowshock speed with the mean proper motion ($\sim 240 \text{ km s}^{-1}$) measured by Herbig and Jones (1981) for the optical emission knots at the jet head, and $\dot{M}_j \gtrsim 2 \times 10^{-6} r_{h,16} \text{ M}_{\odot} \text{ yr}^{-1}$ if V_{bs} is set equal to the measured proper motion ($\sim 350 \text{ km s}^{-1}$) of knot F at the apex of the bow shock. The latter limit, in particular, is significantly larger than the value $\lesssim 4 \times 10^{-8} (V_{j,7}/5) \text{ M}_{\odot} \text{ yr}^{-1}$ calculated using the low- ρ_j estimates of Mundt et al. (1987) and Rodríguez et al. (1990) for this source. This limit could, however, be reduced if the jet is “heavy” ($\rho_j > \rho_a$) and has a speed relative to the jet head that is significantly lower than V_{bs} . In that case, the jet material (which passes through a shock of speed $V_{\text{js}} = V_j - V_{\text{bs}}$) may be able to cool within the jet head even if the cooling

length of the shocked ambient gas at the apex exceeds r_h . In this picture, the emission from the apex is dominated by the jet shock, and the bow shock only becomes visible at the wings (where it is oblique and hence weaker). According to this interpretation (which could in principle be tested by future high-resolution imaging), the bound given by Eq. (36) could be lowered by as much as $(V_{js}/V_{bs})^6 (A_j/A_h)$. For knot F in HH 1 (setting $V_{js} = 150 \text{ km s}^{-1}$ on the basis of shock emission models), this factor reduces the lower limit on \dot{M}_j to $\sim 1 \times 10^{-8} r_{h,16} (A_j/A_h) M_\odot \text{ yr}^{-1}$, which is consistent with the above-mentioned low-density estimates.

A. Jets as Disk-Driven Winds

The idea that jets with high mass and momentum discharges could be associated with disk-driven winds is supported by the calculated thermal structure of CDWs from Keplerian disks (Safier and Königl 1992; see Fig. 7). These calculations have revealed that ambipolar-diffusion heating in the wind could readily maintain a degree of ionization approaching (or even exceeding) 10% on the scale of the observed jets. An apparent difficulty with this interpretation is that the dynamical ages of jets are significantly shorter than those of bipolar flows (see Sec. I.A). This difference may, however, just be a reflection of the fact that the jets are launched intermittently, with each outflow episode lasting only a fraction $\lesssim 0.1$ of the total YSO outflow phase. This scenario is supported by the fact that the estimated duration of YSO jet visibility ($\gtrsim 10^4 \text{ yr}$) is comparable to the characteristic dynamical age of bipolar flows (Mundt et al. 1987) and by the direct observational evidence for nonsteady mass ejection in jets (Sec. I.A). The outflow episodes may be associated with FU Orionis outbursts, which apparently represent rapid disk accretion events ($\dot{M}_{in} \gtrsim 10^{-4} M_\odot \text{ yr}^{-1}$) accompanied by massive ($\dot{M}_w \approx 10^{-5} M_\odot \text{ yr}^{-1}$) outflows (see Chapter by Hartmann et al.). In the context of the magnetized disk model discussed in Sec. II.A, the rapid accretion events may be linked to the episodic release (by gravitational instabilities) of mass that has accumulated in the disk as a result of a drop in the efficiency of magnetic angular momentum transport at small radii (Pudritz and Norman 1986).

The association with accretion disks underlies several other proposals for the origin of the jets. Torbett (1984) suggested that the outflows could be powered by the rotational kinetic energy liberated in the shear boundary layer that develops between a Keplerian disk and a slowly rotating star. In this picture, the layer is sufficiently optically thick for the emitted radiation to contribute to the thermal pressure driving rather than diffuse out. Pringle (1989a) has similarly considered a boundary layer origin for the outflows but assumed that radiative cooling is not inhibited. He suggested that the jets are driven, instead, by strong toroidal magnetic fields that had been amplified by the shear and then risen to the surface of the layer while separating from the matter. Although tapping the substantial free energy of the boundary layer is a promising idea, more detailed calculations (involving two-dimensional numerical simulations; cf. Kley 1989) are needed to confirm the validity of

these scenarios, to establish the mass-loss efficiencies, and to determine the amount of outflow collimation. Yet another idea, which combines a rotating magnetic star (as the source of energy) and a disk (as the source of mass), was put forward by Arons et al. (1984; see also Arons 1987). They proposed that mass is loaded (by means of turbulent mixing) onto stellar field lines that sweep past the disk and is then flung out in the form of a CDW. It is not clear, however, that the loaded field lines would assume an open configuration rather than penetrate into the disk (see Lamb 1989). Again, final judgment must be reserved pending the construction of a more quantitative model.

B. Jets as Stellar Winds

We now consider the possibility, indicated by the low mass-discharge estimates for optical jets, that the ionized outflows represent collimated stellar winds. In the case of CTTS with typical (low) rotation rates and a dipole magnetic-field geometry, centrifugal driving is not expected to be efficient (see, e.g., Mestel 1968). However, stellar magnetic fields could in principle drive the observed CTTS winds through the action of MHD waves (see, e.g., DeCampli 1981; Hartmann et al. 1982; Lago 1984). In this picture, Alfvén waves generated in the stellar convection zone deposit their momentum on the way out and can produce winds with mass outflow rates of up to a few times $10^{-8} M_{\odot} \text{ yr}^{-1}$ for typical stellar parameters, which is consistent with the low- \dot{M}_j estimates discussed above. (A similar mechanism could also operate in a convective accretion disk; cf. Galeev et al. 1979*b*.) The predicted terminal speeds of the winds are of the order of the escape velocity from the stellar surface (a few hundred km s^{-1}) and thus are also compatible with the proposed identification with jets. In order for the waves not to be too rapidly damped, the surface magnetic-field strength must be at least a few hundred gauss, which is consistent with the observational constraints (see Sec. I.C). The wave flux can be estimated from the measured chromospheric and coronal emission. Although the observational implications of these models have been considered in some detail, they are still hampered by the incomplete theory of MHD wave generation and propagation in stellar envelopes.

The collimation of the (quasi-spherical) stellar wind into a pair of directed jets is most likely achieved through a dynamical interaction with the surrounding (magnetically collimated) neutral outflow (see, e.g., SLRN; Kwan and Tademaru 1988). Optical and radio continuum images of the jets imply that at least some jets are already collimated on scales $\lesssim 10^{15}$ cm. One attractive possibility is that the winds are shocked and subsequently collimated by passing through a transonic de Laval nozzle (Königl 1982). However, this mechanism would only be efficient if the shock remained nonradiative (Raga and Cantó 1989). This requires the postshock cooling length (given by Eq. [34] with V_{bs} and n_a replaced by the preshock wind speed and density, respectively) to be *greater* than the shock radius R_s , which, in turn, implies

that the jet velocity must exceed

$$V_{j,\text{cool}} \approx 470 \left(\frac{\dot{M}_j}{10^{-8} M_\odot \text{ yr}^{-1}} \right)^{0.2} \left(\frac{R_s}{10^{14} \text{ cm}} \right)^{-0.2} \text{ km s}^{-1}. \quad (37)$$

It is interesting to note that jets that are associated with radiative bow shocks at their heads and satisfy the condition given by Eq. (36) would have

$$\frac{d_{\text{cool}}(R_s)}{R_s} = 0.2 \left(\frac{R_s}{10^{-2} r_h} \right) \left(\frac{V_{bs}}{0.5 V_j} \right)^{-6} \left(1 - \frac{V_{bs}}{0.5 V_j} \right)^2 \quad (38)$$

and thus are not likely to be collimated by this mechanism.

A similar model to the one just outlined for CTTS jets can plausibly be expected to apply to the jets in DEIS, as stellar magnetic activity is probably triggered by the onset of convection at an early phase of the YSO evolution (see Chapter by Stahler and Walter). In fact, in the case of the embedded object IRS 5 in L1551, there is evidence from scattered light that a high-velocity wind is present at the source (Mundt et al. 1985). Furthermore, as we noted in Sec. I.A, there is also evidence in this source for a distinct lower-velocity (but higher-momentum-discharge) wind that pervades the space around the jets and that could conceivably contribute to their collimation.

While the expanding molecular lobes around L1551 IRS 5 are apparently driven by a relatively low-velocity wind that is distinct from the ionized jets, the fact that the kinetic powers of the jets and of the molecular flows are comparable in those sources in which they are both detected has motivated the suggestion that some of the bipolar lobes are driven by the “cocoon” of shocked jet material that expand like energy-driven interstellar bubbles (see Sec. I.A). To evaluate this possibility, one can adopt the model of Scheuer (1974) and assume that the expansion along the jet axis is determined by the jet momentum discharge according to Eq. (35) (where we set $\mathcal{A}_j \approx \mathcal{A}_h \approx \Omega Z^2$, with Z being the distance from the origin and with the solid angle Ω taken to be constant), and that the transverse expansion is driven by the (uniform) thermal pressure of the shocked jet material and is directed (at each point along the boundary) at right angles to the axis. Assuming, furthermore, that the ambient density n_a is uniform and that the expansion speed V_Z along the axis is much smaller than V_j , one finds that the internal energy of the bubble at a given time t after the onset of the outflow is a fraction 6/13 of the energy $\dot{M}_j V_j^2 t$ supplied up to that time by the two jets (with the remainder expended on pushing against the ambient medium), and that the ratio of the major and minor axes of the bubble is given by

$$\frac{Z}{R} \approx 2.8 \left(\frac{\Omega}{2 \times 10^{-2}} \right)^{-\frac{1}{4}} \left(\frac{V_j}{300 \text{ km s}^{-1}} \right)^{-\frac{1}{4}} \left(\frac{V_Z}{15 \text{ km s}^{-1}} \right)^{\frac{1}{4}} \quad (39)$$

where we have scaled by representative parameters. This value is consistent with the observed morphologies of bipolar CO lobes (see, e.g., Bally and Lada

1983). The mass loss rate implied by Eq (35) is

$$\begin{aligned}\dot{M}_j &= \frac{\Omega Z^2 V_Z^2 \rho_a}{V_j} \\ &\approx 10^{-8} \left(\frac{\Omega}{2 \times 10^{-2}} \right) \left(\frac{Z}{0.2 \text{ pc}} \right)^2 \left(\frac{V_Z}{15 \text{ km s}^{-1}} \right)^2 \\ &\quad \times \left(\frac{n_a}{500 \text{ cm}^{-3}} \right) \left(\frac{V_j}{300 \text{ km s}^{-1}} \right)^{-1} M_\odot \text{ yr}^{-1}\end{aligned}\quad (40)$$

which for typical parameters is compatible with the low-jet-density interpretation of the spectroscopic data. The energy-driven-bubble approximation should be valid so long as the cooling time of the bubble interior exceeds the dynamical time $t_{\text{lobe}} = Z/2V_Z$. If the density in the interior is dominated by the mass deposited by the jets, then, using Eq. (34),

$$\begin{aligned}\frac{t_{\text{cool}}}{t_{\text{lobe}}} &\approx 4 \left(\frac{V_j}{300 \text{ km s}^{-1}} \right)^{\frac{9}{2}} \left(\frac{V_Z}{15 \text{ km s}^{-1}} \right)^{-\frac{1}{2}} \left(\frac{Z}{0.2 \text{ pc}} \right)^{-1} \\ &\quad \times \left(\frac{\Omega}{2 \times 10^{-2}} \right)^{-\frac{1}{2}} \left(\frac{n_a}{500 \text{ cm}^{-3}} \right)^{-1}\end{aligned}\quad (41a)$$

whereas if it is dominated by the mass evaporated from the shell of swept-up ambient gas (see Weaver et al. 1977), this ratio decreases to

$$\begin{aligned}\frac{t_{\text{cool}}}{t_{\text{lobe}}} &\approx 0.7 \left(\frac{V_j}{300 \text{ km s}^{-1}} \right)^{\frac{3}{14}} \left(\frac{V_Z}{15 \text{ km s}^{-1}} \right)^{\frac{13}{14}} \left(\frac{Z}{0.2 \text{ pc}} \right)^{-\frac{2}{7}} \\ &\quad \times \left(\frac{\Omega}{2 \times 10^{-2}} \right)^{\frac{3}{14}} \left(\frac{n_a}{500 \text{ cm}^{-3}} \right)^{-\frac{2}{7}}.\end{aligned}\quad (41b)$$

Equations (41a) and (41b) indicate that the assumption of an energy-driven bubble can be justified for low- \dot{M}_j sources with characteristic parameters and that it remains adequate even when thermal evaporation effects become important. In fact, as was pointed out by Weaver et al. (1977), a bubble in which evaporation is the main source of mass may be expected to act as a self-regulating thermostat that would keep the internal thermal pressure at a dynamically significant level.

It thus appears that stellar jets expanding into a moderately dense molecular cloud could, in principle, drive the observed bipolar lobes by a combination of ram pressure (along the jet axis) and thermal pressure (in the transverse direction). The heads of these jets would not give rise to visible Herbig-Haro objects because the bow shock would be too slow to emit strongly in the optical and the shocked jet material would be too hot to satisfy $d_{\text{cool}}/r_h < 1$ (see Eq. [34]). We have already noted in Sec. I.A that, at least in the case of L1551 IRS 5, there is direct evidence from infrared measurements that the

associated lobes are *not* energy driven. It may also be possible to test this scenario by high-resolution measurements of the molecular line profiles near the boundaries of the lobes (see Lada 1985).

According to the evolutionary scenario developed by SLRN (see also Chapter by Shu et al.), the neutral X-celerator outflow drives the bipolar molecular lobes and ultimately disperses the ambient molecular cloud core. Ionized jets originate from the polar regions of the star as “ordinary” stellar winds (i.e., outflows launched by MHD wave stresses as opposed to the X-celerator) and are collimated by the surrounding dense neutral wind. As the cloud core is dispersed, both the mass-accretion rate through the disk and the neutral-wind mass-outflow rate drop (see Eq. [19]). The “ordinary” wind can no longer be fully confined by the neutral wind and, as the effective lever arm of the outflow (the Alfvén radius r_A) increases, it begins to spin the star down by magnetic braking (Weber and Davis 1967). The mass-loss rate of the X-celerator declines rapidly as the rotation of the star decreases, and the system takes on the characteristics of a CTTS: moderate stellar rotation and moderate mass loss.

We now make a rough estimate of the spindown time by the ordinary stellar wind, which is also the time scale over which the X-celerator shuts off. A star loses angular momentum to the wind at the rate $\dot{J}_* \approx -\dot{M}_w \Omega_* r_A^2$ (Weber and Davis 1967; Mestel 1968; Belcher and MacGregor 1976; Hartmann and MacGregor 1982). For a star with angular momentum $J_* = \beta M_* \Omega_* R_*^2$, where $\beta < 1$ is a dimensionless moment of inertia factor (see Sec. II.B), the spindown time is

$$t_{\text{spin}} = - \frac{J_*}{dJ_*/dt} \approx \beta \left(\frac{M_*}{\dot{M}_w} \right) \left(\frac{R_*}{r_A} \right)^2 \quad (42)$$

which is much shorter than the time scale for the star to lose mass because $r_A \gg R_*$. For winds from rapidly rotating stars, the terminal wind speed and the Alfvén radius scale roughly as $V_\infty \approx \Omega_* r_A$ (Belcher and MacGregor 1976; see Eq. [4]). The terminal wind speed may also be related to the stellar magnetic-field strength by $V_\infty \approx (B_*^2 R_*^4 \Omega_*^2 / \dot{M}_w)^{1/3}$, which can be derived by equating the Alfvén speed at the Alfvén radius to the terminal velocity (Michel 1969; Belcher and MacGregor 1976). Substituting these results into Eq. (42) allows us to write

$$t_{\text{spin}} \approx \beta \left(\frac{M_* V_\infty}{B_*^2 R_*^2} \right) \quad (43)$$

which has the advantage of being formally independent of the mass-loss rate. For a typical CTTS ($M_* \approx 0.5 M_\odot$, $R_* \approx 4 R_\odot$) which has a 100 gauss surface magnetic field and which blows a 200 km s^{-1} wind, the spindown time from near breakup ($\beta \approx 0.4$) is only $3 \times 10^5 \text{ yr}$. Although the actual value of t_{spin} is probably somewhat higher because of the reduction in the angular momentum loss rate brought about by the presence of “dead zones” in the magnetic-field

geometry (see Mestel 1968), it is nevertheless evident from this estimate that, in the X-celerator picture, the protostar makes a fairly rapid transition from rotating near breakup to the more moderate rates associated with CTTS.

An alternative explanation of the observed low rotation rates of CTTS has been proposed by Königl (1991) and is based on the Ghosh and Lamb (1979*a, b*) model of accreting magnetic neutron stars and white dwarfs. In this picture, the star possesses a kilogauss-strength dipole magnetic field which disrupts the accretion disk at a distance of a few stellar radii from the center and channels the inflowing matter into high-latitude accretion columns on the stellar surface (see Sec. I.C). In a steady state, the braking torque transmitted by the field lines that penetrate the disk outside the corotation radius r_{co} (where the Keplerian angular velocity $\Omega_K[r_{\text{co}}]$ is equal to Ω_*) exactly balances the spinup torque exerted by the material inside r_{co} . A YSO that initially rotates near breakup will have angular momentum \mathcal{J}_* much higher than the equilibrium value and will approach a steady state over a spindown time $t_{\text{spin}} = -\mathcal{J}_*/\dot{\mathcal{J}}_*$ that can be estimated by setting $\dot{\mathcal{J}}_* \approx -B_*^2 R_*^6 r_{\text{min}}^{-3}$ (see, e.g., Davidson and Ostriker 1973), where the inner radius r_{min} of the disk is given by

$$r_{\text{min}} \approx B_*^{4/7} R_*^{12/7} (GM_*)^{-1/7} \dot{M}_{\text{in}}^{-2/7} \quad (44)$$

(determined from the requirement that the magnetic stress be large enough to remove the excess angular momentum of the nearly Keplerian flow over a narrow transition zone). The value of t_{spin} estimated in this way for representative parameters ($M_* \approx 0.5 M_\odot$, $R_* \approx 4R_\odot$, $B_* \approx 10^3$ G, $\dot{M}_{\text{in}} \gtrsim 10^{-7} M_\odot \text{ yr}^{-1}$) is comparable to that obtained in the stellar wind model and in reality is likely to be shorter than the age of the youngest visible CTTS. An important test of this scenario will be provided by direct measurements of the surface magnetic field strengths in CTTS. In addition, this model predicts that changes in the mass accretion rate (which would be manifested as changes in the bolometric luminosity) should lead to episodes of spinup or spindown in the stellar rotation rate (corresponding, respectively, to increases or decreases in \dot{M}_{in} relative to the equilibrium value; see Ghosh and Lamb 1979*b*).

In closing this section we note that, although the question of whether the jets emanate from the disk or from the star cannot yet be answered by direct imaging, it nevertheless appears that some important clues might be provided by high-resolution spectral measurements (see, e.g., Hamann and Persson 1989; Hartmann et al. 1990).

IV. STAR FORMATION AND THE ORIGIN OF BIPOLAR FLOWS

Bipolar outflows play a crucial role in the physics of star formation by dispersing the infalling molecular cloud core that surrounds a protostar. Observational evidence indicates that outflow activity begins early in the evolution of a YSO, is common during the DEIS stage, and is rare once the star is optically revealed (Lada 1988*b*). Both theoretical calculations (Shu et al.

1987a; see Chapter by Shu et al.) and interferometric observations (Terebey et al. 1989) suggest that bipolar flows occur during an evolutionary phase when infall (along the equatorial regions) and outflow (along the poles) take place simultaneously. At very early times, the ram pressure of the infalling molecular gas is sufficient to contain the wind, whether it comes from the disk (Sec. II.A) or from the protostar (Sec. II.B). With the passage of time, the wind first breaks through in the direction of least resistance along the rotation axis and subsequently reverses the molecular infall within an ever increasing solid angle about each pole. We now discuss a simple dynamical model (Shu et al. 1991) that interprets the bipolar outflow phenomenon in the context of star formation.

We consider an axially symmetric molecular cloud core that has the density distribution of a (flattened) singular isothermal sphere,

$$\rho(r, \theta) = \frac{a^2}{2\pi Gr^2} Q(\mu) \quad (45)$$

where a is the effective isothermal sound speed, which includes contributions from all mechanical support processes: thermal, magnetic and turbulent (Shu et al. 1987a). We have adopted spherical coordinates (r, θ, ϕ) , with θ being the polar angle measured from the symmetry axis. The flattening of the isodensity contours is due to rotation (Terebey et al. 1984) and to magnetic fields (Lizano and Shu 1989) and is determined by the function $Q(\mu)$ (with $\mu \equiv \cos \theta$), which has been normalized so that

$$\int_0^1 Q(\mu) d\mu = 1. \quad (46)$$

Isodensity contours are given by $r(\mu) \propto \sqrt{Q(\mu)}$, so a 2:1 flattening of the core implies $Q(0)/Q(1) = 4$.

Lizano and Shu (1989) have shown that the r^{-2} density dependence of Eq. (45) arises in a natural manner during the later stages of cloud evolution as the core loses its magnetic and turbulent support. Dynamical collapse of the central regions ensues in an "inside-out" manner that produces a mass infall rate equal to

$$\dot{M}_{\text{in}} \approx \frac{a^3}{G} \approx 2 \times 10^{-6} \left(\frac{a}{0.2 \text{ km s}^{-1}} \right)^3 M_{\odot} \text{ yr}^{-1} \quad (47)$$

(Shu 1977). Accretion of this infalling material onto the disk and the protostar produces a powerful CDW (see Secs. II.A and B) whose outflow rate is related to the infall rate by

$$\dot{M}_{\text{w}} = f \dot{M}_{\text{in}} \quad (48)$$

where $f \approx (r_0/r_A)^2$ for a disk-driven wind (see Eq. [3]) and $f \approx 0.3$ for the X-celerator mechanism (see Eq. [19]). The wind momentum discharge per steradian can be written as

$$\frac{\dot{M}_{\text{w}} V_{\text{w}}}{4\pi} P(\mu) \quad (49)$$

where the angular distribution function $P(\mu)$ describes the collimation of the wind by MHD stresses (and, in the case of a wind from a Keplerian disk, also reflects the radial dependence of the disk parameters; see Fig. 1) and is normalized so that

$$\int_0^1 P(\mu) d\mu = 1. \quad (50)$$

There is indeed observational evidence for the existence of a latitude-dependent wind from the young star R Mon, whose wind speed varies from $\sim 50 \text{ km s}^{-1}$ near the equator ($\mu = 0$) to $\sim 250 \text{ km s}^{-1}$ near the pole ($\mu = 1$) (Jones and Herbig 1982; Dutkevitch et al. 1989).

The wind sweeps up a thin shell of matter (see Sec. I.A) which moves outward with speed $V_{\text{lobe}} = dR_{\text{lobe}}/dt$ that can be a function of μ . To describe the interaction of the wind with the circumstellar medium, Shu et al. (1991) adopted a momentum-conserving snowplow model which assumes that no redistribution of matter occurs in the θ direction and that the outward motion of each segment of the shell is strictly radial so as to satisfy the vector conservation of momentum. In this approximation, the mass \mathcal{M} (per steradian) of swept-up gas in the lobe increases with time as

$$\frac{d\mathcal{M}}{dt} = \frac{a^2}{2\pi G} Q(\mu) V_{\text{lobe}} \quad (51)$$

where we have used Eq. (45) for the circumstellar density and have ignored the small amount of mass contributed by the wind. Neglecting the small external pressure of the circumstellar gas, the momentum (per steradian) of the lobe, $\mathcal{M}V_{\text{lobe}}$, increases with time as

$$\frac{d}{dt} (\mathcal{M}V_{\text{lobe}}) = \frac{\dot{M}_w V_w}{4\pi} P(\mu). \quad (52)$$

Because each piece of the shell is assumed to move outward radially, μ is constant along each trajectory, and the solution to Eqs. (51) and (52) is

$$V_{\text{lobe}} = \left(\frac{\dot{M}_w}{2\dot{M}_{\text{in}}} \right)^{1/2} (a V_w)^{1/2} \left(\frac{P(\mu)}{Q(\mu)} \right)^{1/2} \quad (53a)$$

$$R_{\text{lobe}} = V_{\text{lobe}} t \quad (53b)$$

$$M_{\text{lobe}} = 2\pi \mathcal{M} = \dot{M}_{\text{in}} t \left(\frac{V_{\text{lobe}}}{a} \right) Q(\mu) \quad (53c)$$

where we have used Eq. (47) to write a^2/G as \dot{M}_{in}/a and where the time t is measured from the instant the outflow begins to break through the infalling cloud envelope. In this solution, the ram pressure of the incoming circumstellar gas exactly balances the ram pressure of the outflowing wind so that the shell speed (at each μ) is *constant* in time, a result specific to an r^{-2} density

profile. Equation (53a) indicates that the net collimation of the outflow is due both to the intrinsic focusing of the driving wind (through P) and to the anisotropic distribution of ambient matter (through Q).

Using Eq. (48), we can write the outflow velocity as

$$V_{\text{lobe}} = \left(\frac{f}{2} \frac{P(\mu)}{Q(\mu)} \right)^{1/2} (aV_w)^{1/2} \quad (54)$$

which shows that, apart from the first square-root factor (which is typically of order unity), the characteristic velocity of bipolar flows is the geometric mean of the isothermal sound speed in the molecular core and the wind speed. Because a ranges from a few times $10^{-1} \text{ km s}^{-1}$ (for low-mass cores) to a few kilometers per second (for high-mass cores) and the wind speed is typically several hundred kilometers per second, we have an explanation for why the observed values of V_{lobe} are intermediate between these two scales, ranging from a few to $\gtrsim 10 \text{ km s}^{-1}$. Furthermore, this characteristic velocity is maintained for as long as the outflow propagates through a region with an r^{-2} density profile and is independent of the overall size (or, equivalently, the age) of the molecular lobes.

Equation (53b) indicates that a snapshot of the outflow at any given time will produce a linear ‘‘Hubble law’’ $V_{\text{lobe}} \propto R_{\text{lobe}}$, which is a natural consequence of a latitude-dependent wind propagating into an anisotropic medium. If the major axis of the lobes is oriented at an angle i to the direction of an external observer, then the line-of-sight velocity v_{\parallel} measured by the observer is related to the projected distance r_{\perp} from the central source by

$$\frac{v_{\parallel}}{r_{\perp}} = \frac{\cot(\theta - i)}{t}. \quad (55)$$

This will result in an apparent linear law, as observed in several well-resolved outflows (see Sec. I.A), provided that the opening angle of the outflow is not too large compared to the inclination angle (i.e., if the source is fairly well collimated).

It is worth pointing out in this connection that an approximate Hubble law may also be expected to apply in the case of molecular lobes that are driven by a combination of the ram pressure of collimated jets and the thermal pressure of the cocoon of shocked jet material (see Sec. III.B) instead of purely by the ram pressure of a latitude-dependent, quasi-spherical wind. This is because an energy-driven bubble that expands into a medium with an r^{-2} density distribution will move with a constant speed just like a momentum-driven bubble (Königl 1982). Using the simple model outlined in Sec. III.B, one can arrive at this conclusion directly from Eq. (39), which shows that the ratio ($\gtrsim 2$) of the major and minor axes of the bubble is independent of the ambient density.

Finally, the total amount of mass accreted by the star–disk system is $M_{*} + M_{\text{disk}} = \dot{M}_{\text{in}} t_{\text{tot}}$, where t_{tot} is the time elapsed since the onset of the

infall. Equation (53c) shows that the total swept-up mass in each lobe is approximately

$$M_{\text{lobe}} \approx M_{\text{tot}} \left(\frac{t}{t_{\text{tot}}} \right) \left(\frac{V_{\text{lobe}}}{a} \right) \quad (56)$$

which is larger than the star-plus-disk mass by roughly the ratio of the bipolar flow speed to the cloud core sound speed. This relationship would cease to hold if the time since the onset of the flow were significantly shorter than the duration of the infall ($t < t_{\text{tot}}$). However, because outflows have been detected even in very young objects (Terebey et al. 1989), the duration of the pure infall phase is apparently quite short (i.e., $t \approx t_{\text{tot}}$) and protostars probably spend most of their DEIS phase as combined inflow-outflow sources (see also Chapter by Shu et al.).

V. CONCLUSIONS

Recent observational findings concerning the apparent connection between energetic outflows and circumstellar disks and the presence of massive neutral winds have led to significant advances in our understanding of outflows and winds in young stellar objects. Although we are still far from possessing a complete theory, it seems that at least some of the basic ingredients of a viable model have already been identified and that ongoing research efforts should lead to further progress in the near future. Our discussion of the current state of the theory can be summarized as follows:

1. Magnetic driving is the most promising mechanism for launching the high-momentum neutral winds that give rise to the bipolar molecular lobes. We have focused on centrifugally driven winds in which particles are accelerated along inclined magnetic-field lines like beads on rotating wires. We considered both CDWs from Keplerian disks that are threaded by interstellar magnetic-field lines and winds launched along stellar field lines from the boundary between a disk and a rapidly rotating protostar. In both cases, most of the energy and momentum injection into the wind occurs near the stellar surface. Efficient production of CDWs depends, in the case of disks, on the presence of sufficiently strong magnetic fields and on their adequate coupling to the matter, and, in the case of the X-celerator mechanism, on the equatorial regions of the star rotating near breakup and having a suitable field geometry. Disk-driven winds may regulate the transport of the excess angular momentum of the accreted matter whereas the X-celerator mechanism could enable YSOs to continue accreting even after they had been spun up to breakup speeds. Such winds may thus be an essential ingredient of the accretion process, which could be the reason for the observed correlation between accretion and outflow in YSOs.
2. The kinematic, thermal and chemical properties of CDWs lead to specific predictions that can be tested by observations. In particular, the distribution of uplifted dust in disk-driven winds may have a significant impact

on the infrared continuum spectra and on the optical and infrared polarization properties of YSOs. Furthermore, ambipolar diffusion heating in disk CDWs may give rise to extended ($\gtrsim 100$ AU), high-temperature ($\sim 10^4$ K) and high-ionization ($f_e \lesssim 0.1$) regions that would be detectable through their optical forbidden line and radio continuum emission. In a similar vein, YSO-driven neutral outflows have calculable freeze-out abundances of various molecular species that could be detected at large distances from the origin.

3. Magnetic fields (in the form of Alfvén waves generated in the stellar convection zone) could play a central role also in driving the high-velocity, ionized jets. In this interpretation, the jets arise from a quasi-spherical stellar wind that is collimated by the surrounding neutral outflow. Alternatively, the jets could be powered by accretion, in which case they either represent the ionized inner regions of a disk-driven wind or else are launched by thermal or magnetic processes from a shear boundary layer between the disk and the YSO. In this picture, the nonsteady mass ejection inferred in several jets may be associated with episodic mass accretion events of the FU Orionis type. Despite their small dimensions, the jet formation regions could be probed by high-resolution spectral measurements. Important constraints on the competing models could also be provided by accurate determinations of the jet mass-outflow rates.

Young stellar objects are characterized by a wide variety of activity phenomena and a strong interaction with their environment, on a wide range of spatial scales. We review the solar-like activity in T Tauri stars, and the X-ray and radio [cm] evidence for extended magnetic structures ($\lesssim 10 R_*$). In the case of classical T Tauri stars, the close circumstellar material ($\lesssim 1000$ AU) comprises circumstellar accretion disks and their associated boundary layers, ionized and neutral winds. By contrast, weak-line T Tauri stars are not necessarily deprived of circumstellar material, but may be surrounded by cold matter at a distance, without boundary layer, which can be best detected in the mm range. A tentative unified picture emerges, linking magnetic fields, accretion disks and mass-loss phenomena up to the much larger spatial scales of molecular outflows (several 10^4 AU). The possible relevance of this new picture for the origin of the solar system is indicated.

I. WHAT IS A YOUNG STELLAR OBJECT?

Thanks mainly to the advent of telescopes operating at wavelengths less sensitive to interstellar absorption than the optical (X-rays, infrared, mm, cm), rapid progress has been accomplished in recent years in our understanding of the earliest stages of star formation. Indeed, very young or forming stars are embedded inside molecular clouds, and it is only at the above wavelengths that one is able to see them. However, when these objects are too embedded to be visible in the optical domain, it is difficult to characterize them in the same way as optically visible stars (absence of HR diagram classification in

many cases, for instance). On the other hand, the very fact that these stars are embedded in molecular clouds testifies of their youth, typically less than a few Myr. In addition, as we shall see, many stars are surrounded by a complex circumstellar environment: magnetic fields, dust shells or disks, ionized or neutral winds, molecular outflows, etc., and therefore do not appear as “stars” in the conventional sense. At the cost of some vagueness, it has become customary in recent years to call the various sources close to, or embedded in, molecular clouds, by the generic name of young stellar objects (YSOs).

In most cases, YSOs can be shown to have moderate masses (\leq a few M_{\odot}) and temperatures (≤ 6000 K). Their luminosities, however, can be quite high (up to several $10 L_{\odot}$), placing them generally high above the main sequence: in that sense, the expressions “pre-main-sequence objects” (PMS objects) and YSOs are synonymous. However, in practice YSO tends to be applied to objects embedded in their parent molecular clouds, while PMS objects are visible in the optical and can be plotted on the HR diagram. In that sense, they constitute a subclass of the YSO population. As a rule, we will follow this distinction here. Other YSOs have higher masses (10 to $20 M_{\odot}$, for instance), and their luminosities may reach several $10^3 L_{\odot}$. Being massive, they are characterized by a much shorter evolutionary time scale, and excite compact H II regions. Since we are interested here primarily in solar-type stars, we will discuss only the *low-mass* objects ($\leq 2 M_{\odot}$). (For a discussion of high-mass stars in general, see, e.g., Lada [1987a], and for a discussion of Herbig Ae-Be stars, see Catala [1989]).

The most well-known (and historically oldest-known) of the low-mass PMS objects are the T Tauri stars. Very good reviews on this subject have recently appeared (Bertout 1989; Appenzeller and Mundt 1989). For details, we refer the interested reader to these, and to the Chapters by Basri and Bertout and by Hartmann et al., but summarize here their relevant properties for the sake of self-consistency of this chapter.

T Tauri stars were discovered in the vicinity of dark clouds (mainly in Taurus and Orion) thanks to their peculiar emission-line spectra, which made them conspicuous for instance in H α objective-prism surveys. In the last few years, however, mainly as a result of X-ray observations by the *Einstein* satellite, these stars have been divided into two broad classes: the classical T Tauri stars (CTTS), and the weak-line T Tauri stars (WTTS), also called naked T Tauri stars (NTTS; see Chapter by Stahler and Walter). Although these last two terms have often been used equivalently in the past on the basis of the initial definition of Walter (1986) and Walter et al. (1988), a better understanding of the circumstellar environment of these stars (including in particular of its cold component) probably warrants a further distinction between both terms using refined definitions.

CTTS constitute the vast majority of the originally catalogued TTS (Herbig and Rao 1972; for a revised list, see Herbig and Bell 1988). Their spectra display strong optical and ultraviolet emission lines. The equivalent width of H α is >5 to 10 \AA , and may reach 200 \AA or more in extreme TTS. The

underlying spectrum is that of a late-type photosphere (K7, typically), with respect to which there is a large ultraviolet and infrared excess. The amount of ultraviolet excess is correlated with the strength of the emission lines, and so does, to a lesser extent, the near-infrared part of the infrared excess. On the contrary, the WTTS show very weak, if any, emission lines ($H\alpha$ equivalent width <5 to 10 \AA , depending on authors, i.e., comparable with solar activity levels), no ultraviolet excess, and little or no infrared excess. Their only conspicuous feature is their large X-ray emission, comparable to that of CTTS, which made their discovery possible. Strictly speaking, the customary definition of the WTTS based only on the strength of the $H\alpha$ emission line is insufficient, because the true line flux depends on the spectral type: for instance, SU Aur, which has a small $H\alpha$ equivalent width (3.5 \AA), is an active CTTS. In practice, however, because most T Tauri stars have more or less similar spectral types (while SU Aur is a rare G2), the use of the $H\alpha$ equivalent width yields a clear cut and easy-to-use classification, but it should be kept in mind that there is a good continuity between CTTS and WTTS. By contrast, because the adjective “naked” refers to a physical property (i.e., absence of circumstellar material), and not to a purely observational one, the proper definition of NTTS must include additional ingredients, such as the absence of near-infrared excess, age determination, etc., and other subtleties may have to be introduced on the basis of recent mm observations which trace the cold dust (see Sec. V). In what follows, we will adopt strictly observational criteria to categorize T Tauri stars, and hence refer in most cases to CTTS and WTTS only, including the NTTS in this last class except otherwise specified.

YSOs too deeply embedded to be visible in the optical and X-ray ($A_V >$ a few magnitudes) generally remain visible at longer wavelengths, and have been characterized by their near- to mid-infrared spectral distribution (Lada 1987*b*, 1988*a*). They have been broken down in Class I (very strong infrared excess, with a λF_λ spectrum ascending with wavelength), Class II (infrared excess comparable to that of CTTS, i.e., flat or moderately descending spectrum), and Class III (no infrared excess, i.e., pure blackbody spectrum). Current theories link this classification of infrared spectra with evolutionary stages, in terms of decreasing amount of warm dust, from the protostar stage (Class I), in which the central stellar condensation is surrounded by a dust shell, to the dustless, advanced PMS stage (optically visible Class III) (see, e.g., Shu et al. 1987*a*, *b*). We shall see that new results in the radio mm and mid-infrared ranges suggest a revision of this scheme.

Perhaps some of the most intriguing characteristics of PMS stars and of embedded YSOs are their intense activity, and a strong interaction with their environment, in the form of mass loss (stellar winds, collimated jets, molecular outflows), accretion from a circumstellar disk, and various magnetic phenomena. In this Chapter, we will be mainly concerned with the question of the “close” circumstellar environment of these objects, i.e., within a radius $\sim 1000 \text{ AU}$. This includes magnetic activity and stellar magnetic fields (Secs. I and II), stellar winds (Sec. III), circumstellar disks (Secs. IV and V), but

excludes a detailed discussion of large-scale phenomena such as jets or bipolar flows, which extend up to a fraction of a pc, or of the related Herbig-Haro objects. (The interested reader is referred, respectively, to Lada [1985], Mundt [1988], and Reipurth [1989c] for reviews on these topics; see also the Chapters by Edwards et al. and by Fukui et al.)

II. SOLAR-LIKE ACTIVITY IN LOW-MASS PMS STARS

A. X-Ray Evidence: Flares

The bulk of the data we now have comes from observations using the *Einstein* X-ray Observatory, the first satellite-borne focusing X-ray telescope, which obtained images in the spectral band ~ 0.4 to ~ 4 keV (for relevant reviews and additional references to the literature, see Montmerle and André [1988], Bertout [1989], Feigelson et al. [1990], Herbig and Bell [1988]). Most of the observed regions were nearby dark clouds, well known to undergo active star formation and contain many T Tauri stars: ρ Ophiuchi (Montmerle et al. 1983), Taurus-Auriga (Feigelson et al. 1987; Walter et al. 1988), Chameleon (Feigelson and Kriss 1989), and others, all at distances ~ 160 pc. Images within the Orion star-forming complex at ~ 450 pc distance also revealed dozens of additional X-ray emitting PMS stars (Ku et al. 1982; Caillault and Zoonmatkermani 1989; Strom et al. 1990). Note that some of these regions also contain stars of earlier spectral types which copiously emit X-rays. From these extensive data sets, a variety of PMS stellar X-ray characteristics have been established, which we now summarize.

X-ray emission between 10^{29} and up to several 10^{31} erg s $^{-1}$ in the *Einstein* band is a general property of low-mass PMS stars, and is not confined to any particular subclass. In particular, existing evidence shows that this emission is present independently of the strength of classical T Tauri properties, such as broad emission lines, ultraviolet and infrared excesses. This indicates that, contrary to earlier predictions, PMS X-ray emission is not an indirect consequence of classical T Tauri winds. It also indicates that the X-ray emission is not generally absorbed (or “smothered” as suggested by Walter and Kuhi [1981]) in classical T Tauri winds.

These X-ray levels are much higher than those seen in the main-sequence stars. The average PMS star emits 10^3 times more than old disk stars and 10 times those seen on young main-sequence stars such as the Pleiades. There is some debate over the exact form of the relation between stellar age and X-ray intensity parameters. Walter et al. (1988) choose selected main sequence stars and X-ray-detected PMS stars in Taurus-Auriga to derive a relation for the surface flux F_X of the form $F_X \sim \exp(-t/t_0)$ with $t_0 = 4 \times 10^8$ yr (for a thorough discussion, see Walter and Barry [1991]). Feigelson and Kriss (1989) use unbiased X-ray luminosity functions of optically selected samples of main-sequence stars and Chameleon PMS stars (Fig. 1), treating X-ray nondetections as well as detections, to derive the relation $L_X \sim t^{-0.6}$ for the entire range $10^6 \leq t \leq 10^{10}$ yr. It is therefore unclear at present whether

X-ray activity decreases with age throughout the PMS phase, or whether it is relatively constant as the star descends the Hayashi track. X-ray emission appears to be present as soon as convection begins when stars emerge from their accreting envelopes at the "birthline" (Stahler 1988; also Chapter by Stahler and Walter), but it is as yet uncertain whether it is already present during the protostar stage.

Figure 1. Integral X-ray luminosity function for the Chameleon PMS stars (solid line), and for main-sequence low-mass stars. (a) Chameleon X-ray sources; (b) H α emission line stars; (c) Pleiades K stars; (d) Hyades K stars; (e) young disk K stars; (f) old disk K stars (for details, see Feigelson and Kriss 1989). One can clearly see the decrease in X-ray luminosity, which traces solar-type activity, with age.

The X-ray spectra from PMS stars are hard and variable. When a good PMS X-ray spectrum is available, it is consistent with bremsstrahlung emission from a hot ($kT \sim 1$ keV, i.e., $T \sim 10^7$ K) plasma with line-of-sight absorption consistent with optical obscuration (typical $A_v = 1-2$ and $N_H = 10^{21}$ cm $^{-2}$). Concerning variability, much evidence has accumulated in favor of the existence of large X-ray flares. This feature is the most conspicuous of the X-ray emission, and is apparent as soon as time-dependent observations are available. By comparison, there is little evidence for quiescent emission in time-dependent data. The coronal emission level therefore seems to be weak, at best barely at the level of sensitivity of *Einstein*, i.e., $\gtrsim 10^{30}$ erg s $^{-1}$ at ~ 160 pc. The most extensive data are from the ρ Ophiuchi cloud, for which several dozen X-ray emitting stars are seen blinking on and off giving the impression of an "X-ray Christmas Tree" (Montmerle et al. 1983a, b).

The variations are typically factors of 2 to 20 in amplitude and are statistically similar to the distribution of peak X-ray emission in solar flares. These flares have X-ray luminosities up to 10^6 times those seen on the modern Sun, are considerably stronger than flares on dMe flare stars (see discussion in Montmerle et al. 1983), and are quite similar to flares observed on RS CVn close binary systems (see, e.g., Agrawal et al. 1986). However, strong flaring activity is estimated to take place only $\sim 5\%$ of the time (Gahm 1988).

More precisely, a few individual rapid X-ray flares that fortuitously occurred during *Einstein* and EXOSAT satellite exposures have been analyzed in the context of simple solar flare loop models (Feigelson and DeCampi 1981; Montmerle et al. 1983a; Walter and Kuhi 1984; Tagliaferri et al. 1988). These largest X-ray flares are characterized by rise times of minutes to hours, fall times of several hours, and peak luminosities up to 5×10^{31} erg s $^{-1}$. Application of simple loop models (based on simplifying assumptions which may not strictly hold) suggest that the temperatures ($T \sim 10^7$ K), plasma densities ($n \sim 10^{10}$ cm $^{-3}$) and magnetic field strengths ($B_* \sim 10^3$ G at the base of the loop) are not remarkably different from solar flares. But the inferred loop sizes ($\ell \sim 10^{11}$ cm) are very large, implying that the size of the X-ray emitting region is in general comparable to R_\odot (i.e., $\sim 2R_*$, typically), and sometimes as large as $2R_*$.

In summary, the soft X-ray band has provided extensive evidence for the presence of very powerful solar-like magnetic activity on the surfaces of low-mass PMS stars. Many additional X-ray observations are currently taking place using the ROSAT X-ray telescope, launched in June 1990, which will provide an all-sky survey (expected to identify several hundred PMS X-ray emitters) and pointed exposures an order of magnitude more sensitive than those obtained with the *Einstein* satellite a decade earlier.

B. Consequences for Molecular Clouds and Star Formation

A major by-product of the X-ray surveys was the identification of dozens of previously unrecognized PMS stars with weak T Tauri properties. Estimates of the ratio of WTTS to CTTS populations range from $\sim 10:1$ for Taurus-Auriga (Walter et al. 1988), to $\sim 3:1$ for L1641 in Orion (Strom et al. 1990), to $\sim 2:1$ in Chameleon (Feigelson and Kriss 1989) and Ophiuchus (Bouvier and Appenzeller 1991). The latter two values are more reliable than the first because the *Einstein* image coverage was very incomplete for the Taurus-Auriga complex. The accuracy of a PMS stellar census in any cloud is limited by several factors: H α line strengths vary in all PM stars, permitting stars to cross the WTTS/CTTS boundary (usually chosen to be 5 to 10 Å equivalent width, as mentioned above); X-ray data have different sensitivities between and within star-forming regions due to different image exposures, distances and obscurations; and the large-amplitude intrinsic X-ray variability causes some stars to be absent in any given X-ray exposure. The possible presence of sub-groups of different ages may also be a source of difficulty (Hartmann et al. 1991). Despite these limitations, the preponderance of evidence shows

that the total population of low-mass PMS stars is 3 to 4 times larger than the population of CTTS ($H\alpha > 10 \text{ \AA}$) stars alone, and is about 2 times larger than the PMS stellar population known prior to X-ray surveys (see, e.g., Cohen and Kuhi 1979). Estimates of low-mass star-formation efficiency in these clouds, and in the Galaxy as a whole, should be correspondingly increased.

An important consequence of the increased population of X-ray emitting objects inside molecular clouds is its influence on star formation and on cloud chemistry. The physical effect is basically the increased ionization degree in large volumes around individual stars. Norman and Silk (1983) have shown that it regulates star formation by preventing stars from collapsing in these volumes; on the other hand, Krolik and Kallman (1983) have found that the relative abundance of radicals such as C_2^+ , C_2H^+ , CH^+ , $C_2H_2^+$, or HCN^+ , may be changed by factors as large as 10^3 or more. Regretfully, these important papers are generally overlooked in current work on star formation and molecular cloud chemistry.

Because the young Sun was presumably a T Tauri star, we should also take the opportunity to mention here the very important role this intense X-ray flux must have played on the irradiation of the primitive nebula (see, e.g., Feigelson 1982), or on the escape of the Earth's primordial atmosphere (see, e.g., Nakazawa and Nakagawa 1981). These points are central to several issues discussed elsewhere (see Walter and Barry 1991), but have largely been overlooked in the past.

C. Optical and Ultraviolet Evidence: Flares and Starspots

T Tauri stars have long been known to be variable from near-ultraviolet to near-infrared wavelengths, on time scales ranging from a few minutes to a few decades. In the early fifties, they were put in the category of "flare stars" by such pioneers as Haro and Ambartsumian. The flare activity is best observed in the near-ultraviolet band, because the contrast with the essentially red photosphere is enhanced. Analysis of the time structure of these flares (Worden et al. 1981) has shown that they are distributed according to a power law, smaller flares being more frequent than larger ones. The optical flares are solar-like, but enhanced several thousand times with respect to solar flares. According to a recent study, there is some difference in the time distribution of ultraviolet flares between CTTS and WTTS (Gahm 1990).

That some TTS exhibit quasi-cyclic light variations on a time scale of a few days has been known for more than 25 years. Yet, it is only during the past decade that systematic photometric studies on such a time scale have been started and this led to the detection of periodic lightcurves for a number of TTS (CTTS and WTTS alike). The amplitude of the photometric wave, usually of the order of a few tenths of a magnitude, decreases from near-ultraviolet to near-infrared wavelengths and can often be modeled by a single large starspot (or an assembly of smaller starspots) covering typically 10% of the stellar surface, cooler than the stellar photosphere by several 100 K (see, e.g., Bouvier et al. 1986*b*; Vrba et al. 1986, 1989; Bouvier and Bertout 1989).

Therefore, in addition to confirming the existence of solar-like activity, albeit on a much larger fractional area, these observations allow the determination of the rotation period of the TTS, a key parameter both for activity-related aspects and for their early evolution (see Sec. IV.C).

The properties of these starspots are very similar to those found on other types of magnetically active stars, such as RS CVn systems and BY Draconis stars. By analogy with the Sun, chromospheric plages are expected to be associated with cool starspots. Spectroscopic evidence for such chromospheric plages has been reported by Herbig and Soderblom (1980), and the co-existence of cool and hot spots at the surface of TTS is sometimes required to model their periodic lightcurves (Vrba et al. 1986). In some cases, only hot spots can account for the large amplitude (up to several magnitudes) of the stellar modulation observed at near-ultraviolet wavelengths. Then, the luminosity of these spots usually amounts to a significant fraction of the star's luminosity, and they have been interpreted as accretion shock regions near the stellar surface, where the accreted material is channelled along magnetic field lines (Bertout et al. 1988; see also Königl 1991). That WTTS only have cool spots while hot spots have only been found on CTTS so far supports this idea.

The lifetime of TTS spots greatly varies from one star to another. Long-term photometric monitoring of the WTTS V410 Tau (Vrba et al. 1988) has shown that two large, cool spots survived for several years at its surface. In other stars, however, the photometric wave has been found to disappear from one season to another. Short spot lifetimes (less than a few days) may explain why rotational modulation was detected in only about one third of the TTS in which it was searched for. In fact, both periodic and nonperiodic variability on a time scale of days usually have comparable amplitudes and similar wavelength dependence. This suggests that modulation of the stellar luminosity by spots is indeed the main mechanism responsible for day-to-day variability in these stars, whether periodic or not (there are some exceptions, however, see, e.g., Gahm et al. [1989]).

The optical variability on a time scale of several years is the most conspicuous, with an amplitude that can reach a few magnitudes. Yet, its origin is still a puzzle. Both magnetic and nonmagnetic processes have been invoked to explain it, e.g., a large disruption of the convective zone by magnetic fields (Appenzeller and Dearborn 1984), a variable obscuration of the stellar disk by a dusty condensation (Bellingham and Rossano 1980), or nonsteady disk accretion (Bertout et al. 1988). All of these mechanisms may in fact be at work at one time or another in TTS. Important clues as to whether nonsteady disk accretion is a likely mechanism may be gained by comparing the long-term photometric behavior of WTTS and CTTS, as well as by investigating how spectral variations correlate with photometric ones (see, e.g., Walker 1987; Holtzman et al. 1986).

D. Radio Evidence: Magnetic Fields

Radio observations of YSOs are doubly interesting. First, starting from the

solar-flare analogy of the X-ray emission of TTS described in Sec. II.B, it is a logical next step to look for radio emission in the cm (GHz) band, as observed on the Sun; in this case, the emission mechanism is expected to be nonthermal and associated with energetic electrons gyrating in magnetic loops. Second, the ionized component of the strong stellar winds observed around some YSOs (see, e.g., Sec. IV.A) is expected to give rise to free-free (thermal) radio emission.

Taking advantage of the increased sensitivity and imaging capability in the cm range offered by the Very Large Array (VLA) interferometer in New Mexico, a number of workers have made radio observations following two approaches. In the first approach, known YSOs, selected according to a variety of criteria, are the targets of pointed observations: optically visible CTTS or WTTS found in early catalogs (see, e.g., Bieging et al. 1984; O'Neal et al. 1990), sources of molecular outflows (Snell and Bally 1986; Rodríguez et al. 1989), or Herbig-Haro objects (see, e.g., Curiel et al. 1989). In the second approach, extended regions are subject to unbiased surveys, with no prior selection of targets.

The first approach gives evidence that $\sim 10\%$ of stars now known as CTTS or WTTS, as well as the majority of outflow exciting sources, are radio emitters at the level of a flux density sensitivity ~ 0.5 mJy, while almost all the classical, low-luminosity Herbig-Haro objects remain undetected at this level (a major exception is the HH 1–2 system; see below). In the case of CTTS and outflow sources, the radio emission is most likely of thermal origin, in agreement with the fact that some of these sources are resolved by the VLA on a scale of $\sim 0.1''$ – $10''$ (i.e., $\sim 10^{14}$ – 10^{16} cm, at the distance of the nearest molecular clouds). This is consistent with the existence of intense ionized stellar winds around CTTS, already suspected to be present on the basis of some H α and NaD (see, e.g., Mundt 1984) or [O III] (Edwards et al. 1987) emission-line profiles. As discussed in Sec. IV.A, the size of the emitting region is typically $R \sim 1000R_*$. However, there are clear examples, like the exciting source of the HH 1–2 system (Rodríguez et al. 1990), where the simple, spherical model does not fit the observed radio spectrum and source shape, suggesting that the wind is rather a bipolar, confined jet (see, e.g., Reynolds 1986). In the case of WTTS, the emission is almost certainly nonthermal, and probably due to gyrosynchrotron radiation occurring in large (several R_*) magnetic loops near the stellar surface. The evidence includes strong variability and detection by the Very Long Baseline Interferometer (VLBI) (see below).

The second approach makes no assumption about the nature of the putative radio emitters, and has revealed the existence of hitherto unknown objects, in ρ Oph (André et al. 1987), CrA (Brown 1987), Orion (Trapezium region: Garay et al. 1987; Churchwell et al. 1987; and L1641: Morgan et al. 1990). Several stellar radio sources had been previously found in X-rays, but many were discovered to be so deeply embedded in the clouds that even the X-rays, if present, would be absorbed. Most of these embedded sources are

associated with optically invisible near-infrared sources, and a few of them are “radio-discovered” YSOs, so far undetected even in the infrared (like VLA 1623 in ρ Oph; André et al. 1990a). The number of radio-emitting YSOs found down to a flux density of ~ 1 mJy is small, on the order of 10% of known near-infrared sources (K -magnitude limit typically 12). However, as the sensitivity increases, the number of radio-emitting objects also increases, as does the fraction of identifications with near-infrared sources, which reaches $\sim 50\%$ in the ρ Oph cloud when the minimum detectable flux density is ~ 0.1 mJy (Leous et al. 1991).

Understanding the nature of the emission from sources detected through unbiased surveys is difficult, precisely because it turns out that a wide range of objects are represented. Conceptually, one may expect YSOs surrounded by circumstellar disks to be thermal radio emitters by analogy with CTTS, and, conversely, young stars deprived of massive circumstellar material to be nonthermal emitters. As a matter of fact, the majority of the stellar radio sources emitting above ~ 1 mJy do not exhibit an infrared excess, and are therefore probably nonthermal and of the WTTS type even when they are embedded. (Sources detected in the radio with a lower flux have in most cases been observed at only one wavelength, and their nature is more uncertain at present; see discussion in Leous et al. [1991].) The direct confirmation of the above picture is the subject of active observational work.

One important first step towards understanding the emission mechanism results from a long-term monitoring of the sources. As in X-rays, strong variability was found by way of long or repeated observations: the discovery of the first radio flare in a PMS star came as early as 1985 (on the ρ Oph star DoAr 21; Feigelson and Montmerle 1985), and was followed by other similar findings (see, e.g., Stine et al. 1988). However, the frequency of occurrence and/or duty cycle of PMS radio flares seems much lower than in X-rays (Stine et al. 1988; Bieging and Cohen 1989). For lack of adequate coverage, the exact time scale for variability is unknown, but variations in flux of factors of at least 2 have been found in a few hours, and up to 10 between observations separated by a few months (see, e.g., Cohen and Bieging 1986). Such time scales can only be explained in terms of a nonthermal emission mechanism, because the interpretation in terms of an ionized wind implies emission sizes of at least several $100 R_*$ and thus long time scales, \sim months or years.

Strictly speaking, only the variability can be considered as evidence for nonthermal, solar-like activity in the form of flares. However, since most of the time the stellar radio flux is not variable, but more or less quiescent, one could then think of generally considering the spectral index α ($S_\nu \propto \nu^\alpha$) to find the emission mechanism, by applying the commonly used criterion stating that if $\alpha > 0$, it is thermal and if $\alpha < 0$, it is nonthermal. This is, however, often a dangerous procedure, because the spectral index reflects only the source *opacity* [resp. optically thick, and optically thin], even if it remains true that $\alpha < -0.1$ is a reliable indicator of a nonthermal mechanism such as synchrotron (see, e.g., André 1987; Dulk 1985). It is then necessary

to do polarization and mapping studies (e.g., by VLBI), as discussed in detail in Sec. III below, to demonstrate that the radio emission of several quiescent sources is also nonthermal and associated with large magnetic fields. In this case, the term “solar activity” should be understood in a much broader, looser sense only because modeling the radio emission still relies mostly on loop models devised for the Sun. But beyond these subtleties, the bottom-line result is that radio studies have provided a quasi-direct evidence for the existence of magnetic fields associated with a small, but important class of YSOs.

III. MAGNETIC FIELD STRUCTURE

A. Radio Polarization Data

The most direct signature of the presence of magnetic fields that radio observations can provide is the detection of circular and/or linear polarization. Circularly polarized radio emission generally traces nonrelativistic or mildly relativistic electrons radiating in magnetic fields of ~ 1 to 1000 G through the gyroresonance, gyrosynchrotron, or even free-free processes, while linearly polarized emission generally traces synchrotron-emitting, ultrarelativistic electrons in weaker magnetic fields, < 0.1 G (see, e.g., Dulk 1985). The main difficulty of this approach is that detecting polarization at a level of a few percent on sources with a flux density at most a few mJy is often a challenge. However, the power of this technique has recently been illustrated in two different stellar cases.

First, André et al. (1988) detected weak ($\sim 7\%$) circularly polarized radio emission in the very young, embedded B3 star S1 associated with the ρ Ophiuchi cloud core A (see Loren et al. 1990 for core names). The modeling of the emission led to the suggestion that S1 was surrounded by a large-scale (i.e., several stellar radii), axisymmetric (possibly dipolar) magnetosphere, oriented essentially pole-on, and with a surface magnetic field similar to what prevails on the well-known magnetic B stars (1–10 kG). This interpretation was later confirmed by the VLBI (see below), and the level of polarization was repeatedly detected in subsequent observations spread over several years.

Second, Yusef-Zadeh et al. (1990) discovered weak (6–8%) linearly polarized emission at 6 cm near the core of an HH-like object, known as the Orion “streamers,” in the L1641 cloud. This detection implies the presence of an organized magnetic field of at least $\sim 5 \times 10^{-4}$ G on a scale of 2500 AU. The authors suggest that this magnetic field is generated by a rapidly rotating, deeply embedded pre-main-sequence star featuring a magnetosphere rather similar to that proposed for S1. In both sources, it is important to stress that the radio emission is essentially non-variable, suggesting a permanent or at least long-lived magnetic field configuration.

B. Very Long Baseline Interferometer Measurements

We have seen above (Sec. II.A) that the X-rays were emitted by bremsstrahlung of a $\sim 10^7$ K optically thin plasma, likely confined in large ($H_X \lesssim 2R_*$)

magnetic loops, as can be shown indirectly from the X-ray emission measures and variability time scales.

More direct measurements of the size of the magnetic structures can be obtained in the radio (cm) range, by means of VLBI observations. Using radio telescopes separated by hundreds or thousands of kilometers, VLBI studies can resolve emission regions on milliarcsecond angular scales, corresponding to linear scales around 10^{12} cm (i.e., a few stellar radii) in nearby star-forming regions. By combining VLBI with simultaneous measurements on arcsecond scales using smaller interferometers like the VLA (Very Large Array), one can determine whether the radio emission is also produced in regions several hundred times larger, such as in ionized winds.

The very young star S1, already mentioned in Sec. III.A, was the first YSO detected by this technique (André et al. 1991). The full width at half maximum (FWHM) size (~ 13 stellar radii) and brightness temperature ($\sim 2 \times 10^8$ K) which were measured at 6 cm are consistent with the main lines of the magnetospheric model proposed on the basis of the circular polarization detection (see above, Sec. III.A). The combination of polarization and size measurements for this source provides good and almost direct constraints on the value of the magnetic field: assuming a dipolar field, a value of B_* ~ 2 kG is derived at the stellar surface. Future multi-wavelength VLBI observations of S1 may further improve this value as they should probe the magnetic field at different distances from the star, and thus test the dipolar hypothesis.

Extensive VLBI studies of the "bright" ($S_{6\text{cm}} > 1$ mJy) stellar radio sources of Taurus and Ophiuchus (mostly WTTS or class III infrared objects) are now in progress, but already prove extremely successful. The first set of observations has demonstrated that most or all of WTTS radio emission is nonthermal, with brightness temperatures between 4×10^8 to $> 2 \times 10^9$ K (Phillips et al. 1991). Two radio-bright WTTS, DoAr 21 and HD283447, were mapped in detail and were spatially resolved, with the radio emission coming from regions 5 to 15 stellar diameters in size. In these cases, the size of the emitting region (but not necessarily that of the magnetic structure) also varies on time scales of days or hours. The radio luminosities are of order 10^{16} erg s $^{-1}$ Hz $^{-1}$, or 10^5 times more powerful than the strongest contemporary solar flares.

These direct imaging results therefore confirm inferences from earlier nonimaging variability characteristics of WTTS radio emission, which, as mentioned in Sec. II.C, suggested radio emitting regions between one and several stellar radii in extent on the basis of models of large solar magnetic loops.

C. Morphology

In spite of these similarities in overall size, it is not clear at present whether the magnetic structures observed around these (late-type) WTTS are of the same nature as the magnetosphere surrounding the earlier-type (B3) star S1. An important difference is that the radio emission appears highly variable

Figure 2. Sketch (to scale) of the magnetic structures of weak-line and classical T Tauri stars, as deduced from their X-ray and radio (cm) properties (updated from Montmerle and André 1988).

on WTTS but nearly stable on S1. The view held by Montmerle and André (1988) was that the morphology of the magnetic field is different (for instance a large dipolar loop in the case of WTTS, a dipolar magnetosphere in the case of S1; see Fig. 2), and that variability in WTTS was due to injection and acceleration of electrons basically solar-like in origin, while the constancy of the radio flux of S1 was due both to an axisymmetric magnetosphere and to a steady injection of electrons from outside, in a fashion similar to that of the giant planets (see André et al. 1988 for details). More recent work suggests that the magnetic field configurations may be more similar, based on the analogy between radio-emitting WTTS and the tidally spun-up, close binaries known as RS CVn- and Algol-type systems. These active, late-type post-main-sequence stars, which also emit (variable) nonthermal radio emission

Figure 3. Map of the gas column density of the molecular concentration in L1495E in Taurus-Auriga as traced by recent $C^{18}O$ ($1 \rightarrow 0$) observations made at the NRAO 12-m telescope (André et al., in preparation). The PMS stars and bright infrared sources known in this region are superimposed. All have been observed at the VLA, but the only clear detections ($S_{6cm} > 1$ mJy; framed on the figures) are the WTTS V410 Tau, Hubble 4, HD283447, and Anon 1, all of which are nonthermal emitters (see O'Neal et al. 1990). ρ Oph cloud core region (André et al. 1987), and must therefore be very young, in spite of the absence of evidence for the circumstellar material generally typical of young stellar objects.

of order 10^{16} erg s^{-1} Hz^{-1} , were in fact the first stars detected by VLBI (see Lestrade 1988 for a review). The most recent model of the numerous circular-polarization and VLBI measurements made on RS CVns calls for a stable, large-scale and axisymmetric magnetosphere associated with a single active component (Morris et al. 1990). It is therefore not excluded that this model, which presents many similarities with the one proposed for S1, may, in essence, apply to radio-bright WTTS as well.

In any case, the main conclusion which can be drawn from the recent VLBI studies described in Sec. III.B is that the extent of the magnetic fields surrounding nonthermal young radio stars is much larger than on the Sun and reaches several stellar radii. In particular, this excludes an alternative model, initially proposed for RS CVn radio flares, and which involves magnetic fields erupting through the stellar surface rather than large magnetic structures (Mullan 1985). By contrast, the derived strength of the surface magnetic field (B_*

Figure 4. Same as for Fig. 3 but for the molecular concentration L1495W in Taurus-Auriga.

between a few 100 G and a few kG), which agrees well with the first direct measurement recently obtained by Basri and Marcy (1991) on a WTTS ($\langle B \rangle = 1700 \pm 500$ G), does not appear to be much higher than the peak values measured on the Sun. There is an important difference with the Sun: the “filling factor” for strong magnetic fields is much larger, a result consistent with that derived from X-ray flares, and optical and ultraviolet starspot observations (see above, Secs. II.C and D). In other words, the magnetic field of young radio stars is not significantly stronger but, at least in the case of the large radio-emitting loops, is probably much more organized than the tangled fields observed in solar active regions.

It seems that only a fraction of WTTS possess these large magnetic structures. Nonthermal radio emission has been confidently detected at levels $3 \times 10^{16} \text{ erg s}^{-1} \text{ Hz}^{-1}$ in only $\sim 10\%$ of WTTS (O’Neal et al. 1990). In the ρ Ophiuchi cloud, up to half of the embedded YSOs emit at levels $\sim 2 \times 10^{15} \text{ erg s}^{-1} \text{ Hz}^{-1}$, but it is unlikely that the emission is nonthermal in all these cases (Leous et al. 1991). (As for CTTS and related embedded objects, their partially ionized, massive circumstellar material may make their “peristellar” magnetic field inaccessible in the radio; see, e.g., Montmerle and André

1988.) The radio-emitting, WTTS-like objects therefore make up a specific, and apparently quite rare, population of YSOs, precisely distinguished by the large extent of their closed magnetic structures. These nonthermal radio YSOs display another remarkable feature: they are probably younger on average than nondetected WTTS, and perhaps even younger than some CTTS (see, e.g., O'Neal et al. 1990). In particular, both in ρ Ophiuchi (André et al. 1987) and in Taurus (O'Neal et al. 1990), as shown in Figs. 3 and 4, they appear to be concentrated at the edge of the highest column-density regions, in contrast to WTTS and CTTS in general. We shall return to this point in Sec. IV.D.

D. Origin of Magnetism

As on the Sun, the origin of the magnetism is widely thought to be the dynamo mechanism, in which seed magnetic fields are amplified by the combined action of convection and differential rotation (the so-called $\alpha\omega$ mechanism; see, e.g., Gilman 1983). Unfortunately, dynamo theory is not developed well enough in stars to lead to any quantitative prediction. In particular, it is not clear why the dynamo mechanism should operate in fully convective stars such as T Tauri stars: in principle, the amplification of the magnetic field requires it not to escape owing to excessive buoyancy, which implies that the field must be somehow anchored to the bottom of the convective zone—which does not exist in fully convective stars. In the most elementary scenario, one simply expects some correlation between the level of magnetic activity and rotation (itself somehow correlated with differential rotation), both being defined in a broad sense. Because, in the case of embedded YSOs, there is currently no observational access to rotation (such as could be given by high-resolution near-infrared lines), the existing evidence for a dynamo mechanism comes only from observations of optically visible PMS stars.

In these stars, different authors use different parameters to quantify the "magnetic activity": it can be the X-ray luminosity, or chromospheric activity tracers such as the MgII H + K or CaII H + K line fluxes (see, e.g., Rutten and Schrijver 1987; Bouvier 1990). "Rotation," on the other hand, is also ill defined: it can be the projected rotational velocity ($v \sin i$, with an embarrassing unknown geometrical factor), the rotational period (which can be directly measured from rotational modulation, see Sec. II.D), or even the so-called "Rossby number" (see, e.g., Mangeney and Praderie 1984; Hartmann and Noyes 1987), which is a mixture of rotation and convection (and equal to the ratio of the observed rotation period and of the computed convective turnover time). As it turns out, however, all combinations tend to yield the same rather comforting trend, namely a decreasing magnetic activity with an increasing rotation period, as expected from dynamo theory (for a more extensive discussion, see e.g., Montmerle 1987). In addition to the properties of dark spots covering the surface of TTS, the most direct evidence for dynamo-generated magnetic fields comes from the correlation between X-ray luminosity and rotational period found for TTS (Bouvier 1990). This correlation is similar to that existing in more evolved, magnetically active stars, such as RS CVn

systems, and reinforces the conclusion that surface magnetic fields in TTS, CTTS and WTTS alike, are of the order of a few 10^3 G. Other activity diagnostics, such as the MgII and CaII lines, are more ambiguous. In WTTS, these lines are weak and narrow, and the line flux is consistent with a purely chromospheric origin. The broad emission-line profiles of CTTS such as H α , however, cannot be reproduced by chromospheric models, and the measured line flux is far too large to be accounted for by a solar-type dynamo mechanism (Calvet and Albarrán 1984; Bouvier 1990). Other nonsolar mechanisms that might be at work in TTS are discussed in the next section.

Considering young stars of earlier spectral types may yield some additional clues on the dynamo mechanism. The PMS counterparts of A stars known as the Herbig Ae-Be stars have masses just above those of T Tauri stars, i.e., $\sim 2 M_{\odot}$ and up (see, e.g., Catala 1989). According to the standard models, stars of such masses are already entirely radiative in their PMS phase. Yet the large sample of X-ray-discovered young intermediate mass stars found by Strom et al. (1990) in L1641 and by Caillault and Zoonematkermani (1989) in Orion shows that these stars share many X-ray properties of the T Tauri stars and give a puzzling evidence for magnetic activity. One possible interpretation is that all have invisible, X-ray emitting low-mass companions, as is often found for main-sequence A stars. A perhaps more exciting possibility is suggested by very recent work by Palla and Stahler (1991) on PMS evolution of accreting stars in the ~ 1 to $8 M_{\odot}$ range (see also the Chapter by Stahler and Walter; Palla 1991). For a mass $\geq 2.5 M_{\odot}$, deuterium burns in a subsurface shell, and may drive an outer convective zone. It is therefore conceivable that the dynamo mechanism may operate in such particular conditions and give rise to the observed magnetic activity traced by the X-rays.

As for stars of earlier types like S1 (and for the large fraction of all B stars which are magnetic "Bp" stars), the dynamo mechanism probably cannot be invoked, because these stars most likely lack a sizable outer convective zone. The youth of S1 (\sim a few thousand years only, based on the existence of a small H II region associated with it; see André et al. 1988) rather suggests that its dipolar magnetic field is a fossil from its formation stages. At any rate, the S1 case should help understand the origin of magnetic fields of B stars in general, which is unclear at present (see Borra et al. 1982).

IV. NONSOLAR ACTIVITY AND CIRCUMSTELLAR MATERIAL

A. Mass-Loss Phenomena in Pre-Main-Sequence Stars

As mentioned above, there are several indications that strong stellar winds are associated with CTTS. The standard interpretation is that they are high-temperature, fully ionized winds, possibly accelerated by Alfvén waves generated in the outer convective zone (Lago 1984; Hartmann et al. 1982). However, it is very difficult to account in particular for the strength of H α in such winds (see DeCampli 1981), unless one makes particular assumptions on the expansion velocity field (Hartmann et al. 1990).

A new approach suggests that these winds are in fact *cold* ($T_w \sim$ a few 10^3 K) and only partially ionized (Natta and Giovanardi 1990; see the review by Natta 1989). The actual mass-loss rate would then be the radio rate multiplied by a factor $1/[\text{ionization degree}]$, i.e., by at least an order of magnitude. Although the cold wind model depends on some unmeasured parameters, there is some direct observational support for the existence of “neutral” extended winds with the detection of H I moving at several tens of km s^{-1} near a few well-known embedded objects, like HH 7–11 and L1551 (Lizano et al. 1988; Natta 1989). The associated crossing times ($= \text{size/flow velocity}$) are \sim several 10^3 yr, pointing to very young exciting sources. Additional, indirect support comes from the consideration of the energetics of CO outflows. Indeed, these large-scale phenomena, extending over several 10^4 AU, imply high mass-loss rates (up to several $10^{-6} M_\odot \text{ yr}^{-1}$, but there are large uncertainties on the published figures, Cabrit and Bertout 1990), much higher than those computed for fully ionized stellar winds, (see, e.g., Evans et al. 1987). One can causally link molecular outflows and stellar winds if a momentum-conserving shock transfers the cold material from one to the other (Natta 1989). The driving mechanism for such high mass loss is still controversial; we will return to this question in Sec. VI.

B. Accretion Disks Around Young Stellar Objects

In the case of CTTS, other activity tracers, like the ultraviolet emission lines, and perhaps more conspicuously $\text{H}\alpha$ (which cannot, as we have seen, be easily explained by stellar winds), are in excess by up to 2 orders of magnitude with respect to the other tracers as a function of rotation (Bouvier 1990; see Fig. 5). By contrast, for WTTS, $\text{H}\alpha$ for instance (which has a few Å equivalent width at most), seems to be entirely of solar-like (chromospheric) origin. In other words, there is clear evidence in CTTS that an intense *nonsolar* activity exists. As we shall now discuss, the current paradigm is that the reason for this does not lie in the stars themselves, but in the presence of close circumstellar material, and that there is in fact a continuum across the YSO classes (including TTS).

Let us begin with the YSOs for which the most advanced models are available, the CTTS. Current models (see Bertout et al. 1988; Hartmann and Kenyon 1987*a, b*; Chapter by Basri and Bertout) depict a CTTS as a complex object comprizing three distinct components: a late-type star; a circumstellar disk; a boundary layer between the star and the disk.

The existence of a Keplerian circumstellar disk of gas and dust has first been inferred from the infrared excess. The idea is that this excess comes from the existence of an additional energy source, which the star itself is unable to provide. The introduction of a disk is natural: it is the logical outcome of the gravitational collapse of rotating structures like the dense “ammonia cores” (Myers et al. 1987), half of which contain infrared sources thought to be protostars. It is worthy of note that this idea has been around since Kant and Laplace in the late 18th century. Laplace (1796) remarked that the coplanar

Figure 5. Relation between the $H\alpha$ emission line flux $F(H\alpha)$ (in $\text{erg s}^{-1} \text{cm}^{-2}$) and the rotation period P (in days) deduced from the modulation of the stellar light by large starspots for a sample of T Tauri stars, as compared with other magnetically active stars (Bouvier 1990). The excess $H\alpha$ emission of TTS over the other stars reaches 2 orders of magnitude. Symbols: \bullet = TTS, $+$ = late-type dwarfs, \oplus = dMe stars, \square = RCVn close binary systems.

orbits of the main bodies of the solar system implied the past existence of a flat, rotating “primitive nebula” out of which planets would form.

To first order, the infrared excess can be fitted by a continuous blackbody temperature distribution as a function of radius, implying in turn a continuous, optically thick matter distribution. This has a fundamental consequence: because the Keplerian rotation velocities are different at r and at $r + dr$, there must be some shear between successive rings, hence viscous stresses and heating. The energy radiated in the process at r must exactly balance the input of potential energy from $r + dr$ to r . But this also means that matter must slowly spiral inwards, and eventually fall onto the star. In other words, any spatially continuous disk losing energy by viscous processes must be an *accretion disk*. Because viscosity is a poorly known process on a microscopic scale (especially under these astrophysical conditions), the temperatures and densities used in modeling the disks are generally taken as power laws as a function of radius, resulting in a power-law for the infrared excess, which in many cases gives a satisfactory fit to the observational data. In spatially thin, optically thick viscous Keplerian disks, for instance, the temperature decreases with radius as $r^{-3/4}$, and the density as r^{-2} ; the resulting near-infrared spectrum λF_λ has a slope $-4/3$. The radiated infrared luminosity is $\sim 1/2$ of the available gravitational energy, and is proportional to the accretion rate (see, e.g., Lynden-Bell and Pringle 1974; Pringle 1988). Typical

accretion rates computed from such models are \sim a few $10^{-7} M_{\odot} \text{ yr}^{-1}$. The near-infrared ($\sim 2 \mu\text{m}$) traces warm material ($\sim 1500 \text{ K}$) relatively close to the star ($\leq 0.1 \text{ AU}$); longer infrared wavelengths (up to the longest IRAS band, i.e., $\sim 100 \mu\text{m}$) trace cooler material (a few $10\text{--}100 \text{ K}$) and correspond to a few AU. Because these dimensions are small with respect to the overall size of the disk (which possibly extends up to 1000 AU or more; see below, Sec. V.A), and because the disk is optically thick, it is clear that the infrared is essentially a temperature tracer, not a mass tracer; to trace the mass, one has to go to longer wavelengths, where, in addition, there is mounting direct evidence for the existence of extended dust disks (mm range, where they are mostly optically thin; see Sec. V.B).

C. Boundary Layers

Close to the star, an additional, very important phenomenon must occur. At $r \simeq R_*$, the Keplerian velocity in the disk around a $\sim 1 M_{\odot}$ star is $\sim 250 \text{ km s}^{-1}$, which is also (by definition) the break-up velocity of this star. But rotation velocity measurements (like the abovementioned starspot analysis; Sec. II.C) show that, contrary to early expectations, T Tauri stars (in general) are slow rotators, with equatorial velocities in the range $\sim 20 \text{ km s}^{-1}$ or even less, implying that they have very quickly lost most of their initial angular momentum. As a result, near the equator, the star rotates ~ 10 times more slowly than the disk. Then a *boundary layer* (a well-known phenomenon in aerodynamics) must develop, to ensure a continuous transition of the fluid velocities between the disk and the star. However, again because viscosity is the central dissipative mechanism and is poorly known, the physical conditions within the boundary layer, its dimensions, etc. are also poorly known and are the subject of active research (see, e.g., Basri and Bertout 1989; Bertout et al. 1991*b*; for basic principles, see, e.g., Frank et al. 1985). The condition of energy balance of the accretion disk shows that the other $\sim 1/2$ of the gravitational energy lost during the inward motion of the material must be radiated at the level of the boundary layer. The way in which this energy is radiated will of course depend on the opacity. Several arguments lead us to think that it must be optically thick (Bertout et al. 1988); some of the emission, like the Balmer jump, must however arise from optically thin regions (Basri and Bertout 1989). The temperatures reached are, much like in H II regions (balance between *in situ* heating and cooling), $\sim 8000 \text{ K}$. The bulk of the radiation will therefore belong to the optical and near-ultraviolet domains, and this is why it is believed that the observed emission lines (and in particular $\text{H}\alpha$) and the ultraviolet excess originate in the boundary layer. No definitive calculations on this point exist yet, because these require a knowledge of the physical conditions within the boundary layer which we do not have at present. But this explains qualitatively nicely the correlation between the infrared and ultraviolet excesses and the strength of the emission lines. In some models (see Bertout 1989) the combined contribution to the overall spectrum of the boundary layer (ultraviolet range) and the disk

(infrared range) is so high that it can completely dominate the photospheric contribution (optical range): from the point of view of spectral emission properties, the star light is then completely dominated by the disk.

D. What about Weak-Line T Tauri Stars?

At the other extreme, the implication is that because they have no ultraviolet or infrared excess, and little, if any, $H\alpha$ emission, the WTTS should not be surrounded by circumstellar material, but simply represent evolved, active, solar-like PMS stars. However, many young stars, although visible in the near-infrared (see, e.g., Wilking et al. 1989a), display no infrared excess: this is the case of the radio-emitting ones found by André et al. (1987) in the ρ Oph cloud, and by O'Neal et al. (1990) in the Taurus-Auriga clouds. In spite of the absence of infrared excess, these stars are probably very young because they are located just at the edge of dense cores (see Fig. 6). Strictly speaking, however, no age can be attributed to most of them because the majority are not seen in the optical and hence cannot be placed on an HR diagram. According to the infrared classification, they are Class III objects. So we are faced with a problem: how is it that very young stars, still embedded in the vicinity of cloud cores, apparently do not show evidence for circumstellar material?

A related problem exists more generally when considering optically visible CTTS and WTTS as a whole. Indeed, when put on an HR diagram, these two classes of PMS stars appear mixed (see discussion in Sec. V.B), whereas, according to "standard" evolutionary models (see, e.g., Adams et al. 1987), CTTS, being surrounded by accretion disks, should be younger, and WTTS, deprived of such disks, should represent a more advanced evolutionary stage.

One probable answer to this problem lies in the fact that the "standard" scenario of early stellar evolution is based on infrared data, which, as mentioned above, traces only warm material comparatively close to the star ($\lesssim 1$ AU). Outer ($\gtrsim 10$ AU), cold (< 100 K) material is visible most conveniently in the mm range, and we shall discuss in the next section how recent work in this range has given new insight into the presence of circumstellar matter around young stars, and into the possible role of magnetic fields (see Montmerle and André 1989). However, other properties, more intrinsic to the stars themselves, may also play a role, like rapid rotation or binarity (see discussion in Montmerle and André 1988). At any rate, an important conclusion is that the near-infrared data alone are not sufficient to qualify the evolutionary state of YSOs.

V. NEW DEVELOPMENTS: MILLIMETER DATA AND EVOLUTIONARY IMPLICATIONS

A. Observational Results

The first evidence for a flattened molecular structure around a YSO has been the detection by Beckwith et al. (1986) of strong emission near 2.6 mm from the extreme TTS HL Tau, both in continuum (dust) and in the ^{12}CO ($1 \rightarrow 0$) line. Because these observations were performed with an interferometer (at Owens Valley, California) yielding maps with an angular resolution of $\sim 6''$, the fact that the continuum source was unresolved implied a size < 1000 AU, whereas the resolved $\sim 30''$ size of the elongated ^{12}CO source implied a size ~ 4000 AU. Later ^{13}CO observations with the same instrument led Sargent and Beckwith (1987) to the conclusion that this structure was consistent with a circumstellar disk of gas and dust in Keplerian rotation. We note, however, that current models linking near-infrared emission with the presence of an accretion disk require only the inner disk (e.g., < 1000 AU) to be Keplerian. The outer gaseous disk may simply be a distinct structure orbiting the star, up to large distances (several 10,000 AU; see, e.g., Rodríguez 1988).

More extensive mm studies of several tens of T Tauri stars have recently been reported, as new, large single-dish telescopes and sensitive receivers (bolometers) came into operation. With the James Clerk Maxwell telescope in Hawaii, operating in atmospheric windows from 0.35 to 1.1 mm, Weintraub et al. (1989) and Adams et al. (1990) selected small samples comprising almost exclusively CTTS, and found a very high detection rate. Beckwith et al. (1990) used the IRAM 30-m radio telescope near Granada, Spain, equipped with the MPIfR (Max-Planck-Institut für Radioastronomie) bolometer operating at 1.3 mm, to study a much larger sample of 86 CTTS and WTTS stars in Taurus-Auriga: 53% of the CTTS, and 29% of the WTTS were detected. André et al. (1990*b*) have independently undertaken a study similar to that of Beckwith et al. (1990) in the ρ Oph core using the IRAM 30-m telescope, but selecting a sample of embedded sources spanning a broader range of infrared properties than CTTS and WTTS from Class I to Class III, with a very good sensitivity (down to a detection level of ~ 5 mJy). Out of 18 such objects, 14 were detected, belonging to all classes and spanning a large range in fluxes, from ~ 30 to ~ 400 mJy. In addition, the sample included two exceptional objects exciting molecular outflows and believed to be extremely young (a few 10^3 yr), IRAS 16293 (Walker et al. 1988) and VLA 1623 (André et al. 1990*a*); both are very bright at mm wavelengths (resp. 5 and 0.9 Jy in the 30-m beam).

While the high detection rate of Weintraub et al. (1989) and Adams et al. (1990) was not unexpected, because there was already from infrared data strong independent evidence for circumstellar material around their program stars, the results of Beckwith et al. (1990) are more surprising. Indeed, a significant fraction of the WTTS turn out to be surrounded by cold material, whereas there are indications that no or little warm material is present. Indeed,

Figure 6. Scatter diagram of the 1.3 mm flux density vs the near-infrared spectral index (slope of the λF_{λ} spectrum between $2.2 \mu\text{m}$ and $10 \mu\text{m}$) for a selected sample of sources in the ρ Oph cloud (André et al. 1990b). Class I, Class II and Class III infrared sources lie to the right, center, and left parts of this diagram, respectively. There is no obvious correlation between the mm flux (which traces optically thin, cold dust, at several AU from the central star) and the near-infrared spectral energy distribution (which traces the optically thick, warm material within 1 AU).

André et al. (1990b) find a lack of obvious correlation between the mm emission and near-infrared excess of the objects in the sample. In particular, as shown on Fig. 5, heavily obscured (Class I) objects do not appear brighter at 1.3 mm than CTTS (Class II) in general. On the other hand, there is one case of an object without near-infrared excess (Class III) showing a mm emission. Although the samples of Beckwith et al. (1990) and André et al. (1990b) are qualitatively different, the two results are quite consistent with each other. In the framework of the disk interpretation of the emission of YSOs at long wavelengths, this suggests that, in several cases, these disks are not continuous. More precisely, Beckwith et al. (1990) found that a sizable fraction ($\sim 25\%$) of the stars classified as WTTS have substantial mm emission ($>3\sigma$ detections, i.e., above ~ 20 mJy). Now a distinction may be made here between the WTTS and NTTS using the study by Skrutskie et al. (1989) of K ($2 \mu\text{m}$) and N ($10 \mu\text{m}$) excesses of various classes of TTS. These

authors find that a number of WTTS stars have optically thin near-infrared emission ($\Delta K < 0.2$ and $\Delta N < 0.8$): in the current definition, these stars would constitute the “naked” subsample of the WTTS. In addition, one NTTS (WK X-ray 1) is detected, hence is not, strictly speaking, “naked.” Other such stars might be detectable at lower mm fluxes. Even though they are not numerous, these stars are particularly interesting in that the combination of optically thin near-infrared emission and detectable mm emission suggests that they are surrounded by hollow, “45 rpm” disks. Such a picture is consistent with the absence of ultraviolet excess or of significant H α emission, since this implies the absence of a boundary layer, in other words that there is indeed no physical contact between the star and the disk. The optically thin near-infrared emission of these stars can be attributed to a small amount of warm dust in the inner “hole.” On the other hand, CTTS with weak or absent mm emission ($\sim 50\%$) could be surrounded by much less massive dust disks, perhaps already partially condensed in large grains or protoplanets.

The mm flux density gives the total mass (H_2 + dust) of the detected disks, irrespective of their structure. As discussed by André et al. (1990*b*) and Beckwith et al. (1990), because of uncertainties in the dust emissivity at mm wavelengths, this mass is uncertain. It is found to lie within the range ~ 0.001 to $\sim 0.5 M_\odot$, which, interestingly, encompasses the estimated mass of the primitive solar nebula, ~ 0.005 to $0.1 M_\odot$ (see, e.g., Cameron 1988). There is no evidence that any of the detected T Tauri stars is resolved within the $\sim 12''$ resolution of the 30-m observations, but there is evidence that embedded objects like VLA 1623 or IRAS 16293 are slightly extended. This implies that in all cases most of the mass of such dust disks must be comprised within radii of 1000 AU at most.

B. Evolutionary Consequences

The consequences of the new picture presented above are important for the evolution of low-mass YSOs. Indeed, it is now well established that WTTS and CTTS co-exist in large regions of the HR diagram, corresponding to ages from $\sim 3 \times 10^5$ yr to $\sim 3 \times 10^7$ yr (Strom et al. 1989; see also Skrutskie et al. 1989; Walter et al. 1988; Chapter by Strom et al.). One may argue that, precisely because of the presence of the disks, the positions of CTTS in the HR diagram are uncertain (Kenyon and Hartmann 1990); still, this cannot seriously affect the fact that the range of ages is very large. As Strom et al. (1989) point out, on average, CTTS tend to be younger than WTTS, but some WTTS are very young ($< 3 \times 10^5$ yr; the nonthermal radio-emitting WTTS or Class III sources of ρ Oph and Taurus-Auriga, as discussed above, are also probably very young), and some CTTS are very old ($> 3 \times 10^7$ yr), as are stars surrounded by conspicuous disks like β Pic (A star, \geq several 10^6 yr; see, e.g., Smith and Terrile 1984; Lagrange-Henri et al. 1989).

Therefore, the transition between CTTS and WTTS occurs at different times from star to star, somewhere between $< 3 \times 10^5$ and $> 3 \times 10^7$ yr. In our framework, this transition is linked not to the disappearance of the disk, but to

the disappearance of the boundary layer. Its duration is estimated at $<10^6$ yr (perhaps as short as a few 10^5 yr), compatible with the age of the younger CTTS and short compared to the age of the older WTTS (Walter et al. 1988, Skrutskie et al. 1989). The WTTS having detectable mm emission would then be objects undergoing this transition, while the mm-emitting NTTS, having a central hole devoid of dust, would represent the final stage. Based on the frequency of these stars (1 case, i.e., $\sim 10\%$ at face value), this last stage must last a short time: a time scale of a few 10^5 yr can be estimated, consistent with the above figures.

This means that the disk evolution of YSOs must be decoupled from the stellar evolution. Comparable stars (that is, identically located on the HR diagram) have different disks: continuous “accretion” disks, or more or less “hollow” ones (WTTS). At least to a first approximation, a star of a given initial mass evolves according to standard laws of stellar structure, but some additional factors make the disks evolve differently for a given star, some quickly, some slowly, with a comparatively abrupt transition between CTTS and WTTS. This is a complex subject, because the problem of disk evolution *per se* is still in its infancy. In addition to the fact that, after all, what we call a “disk” is in fact still very poorly known observationally, probably important factors which must be incorporated in any theory include:

1. Stellar or *in situ* generated magnetic fields;
2. Spatial evolution: appearance of a central cavity, perhaps even of rings, etc. (possibly under the influence of the stellar magnetic field, see below), or disappearance of the outer regions; change in thickness;
3. Dust grain evolution and possible condensation or evaporation phenomena, presumably (but not necessarily) leading to planet formation;
4. Influence of mass loss (likely also from the disk itself; Sec. VI and possible sporadic bipolar flow phases, or intense winds, as is the case for FU Orionis events (in which the mass-loss rate is typically 100 times stronger than in CTTS: Herbig 1989a; Kenyon and Hartmann 1988; Chapter by Hartmann et al.);
5. Appropriate initial conditions (in particular initial angular momentum).

Of course, binarity (Zinnecker 1989a) may also play an important role on disk evolution as a result of tidal effects, in the case of a sufficiently tight system (separation $\lesssim 100$ AU). Impressive results on finding binary or multiple systems with angular separations down to a milliarcsecond scale have already been obtained (Simon et al. 1987, 1991), and will likely also play an important role in the future.

C. Disk Stability and Magnetic Fields

One recent avenue is that of the intrinsic stability of the accretion disks around single stars, and some promising theoretical developments have recently appeared. Adams et al. (1989) and Tagger et al. (1990) have shown that spatially thin disks (scale height \ll size) are subject to efficient dynamical instabilities

("swing amplification phenomenon"; see also Chapter by Adams and Lin). Supplementing the initial work of Papaloizou and Pringle (1987) by including magnetic fields (here assumed to be locally perpendicular to the disk) in addition to gravitation, Tagger et al. (1990) have shown that, depending on the respective strength of the magnetic field and the local gravity, several instabilities are possible. (The magnetic field may be of stellar origin, or produced locally by some kind of dynamo resulting from differential rotation.)

If the magnetic field dominates gravity, these instabilities may result in a cavity in the inner regions of the disk and thus explain the existence of hollow disks, although it is premature to say whether they will explain the transition from a regular accretion disk to a hollow disk and the subsequent disappearance of the boundary layer. Support for this situation may be found in the existence of generally large magnetic structures around the nonthermal radio sources; we also note that the widespread X-ray activity of WTTS is indicative of strong surface magnetic fields (see Montmerle and André 1988; Sec. III). Farther out, other instabilities are possible: if the magnetic field is negligible and the self-gravity small, the hydrodynamical instabilities of Papaloizou and Pringle (1987) occur, and if self-gravity is large enough, the spiral instabilities suggested to be present in galactic disks take over (Pellat et al. 1990). Unfortunately, information about the magnetic vector orientation cannot be gained through the interpretation of dust polarization observations (Bastien and Ménard 1990). Work is in progress to determine the time scales over which such instabilities develop in circumstellar disks, but obviously such considerations leave ample room for many possible, time-dependent configurations (including spiral arms in the outer regions).

VI. CONCLUSIONS

There is today no doubt about the presence of warm and cold circumstellar material around YSOs. Its exact morphology is in general not known, but the existing evidence supports, albeit indirectly, the idea that this material should be close to the central star in the form of a flattened, disk-like structure, perhaps as small as a few 100 AU in radius or less. The disk masses are highly uncertain, but still roughly within one order of magnitude both ways of the mass of the primitive solar nebula. This recent image therefore essentially confirms what had been guessed, or speculated, over more than two centuries.

But what is perhaps more surprising is that many YSOs *do not* have continuous disks around them. Would we then be witnessing some fragmentation of the initial, supposedly continuous disks, in other words, the birth of planetary systems? It is certainly premature to answer this question, because we have yet to elucidate many aspects of the stability of circumstellar disks, and in particular the role of magnetic fields. In the above discussion, we have shown ample evidence of their presence on YSOs, and we have mentioned the possible role extended stellar magnetic fields may play.

However, magnetic fields probably also play a key role in another important and related aspect of the circumstellar environment of YSOs, namely the mass loss associated with CTTS or embedded molecular flow sources. An assumption common to all existing models is that open magnetic field lines confine the outflowing material in a bipolar fashion; we have seen that a number of arguments point to the possibility that the stellar wind is in fact mostly neutral even close to the star, and becomes molecular farther out. Because the implied mass-loss rate is very high (possibly up to a few $10^{-6} M_{\odot} \text{ yr}^{-1}$), it is very difficult to account for it in terms of a purely stellar mechanism. For instance, Alfvén waves, generated by convection at the stellar surface, act only on the ionized part of the wind, but likely cannot, even through friction between ions and neutral atoms, lift the remaining neutral part. This is why current models draw the mass lost through the wind from the accretion disk itself, much in the way the disk is also invoked to explain the extra ultraviolet and infrared luminosity. In other words, we are led to the concept that *accretion drives mass loss*. The general scheme is that accretion is equatorial (disk), and mass ejection is polar (jets) or, at least, confined to a relatively small angle to the polar axis of the star. And what about the energetics? In many cases (see, e.g., Lada 1985), molecular outflows have a kinetic “luminosity” which approaches, or even exceeds, that of the exciting source. Again, the trick is to tap this energy from the ultimate reservoir, namely gravity, by using the rotation of the star, or of the disk.

In one school of thought (Shu et al. 1988), the central star is strongly magnetized and rotates near break-up; the disk material flows inwards, touches the stellar equator at the critical, “X point,” and then “rebounds” in open magnetic field lines bending away from the disk (so-called “X-celerator” mechanism). Because this magnetic field is anchored to the star, the ex-disk material is dragged along the lines by the centrifugal force and follows their direction, increasingly parallel to the rotation axis. Obviously, given the fact that no YSO has yet been observed to rotate close to the break-up velocity, this model could be applied only to the youngest stellar objects, before their initial angular momentum is lost. An alternative would be that the inner disk is kept in corotation with the star by the magnetic field, so that the X-celerator mechanism takes place farther out, at the corotation radius, where the Keplerian velocity is much smaller. This, however, requires large magnetic fields at the surface, like in the case of S1 in ρ Oph (see Sec. II.D). Deeply embedded sources with outflows having very short dynamical time scales (like IRAS 16293 and VLA 1623 in ρ Oph) might be in this case, but none of these sources shows at present evidence for strong or extended magnetic fields, as would be indicated by nonthermal radio emission.

A second school of thought assumes that the accretion disk is itself entirely responsible for the mass loss: the disk “evaporates,” its material flowing along magnetic field lines this time anchored to the disk (Uchida and Shibata 1985; Pudritz and Norman 1986; Königl 1987; Kwan and Tademaru 1988; Camenzind 1991; see Chapter by Königl and Ruden). Here again

the centrifugal force plays a role, but so does the shear and spiraling of the magnetic field lines, following the shear of the disk material. The bending of the field lines is more efficient in this case (they even join at some distance from the star along the polar axis), and it seems that the collimated jets are easier to explain in this framework. In addition, the central star plays no other role than to set up a gravitational potential well holding the accretion disk together, thus removing the stellar rotation velocity constraint. Other arguments, for instance based on forbidden optical lines (see Cabrit et al. 1990), tend to support a mass loss directly from the disk, at least in the case of CTTS.

An interesting consequence is that, in the X-celerator mechanism, a physical contact is required between the star and the disk (which is not a boundary layer, since the star and the disk are assumed to rotate at the same velocity). Thus, irrespective of the stellar rotation, this mechanism could not exist for WTTS surrounded by a hollow disk, whereas the “evaporation” mechanism could conceivably still work: a possible test would be the existence of cold outflows from these stars, for which there is no evidence up to now.

Whatever the (significant) differences between these models, a unified picture of YSOs tends to emerge. At an early stage, the initial protostar, at the center of a rotating spheroidal shell of gas and dust, evolves into a star surrounded by a (possibly, but not necessarily massive) accretion disk. Then, by means of the rotation of either the star or the disk, and because of the presence of stellar and/or disk magnetic fields, an intense, mostly neutral wind is accelerated and collimated. This wind gives rise to bipolar jets and molecular outflows farther away, and disperses what is left of the protostellar shell. Probably because of this intense magnetic field-driven mass loss, the central star slows down quickly, and a boundary layer appears, giving rise to a CTTS if optically visible. Under the influence of these magnetic fields, gravitational instabilities occur, and at some point the disk breaks, forming for instance rings or spiral arms. If only the outer part breaks, we have CTTS with near-infrared excess but no mm emission; if, on the contrary, a central cavity forms, the boundary layer disappears, leading to a WTTS with little, if any, near-infrared excess but surrounded by cold, mm emitting material. This transition may take place at any time (depending on as yet unidentified conditions, as discussed in Sec. V.C) between a few 10^5 yr and a few 10^7 yr, and is rather fast ($<10^6$ yr). Furthermore, the transition is not necessarily unique: if it is confirmed that there is a strong causal link between accretion disks and outflow phenomena, the increasing evidence for structure in bipolar flows, e.g., “blobs” (André et al. 1990a) or “bullets” (Bachiller et al. 1990a) suggests that accretion disks may be in contact with the stars several times, perhaps as a result of instabilities. The lifetime of the outer material is not known, but at some point between $\gtrsim 10^5$ and $\gtrsim 10^7$ yr all the remaining disk material rapidly disappears, leading to a truly naked TTS on its way to the main sequence. One reason for this disappearance may be, of course, the formation of planetary systems.

Admittedly, such a scheme is still qualitative, and even (in part) speculative. But it provides at least a stimulating line for future work, and the advent of many new instruments operating at many wavelengths, both on the ground and in space, as well as of improved theoretical tools (plasma physics, etc.), should help us very soon to give a better answer to the ultimate question: where do the Sun and the solar system come from?

PART IV

Disk Processes and Planetary Matter

TRANSPORT PROCESSES AND THE EVOLUTION OF DISKS

FRED C. ADAMS

University of Michigan

and

D. N. C. LIN

Lick Observatory

In this chapter, we discuss the evolution of circumstellar disks and review the physical mechanisms which lead to the transport of angular momentum and energy. Circumstellar disks arise naturally during the star-formation process. One observational signature of these disks is the infrared and ultraviolet excesses in the spectra of young stellar objects. Analysis of the observed properties of these disks is important for the investigation of star formation in general and for determining the initial conditions for the formation of the solar system (especially formation of the planets). The evolution of circumstellar disks is largely determined by the efficiency of angular momentum transport. During the formation stages, disk dynamics is greatly affected by the addition of material from the infall-collapse flow. In this phase of evolution, the disk mass is likely to be comparable to the stellar mass; as a result, the self gravity of the disk can excite the growth of nonaxisymmetric perturbations, which can induce angular momentum transport and may also lead to the formation of binary companions if the disk is sufficiently massive. As infall gradually ceases, convectively driven turbulence may play an important role in inducing angular momentum transport. In this case, a disk with mass $M_D \approx 0.02 M_\odot$ and a physical extent comparable to that of the solar system will evolve viscously on a time scale of 10^5 to 10^6 yr. Transport instabilities may induce modulations in the mass transfer through the disk. Analysis of observed time dependent variations provides valuable information on the mass and temperature distribution as well as the magnitude of the viscosity. When the mass of the disk is sufficiently depleted, surface heating from the central star can stabilize the disk against convection. In the absence of other sources of viscosity, grains will settle towards the midplane of the disk and the disk will become optically thin. Thereafter, the system evolves towards a naked T Tauri phase. The eventual clearing of the protoplanetary disk may be due to photoevaporation.

I. INTRODUCTION

The purpose of this review is to describe the structure and evolution of disks associated with young stellar objects (YSOs). In order to fully understand these disks, we must begin by considering the current paradigm of star formation (see the Chapter by Shu et al.). In this paradigm, stars form within

the core of molecular clouds. These core regions, which are small subcondensations within the much larger molecular clouds, evolve in a quasi-static manner through the process of ambipolar diffusion. In this process, magnetic field lines slowly diffuse outward and the central regions of the core become increasingly centrally concentrated (see Shu 1983; Lizano and Shu 1989). The magnetic contribution to the pressure support decreases with time until the thermal pressure alone supports the core against its self gravity (at least in the central regions). At this point, the core is in an unstable quasi-equilibrium state which constitutes the initial conditions for dynamic collapse.

When a core begins to collapse, a small hydrostatic object (i.e., the protostar) forms at the center of the collapse flow and an accompanying circumstellar disk collects around it. This phase of evolution—the *protostellar phase*—is thus characterized by a central star and disk, surrounded by an infalling envelope of dust and gas. In this phase of evolution, the disk is greatly affected by the infall.

As a protostar evolves, both its mass and luminosity increase; the protostar eventually develops a strong stellar wind which breaks through the infall at the rotational poles of the system and creates a bipolar outflow. During much of this *bi-polar outflow phase* of evolution, the outflow will be well collimated (in angular extent) and *infall* will be taking place over most of the solid angle centered on the star. The outflow gradually widens in angular extent and the visual extinction to the central source gradually decreases. The outflow eventually separates the newly formed star/disk system from its parental core and the object enters the *T Tauri phase* of evolution. The newly revealed star then follows a pre-main-sequence track in the HR diagram and evolves toward the main sequence.

Circumstellar disks play an important role in the process of star formation outlined above. In recent years, compelling observational evidence (cf. the reviews of Appenzeller and Mundt 1989; Bertout 1989; Shu et al. 1987a) has established the presence of disks associated with YSOs, although the exact properties of such disks remain controversial. The available observational evidence (see, e.g., Bertout et al. 1988; Adams et al. 1988, 1990; Kenyon and Hartmann 1987; see also the Chapters by Strom, Beckwith and Sargent, Basri and Bertout, Hartmann et al.) indicates that YSO disks may produce significant luminosity ($L_D \sim L_* \sim 1 L_\odot$) and may have masses comparable to the stellar mass ($M_D \sim M_* \sim 1 M_\odot$). The stability, structure and evolution of these disks are determined by mass, angular momentum and radiation transport processes. In this review, we discuss the possible types of transport processes that can occur in these circumstellar disks. We first review the observational evidence and related theory that determine the basic disk properties (see Sec. II). We then consider the growth of *global* gravitational instabilities in star/disk systems (see Sec. III). These instabilities may lead to accretion through the disk and hence to the observed disk luminosities; in the limit of runaway growth of a single mode, these instabilities may also lead to the formation of a binary companion. Next, we discuss the role of convective instabilities (see

Sec. IV) in circumstellar disks. We then discuss the dynamical evolution of these disks (see Sec. V) and conclude with a summary and a look to the future (see Sec. VI).

II. BASIC DISK PROPERTIES

The basic characteristics of circumstellar disks vary with the stage of evolution. For purposes of this review, we will conceptually divide the evolution of disks into two regimes. The first regime corresponds to the protostellar phase of evolution (see the Chapter by Shu et al.; Shu et al. 1987a), i.e., the phase when the central star/disk system is still deeply embedded within an envelope of infalling gas and dust. The second regime corresponds to the T Tauri phase of evolution where the star/disk system is optically revealed, i.e., the system is essentially isolated from its environment.

A. Protostellar Disks

In the protostellar phase of evolution, the central star/disk system is deeply embedded in an infalling envelope of gas and dust. Essentially all of the intrinsic radiation from the star/disk system is absorbed and re-radiated by dust grains in the envelope. As a result, no direct signature can be measured for these disks. However, we can establish the existence of these disks and estimate their properties through indirect methods. One way to view protostellar evolution is through the $L-A_V$ diagram (Adams 1989,1990), which is roughly analogous to the HR diagram for actual stars. In this diagram (see Fig. 1), protostars evolve toward the upper right as they continually gain mass from the interstellar medium.

As the mass increases, the luminosity increases, and the column density (and hence the visual extinction) decreases (see Shu 1977). Any successful theory of star formation must produce $L-A_V$ diagram tracks that are consistent with observations of protostellar candidates. As shown by the dashed curve in Fig. 1, a purely spherical theory (with no rotation and hence no disk) is overluminous; we can thus conclude that disks must be present in protostellar systems. As shown by the dotted curve in Fig. 1, a theory with rotation and no disk accretion is severely underluminous; we can thus conclude that some disk accretion must occur during the protostellar phase. The solid curves in Fig. 1 are calculated on the basis of the current picture of star formation (see the Chapter by Shu et al.); the amount of disk accretion is determined by the gravitational stability of the disk (see Sec. III below; Shu et al. 1990; Adams 1990).

The comparison of theoretical tracks in the $L-A_V$ diagram with observed sources provides a *necessary* but not *sufficient* condition on the theory. The theory must also be able to account for both the spectral energy distribution and the spatial distribution of emission. In the protostellar (embedded) phase, circumstellar disks are required to produce the correct spectral energy distri-

Figure 1. $L-A_V$ diagram for the Taurus molecular cloud. Solid lines show theoretical tracks for $a = 0.20 \text{ km s}^{-1}$ and $\Omega/(10^{-14} \text{ rad s}^{-1}) = 1.0, 3.0$ and 10.0 . The dashed curve shows the spherical ($\Omega = 0$) limit; the dotted curve shows an alternate model with no disk accretion ($\eta_D = 0$). Symbols represent observed protostellar sources in the cloud.

butions (cf. Fig. 2; Adams et al. 1987; Ladd et al. 1991) and to understand the observed emission distribution (see Keene and Masson 1990).

The properties of protostellar disks can be summarized as follows. The disk masses are likely to be substantial because much of the infalling material falls directly onto the disk rather than onto the star. However, as we discuss in Sec. III below, the disk masses cannot be arbitrarily large because such disks would become highly unstable. Disk accretion must occur to account for the observed protostellar luminosities (again, see Fig. 1) and the intrinsic disk luminosity L_D is expected to be comparable to the stellar luminosity. We therefore expect the protostellar disk mass M_D to be a significant fraction of the total mass M_{total} . The physical size of protostellar disks is determined by the angular momentum of the collapse (see Sec. V below) and is likely to be ~ 10 to 100 AU for much of the protostellar phase of evolution.

B. T Tauri Disks

For T Tauri disk systems, the intrinsic spectral energy distribution is directly measurable and we can study more directly the properties of the circumstellar disks. One of the most striking properties of these systems is the large infrared excesses (see, e.g., Rucinski 1985; Rydgren and Zak 1987) which indicate the presence of circumstellar disks. As the observational qualities of T Tauri disk systems have been extensively discussed elsewhere in this book (see Chapters by Strom et al., Beckwith and Sargent, Basri and Bertout and Hartmann et al.), we will only summarize here the basic properties of these disks. The

Figure 2. The spectral energy distribution of protostellar candidate Haro 6–10. Curves show the theoretical spectrum calculated on the basis of the current protostellar theory; points show the observed data (figure adapted from Adams et al. 1987).

characteristic radial size is ~ 100 AU; this size can be deduced from the characteristics of the spectral energy distributions (Adams et al. 1988, 1990), from studies of spectral lines in outflows (Edwards et al. 1987), or from our own solar system (the mean distance of Neptune from the Sun is ~ 30 AU). The disks in T Tauri systems can be either *passive* and merely reprocess stellar radiation (see, e.g., Fig. 3a), or *active* and possess additional intrinsic luminosity (see, e.g., Fig. 3b).

For sources with active disks, the intrinsic disk luminosity L_D can be comparable to that of the star, i.e., L_D can be a significant fraction of the total luminosity. In addition, the spectral energy distributions of active disk sources indicate that the disk effective temperature distribution is often much flatter than the expected form $T_D \sim r^{-3/4}$ for a classical steady Keplerian accretion disk (Lynden-Bell and Pringle 1974); many disks require temperature profiles of the form $T_D \sim r^{-1/2}$, which suggests that *nonlocal* processes may be at work. The disk mass is estimated to lie in the range

$$0.01M_{\odot} \leq M_D \leq 1.0M_{\odot} \quad (1)$$

(see, e.g., Weintraub et al. 1989b; Adams et al. 1990; Chapter by Beckwith and Sargent). However, these mass estimates depend directly on the assumed dust opacity at submillimeter wavelengths (and this quantity remains uncertain at present).

Notice that the disk masses and radii (and hence the angular momenta) for the T Tauri disks are consistent with that expected from the protostellar theory

Figure 3. (a) Observed and theoretical spectral energy distribution of passive disk system of SR 9. Dashed curve shows a blackbody spectrum; solid curve shows the effects of including a passive disk (figure adapted from Adams et al. 1987). (b) Observed and theoretical spectral energy distribution of active disk system T Tauri. Solid curve shows the spectrum in the limit of an optically thick disk ($M_D \rightarrow \infty$); dotted curves show spectra with finite disk masses of 0.01, 0.1 and 1.0 M_\odot (figure adapted from Adams et al. 1987, 1990).

(see above; Chapter by Shu et al.; Shu et al. 1987a). Note also that both the protostellar disks and the T Tauri disks must be capable of disk accretion, but no definitive theory of disk accretion exists at this time. In the following two sections, we will discuss two important physical mechanisms which may lead to disk accretion. The first mechanism is self-gravitating disk instabilities,

which require a fairly large disk mass (i.e., M_D comparable to M_*) and are expected to be important during the protostellar phase of evolution. The second mechanism is convective instabilities, which are expected to arise during the T Tauri phase of evolution (when M_D is of order $10^{-2} M_\odot$).

III. GRAVITATIONAL INSTABILITIES

The basic objective of accretion disk theories is to identify the physical processes which (1) generate the observed spectrum and luminosity, and (2) determine the structure and regulate the evolution of the disk. From accretion disk models, we can delineate the conditions which lead to the formation of stellar companions and planetary systems. One of the central issues of accretion disk theory is the physical mechanism through which angular momentum is redistributed in the disk. In this section, we discuss gravitational instabilities in star/disk systems. During the early phase of protostellar evolution when the mass of the disk is comparable to that of the forming star itself, these gravitational instabilities may be particularly relevant in producing angular momentum transport in the disk.

A. The Initial Unperturbed State

Two general classes of gravitational instabilities can arise: *global gravitational instabilities* in which extended regions of the disk participate in promoting the growth of some initial disturbance and *local gravitational instabilities* in which the characteristic wavelengths are much shorter than the physical dimension of the disk. Global gravitational instabilities may occur when the mass of the disk is comparable to that of the central star. Local gravitational instabilities may occur in disks which are considerably less massive than the star if the disks are sufficiently cool.

In this section, we concentrate our discussion on the global gravitational instabilities which may be responsible for inducing energy dissipation and global energy transport in disks with relatively flat spectra. In particular, we will calculate the growing normal modes of the system for the case of modes with azimuthal wavenumber $m = 1$ (see Adams et al. 1989; Shu et al. 1990). We begin by specifying the basic unperturbed state. The physical system consists of a star and an accompanying gaseous disk. The growth of spiral modes is mainly determined by three elements: self-gravity, pressure and differential rotation. The gravitational forces are determined by the potential of the star and by the disk's surface density distribution $\sigma_0(r)$, which we take to be a simple power law in radius r from the central star (the disk is also assumed to be infinitesimally thin and in centrifugal equilibrium). The pressure is determined by the temperature distribution, or equivalently, the distribution of sound speed in the disk; we take the sound speed $a(r)$ to be a power law in radius. The rotation curve $\Omega(r)$ in the disk is then determined self consistently from the potential of the star, the potential of the disk, and the pressure gradients. Because the potential well of the star dominates that of the

disk everywhere except near the disk's outer edge, the rotation curve is nearly Keplerian throughout most of the disk's radial extent (for thin gaseous disks, the pressure gradients are small compared to the gravitational forces and do not significantly affect the rotation curve). Finally, we must specify the radial size of the disk. As discussed in the previous section, both observations and theory indicate that the characteristic disk size is approximately 100 AU, i.e., the disk radius R_D can be up to $\mathcal{O}(10^4)$ times the radius R_* of the star (only the ratio R_D/R_* enters into the calculations of self-gravitating instabilities discussed below).

B. Modes with Azimuthal Wavenumber $m = 1$

Our discussion concentrates on modes with azimuthal wavenumber $m = 1$, as these modes can be global in extent and may also be the most difficult modes to suppress in unstable gaseous disks. Modes with $m = 1$ correspond to elliptic streamlines (i.e., eccentric particle orbits), a special characteristic of Keplerian potentials. Thus, for a disk with an exact Keplerian rotation curve and no interactions between particles, $m = 1$ disturbances correspond to purely kinematic modes of the system (see Fig. 4); for realistic disks (with pressure), a relatively "small" amount of self gravity is required to overcome the pressure (and shear) and sustain modal growth.

Figure 4. Schematic diagram of $m = 1$ elliptical streamlines oriented to produce a one-armed spiral. The cross denotes the position of the star (figure adapted from Adams et al. 1989).

In addition, modes with $m = 1$ are the most global, i.e., these modes can affect a larger radial extent in the disk than higher m modes (see Fig. 1 of Adams et al. 1989).

One unique and important aspect of $m = 1$ modes is that the center of mass of the perturbation in the disk does *not* lie at the geometrical center of the system; hence, the frame of reference centered on the star is *not* an inertial reference frame. The star is actually in orbit about the center of mass (i.e., the star is accelerating) and creates an effective forcing potential, the “indirect potential,” which has the form

$$\psi_{\text{ind}} = \omega^2 R_0 r \exp[i(\omega t - \theta)] \quad (2)$$

where ω is the (complex) eigenvalue of the mode. The quantity R_0 measures the strength of the indirect term and is given by

$$R_0 = \frac{\pi}{M_D + M_*} \int_{R_*}^{R_D} r^2 dr \sigma_1(r) \quad (3)$$

where σ_1 is the perturbation of the surface density of the disk. Under some circumstances (see Shu et al. 1990), the indirect potential can have additional contributions from the displacement of the disk edge. Recent results (Adams et al. 1989; Shu et al. 1990) show that this indirect potential is essential for the growth and maintenance of spiral modes with azimuthal wavenumber $m = 1$. In fact, the interaction of this indirect potential with the outer Lindblad resonance in the disk (see below) can be the dominant amplification mechanism for these modes.

C. Wave Physics and Spiral Instabilities in Gaseous Disks

In the simplest description of spiral instabilities, self-excited disturbances (spiral modes) can grow through the feedback and amplification of spiral density waves. In this section, we briefly review the theory of spiral density waves. In the following sections, we describe the feedback cycle and the amplification mechanism for spiral modes, especially those with $m = 1$.

In the asymptotic (WKBJ) limit, the dispersion relation for spiral density waves in a gaseous disk has the form

$$k^2 a^2 - 2\pi G \sigma_0 |k| + \kappa^2 = (\omega - m\Omega)^2 \quad (4)$$

where k is the radial wavenumber, κ is the epicyclic frequency, and where ω is the complex eigenvalue of the system (see, e.g., Lin and Lau 1979). Since the gravitational term is proportional to $|k|$, this dispersion relation has four branches,

$$k = \pm(k_0 \pm k_1) \quad (5)$$

where

$$k_0 \equiv \frac{\pi G \sigma_0}{a^2}, \quad k_1 \equiv \frac{\pi G \sigma_0}{a^2} [1 - Q^2(1 - v_m^2)]^{1/2}, \quad (6)$$

and $v_m \equiv (\omega - m\Omega)/\kappa.$

Here, the quantity Q determines the stability of the system to *axisymmetric* disturbances ($Q > 1 \Rightarrow$ axisymmetric stability) and is defined by (Toomre 1964):

$$Q \equiv \frac{\kappa a}{\pi G \sigma_0}. \quad (7)$$

The overall sign of k determines whether the waves are *leading* ($|k| > 0$) or *trailing* ($|k| < 0$); the inner sign determines whether the waves are *short* [$k \propto (k_0 + k_1)$] or *long* [$k \propto (k_0 - k_1)$].

The quantity ν_m is a dimensionless frequency of the spiral density waves. The radius in the disk where $\nu_m = 0$ [i.e., where $\Re(\omega) = m\Omega$] is known as the *corotation resonance*; the energy and angular momentum of the perturbation (and the action) are positive outside the corotation radius and negative inside. Note that for $Q > 1$, the wavenumber k_1 becomes imaginary for radii sufficiently close to the corotation resonance, i.e., a classical turning point exists for the density waves. The resulting “forbidden” region surrounding the corotation resonance is known as the Q -barrier. Notice also that for long waves, $k \rightarrow 0$ at any radius where $|\nu_m| = 1$. The radius in the disk where $\nu_m = +1$ is known as the *outer Lindblad resonance* and plays an important role in the physics of $m = 1$ modes. In particular, long waves have a classical turning point at the Lindblad resonances and are thus confined to radii in the disk between the Q -barrier and the Lindblad resonances.

Figure 5. The four-wave feedback cycle for $m = 1$ modes. The propagation of each type of wave is shown by the solid lines with arrows. (See text for further discussion; figure adapted from Shu et al. 1990).

D. Feedback Loop: The Four-Wave Cycle

We now describe the feedback cycle for $m = 1$ modes in gaseous disks (see Shu et al. 1990). One unique aspect of this feedback cycle is that all four types of waves are utilized (see Fig. 5):

1. Begin (somewhat arbitrarily) with the excitation of a long trailing spiral density wave at the outer Lindblad resonance by the indirect term. The long trailing wave propagates inward (its group velocity is negative) until it encounters the outer edge of the Q -barrier.
2. At the Q -barrier, the long trailing wave refracts into a short trailing spiral density wave that propagates back outward, through the outer Lindblad resonance to the outer disk edge.
3. The short trailing waves that propagate to the outer disk edge reflect there to become short leading waves. The short leading waves then propagate back to the interior, through the outer Lindblad resonance, until they encounter the outer edge of the Q -barrier, where they refract into long leading spiral density waves that propagate back toward the outer Lindblad resonance.
4. At the outer Lindblad resonance, the long leading waves reflect to become long trailing waves. If the reflected long trailing wave possesses the correct phase relative to the long trailing wave launched from the outer Lindblad resonance by the indirect term in step 1 above, then we have constructive reinforcement of the entire wave cycle, and the basis for the establishment of a *resonant wave cavity*.

Using a WKBJ analysis, this four wave cycle can be used to derive a quantum condition for $m = 1$ spiral modes:

$$\oint k dr + \sum \Delta\phi = 2\pi n \quad (8)$$

where the wavenumber k is integrated over the entire four wave cycle described above; the changes in phase $\Delta\phi$ occur due to the reflection and refractions of the waves at their turning points, and where n is an integer. This quantum condition accurately predicts the pattern speeds (i.e., the real part of the eigenfrequencies) for these modes; for strongly growing modes, the analytical results (Shu et al. 1990) and numerical results (Adams et al. 1989) agree to within $\sim 1\%$.

E. SLING Amplification

In this section, we describe the amplification mechanism for eccentric modes. Detailed analysis indicates that the dominant mechanism for amplification arises from the indirect potential, which provides an effective forcing term. The indirect term varies slowly with radius in the disk; as a slowly varying force can only couple to oscillatory disturbances at the disk edges or at the Lindblad resonances (Goldreich and Tremaine 1979b), the main coupling occurs at the outer Lindblad resonance for the modes considered here. Thus,

this amplification mechanism differs substantially from the previously studied mechanisms, which utilize the process of *super-reflection* across the corotation resonance (super-reflection can still occur in these disks and is implicitly included in the numerical treatment, but it does not dominate the amplification). In an analytic treatment, the growth rates can be determined for the modes under the assumption that *all* of the amplification arises from this coupling of the indirect term to the outer Lindblad resonance in the disk, and that the indirect term arises mostly near the outer disk edge. In other words, the indirect potential is considered as an external forcing term acting on the disk and the torque exerted on the disk at the outer Lindblad resonance is calculated accordingly. Because the long-range coupling of the star to the outer disk provides the essential forcing, this new instability mechanism is called SLING, Stimulation by the Long-range Interaction of Newtonian Gravity.

The combined numerical and analytical treatments indicate the dependence of the growth rates (i.e., the imaginary part of the eigenfrequencies) on the parameters of the problem. Most importantly, a finite threshold exists for the SLING amplification mechanism. When all other properties of the star/disk system are held fixed, this effect corresponds to a threshold in the ratio of disk mass M_D to the total mass $M_* + M_D$. We find that the growth rates are largest for the case of equal masses $M_D = M_*$ and decrease rapidly with decreasing relative disk mass. In the optimal case, $M_D = M_*$, the growth rates can be comparable to the orbital frequency at the outer disk edge, i.e., the modes can grow on nearly a dynamical time scale. On the other hand, the presence of the finite threshold implies a critical value of the relative disk mass, i.e., the maximum value of $M_D/(M_* + M_D)$ that is stable to $m = 1$ disturbances; for the simplest case of a perfectly Keplerian disk and $Q(R_D) = 1$, this critical ratio has the value

$$\frac{M_D}{(M_* + M_D)} = \frac{3}{4\pi} \approx 0.24. \quad (9)$$

This critical value of the disk mass is known as the maximum solar nebula (Shu et al. 1990).

For SLING-amplified modes, the requirement of conservation of angular momentum luminosity leads to the following behavior for the relative surface density perturbation:

$$S \equiv \left| \frac{\sigma_1}{\sigma_0} \right| \propto r^{-1/2} a_0^{-2} \propto r^{-1/2} T^{-1}. \quad (10)$$

For the expected case of $S = \text{constant}$ (see the discussion in Shu et al. 1990), we obtain the temperature profile required for disks with flat infrared spectra: $T(r) \sim r^{-1/2}$ [note that the dynamical calculations ignore the temperature variations in the vertical direction and hence this form for $T(r)$ is that required by the flat-spectrum T Tauri sources (see Sec. II)].

F. Shutting off Gravitational Instabilities

The gravitational instabilities described above can be turned off via several mechanisms. If these instabilities lead to mass accretion through the disk, the fraction of the total mass that resides in the disk must eventually decrease below the critical fraction (see above) and the growth rates for the instabilities will decrease substantially. These instabilities can also be stabilized through excessive heating of the disk. If the Q parameter becomes sufficiently large everywhere in the disk, the growth rates for these instabilities will again decrease. Finally, these modes can be stabilized through the behavior of the outer disk edge. If the disk edge is very efficient at absorbing the (outgoing) short leading waves, the feedback cycle will be broken. However, the SLING amplification mechanism produces a strong amplifier and relatively little feedback is required to sustain the growth of these modes. The disk edge can also distort itself in such a manner as to cancel the effects of the indirect potential (see Shu et al. 1990). However, a fairly wide distribution of disk edge configurations will allow the growth of these modes.

G. Results and Conclusions

Eccentric spiral modes in gaseous disks have been studied using both numerical and analytical treatments of the problem. In both cases the (complex) eigenvalues of the system have been determined and the two approaches are in good agreement. The analysis indicates that the basic modal mechanism involves the four-wave cycle (see Fig. 5; Shu et al. 1990), which provides the feedback loop, and the SLING mechanism, which provides the amplification. The results also indicate that a wide range of YSO disks will be unstable to the growth of these eccentric distortions. When the disk mass is comparable to the stellar mass ($M_D \sim M_*$), these distortions can grow on nearly a dynamical time scale. In addition, these modes can grow when the disk is safely stable to axisymmetric disturbances (i.e., Q substantially > 1). However, the results (e.g., the exact spectrum of unstable modes) are particularly sensitive to the treatment of the outer disk edge (see Shu et al. 1990) and a more complete understanding of these edge effects is a goal of future theoretical studies.

The $m = 1$ modes described here may have important astrophysical applications. In the earliest stage of star formation—the protostellar phase—the mass of the disk is likely to be comparable to that of the star; $m = 1$ modes are thus likely to grow and may lead to mass accretion through the disk and the observed disk luminosities. Perturbations with $m = 1$ prove especially interesting because they force the star to move from the center of mass and thereby transfer angular momentum to the stellar orbit. This effect can be seen in Fig. 6 which shows the lowest-order $m = 1$ mode for a moderately massive disk $M_D = M_*$; note that most of the mass of the perturbation lies in one banana-shaped lump.

These $m = 1$ modes may thus lead to the formation of a binary companion within the disk (or perhaps to the formation of giant planets). Numerical simulations of spherical rotating systems (see, e.g., Monaghan and Lattanzio,

Figure 6. Equidensity contour plot for the lowest order ($n = 0$) SLING amplified $m = 1$ mode. The two dashed circles show the location of the corotation and outer Lindblad resonances. The spiral arm trails in the sense of rotation of the material (figure adapted from Adams et al. 1989).

unpublished calculation) also show the tendency to produce an orbiting pair of mass condensations. However, further calculations, including both dissipation and nonlinear effects, are needed to follow up these possibilities.

H. Other Gravitationally Unstable Modes

In addition to the case of $m = 1$ modes discussed above, other gravitationally unstable modes can arise in circumstellar disks. For example, the condition for stability against the growth of axisymmetric disturbances in a gaseous disk does not require the disk mass to be comparable to the central star. In the cool outer regions of protoplanetary disks, the temperature can be sufficiently cool so that $Q < 1$ even when $M_D/(M_* + M_D) < 3/4\pi$. In this limit, local gravitational instabilities may be excited; in this case, the characteristic wavelength derived from the dispersion relation (see Eq. 4) would be considerably less than the disk radius. Gravitational instability against nonaxisymmetric perturbations, when they can be excited, may also provide an effective mechanism for angular momentum transfer (Paczynski 1978a; Lin and Pringle 1987).

In the context of protoplanetary disk dynamics, two major theoretical issues arise concerning nonaxisymmetric gravitational instabilities: the origin of the instability and the effective magnitude of the torque induced by nonlinear (unstable) modes. Recent progress has been made on both issues (see, e.g., the reviews of Toomre 1981; Sellwood 1989; Papaloizou and Savonije

1989). The motivation for these investigations came mostly from dynamists interested in the spiral structure of disk galaxies. For circumstellar disks with $Q \sim 1$, the effect of self gravity can strongly amplify transient disturbances; however, in the absence of large surface density gradients, these disturbances are damped by shear and their amplification does not lead to genuine growth (Goldreich and Lynden-Bell 1965*b*; Julian and Toomre 1966). For regions with large surface density gradients, Toomre (1981, 1989) showed that genuinely unstable "edge" modes can grow strongly. In a recent series of numerical simulations of self-gravitating particle disks, Sellwood and Lin (1989) found that these edge modes are not only readily excited but also promote a recurrent nonaxisymmetric instability. These growing perturbations scatter particles off their Lindblad resonances through tidal torques and induce "grooves" in the phase-space distribution; these grooves, in turn, provide effective edges for the growth of subsequent edge modes (Sellwood and Kahn 1991).

Nonaxisymmetric normal mode analyses have been carried out for narrow rings and disks composed of both particles and an incompressible gas (Papaloizou and Lin 1989). These analyses indicate that the existence and growth rate of nonaxisymmetric instabilities is determined by the distribution of *vortensity*, i.e., the ratio of the surface density to the specific vorticity. There are at least three classes of unstable models: (1) those associated with extrema in vortensity, (2) those promoted by resonant cavities; and (3) those which have corotation points exterior to the disk. The first two types can exist for non-self-gravitating disks (Papaloizou and Pringle 1984, 1985, 1987) although the effect of self gravity amplifies the growth. The third type can only occur for self-gravitating disks and can promote nonaxisymmetric instabilities even for $Q > 1$.

Nonlinear simulations of self gravitating disks have been performed using a sticky particle hydrodynamics scheme (Anthony and Carlberg 1988) and using a three-dimensional (traditional) hydrodynamics code (Yang et al. 1991); these calculations indicate that nonaxisymmetric perturbations can grow into the nonlinear regime and can indeed transfer angular momentum through their tidal torques (see also Larson 1984). A series of detailed two dimensional hydrodynamic simulations (Savonije and Papaloizou 1989) showed that the amplitude of the perturbation eventually saturates at some finite value. For relatively massive disks, the torque induced by the growing nonaxisymmetric modes transports angular momentum outward and causes a significant amount of matter to spiral inward within a few orbital periods. The growth rate is a sensitive function of Q because the width of the evanescent zone around the corotation resonance (the Q -barrier; see Eqs. [4–7] above) is proportional to $(1 - 1/Q^2)^{1/2}$. When the effect of self gravity is no longer important, propagation through this evanescent region becomes impossible and the disk becomes stable.

For the self-gravitating outer regions of protoplanetary disks with moderate masses, these "local" gravitational instabilities cannot lead to binary star

formation and significant global energy redistribution as we have indicated in our discussion above on the $m = 1$ gravitational instabilities. Nevertheless, the effective angular momentum transport induced by these growing modes can affect the *secular* evolution of protoplanetary disks during their formation epochs (Lin and Pringle 1990; see also the discussion in Sec. V).

IV. VISCOUS EVOLUTION AND CONVECTIVE INSTABILITIES

In the later stages of disk evolution, the disk mass will become small enough that gravitational instabilities will shut off, or at least become less important. In the realm of intermediate mass disks, i.e., $M_D = \mathcal{O}(10^{-1} \text{ to } 10^{-2}) M_\odot$, convective instabilities (and other sources of viscosity) are likely to play an important role (see, e.g., Lin and Papaloizou 1985; Ruden and Lin 1986). We expect this regime of disk mass to occur after the infall has been terminated, i.e., after the disk no longer has a source for gaining mass.

A. Viscous Evolution of Circumstellar Disks

The evolution of circumstellar disks is governed by the laws of fluid dynamics. In the limit that viscous forces drive the evolution of the disk, the behavior is described by a time-dependent diffusion equation (Lüst 1952; Lynden-Bell and Pringle 1974; Lin and Papaloizou 1985), which can be written in the form

$$\frac{\partial \sigma}{\partial t} - \frac{3}{r} \frac{\partial}{\partial r} \left[r^{1/2} \frac{\partial}{\partial r} (\sigma \nu r^{1/2}) - \frac{2S_\sigma(r, t)J(r, t)}{\Omega} \right] - S_\sigma(r, t) = 0 \quad (11)$$

where Ω , σ and ν are the angular frequency, surface density and viscosity of the disk material, respectively, $S_\sigma(r, t)$ and $J(r, t)$ are the mass flux and excess angular momentum, respectively, of the infalling material. The evolutionary time scale and pattern depend on both the magnitude of the viscosity and the properties of the infalling material. During the initial formation of the disk and the entire protostellar phase of evolution, the source term $S_\sigma(r, t)$ will be large and may be particularly important in determining the structure of the disk. In the T Tauri (post-infall) phase of evolution [when $S_\sigma(r, t) = 0$], the mass of the disk will eventually become small enough that self-gravitating modes die out and viscous diffusion dominates the evolution of the disk. Note that the viscosity ν determines the evolution of the disk; in particular, the radial velocity through the disk is given by $u_r \propto -\nu/r$. Note also that viscous effects depend on the *local* disk properties, in contrast to the *global* nature of ($m = 1$) self-gravitating instabilities.

In a differentially rotating, geometrically thin disk, mass flow requires both angular momentum transport and energy dissipation (see, e.g., Lynden-Bell and Pringle 1974). These two processes can operate simultaneously through an effective viscous stress. However, molecular viscosity in accretion disks is generally too small to be of astrophysical interest. In a variety of accretion disks, a “turbulent” viscosity is often assumed to be responsible for

both angular momentum transport and viscous dissipation despite the lack of rigorous proof that turbulence may occur intrinsically (Shakura and Sunyaev 1973; Lynden-Bell and Pringle 1974). In such a prescription, an effective viscosity is introduced through the ansatz

$$\nu_{\text{eff}} = \frac{2}{3} \alpha_s a_s H \quad (12)$$

where a_s is the sound speed, H is the pressure scale height in the disk, and α_s is a dimensionless efficiency factor. The evolution of the disk is specified once the viscosity (or, equivalently, the α_s parameter) is given. The goal of any study of viscous evolution in disks is thus to calculate the parameter α_s in an *a priori* manner. In the case of YSO disks, thermal convection can occur in the direction normal to the plane of the disk (the vertical direction) and can produce turbulent flow and hence an effective viscosity (Lin and Papaloizou 1980,1985; Lin 1981).

B. Intrinsic Nature of Convective Instability

In order to show that YSO disks are intrinsically unstable against thermal convection, we analyze the structure of a turbulent-free disk in which rotation prevents gas from migrating in the radial direction. However, gas can contract in the vertical direction. If the disk is not in hydrostatic equilibrium initially, it will rapidly evolve towards such a state. Using a one-dimensional numerical hydrodynamic scheme, Ruden (1986) showed that a disk of cold gas contracts towards the midplane. After the disk has settled into a quasi-hydrostatic equilibrium, slow contraction continues as thermal energy is lost from the disk surface. In the absence of an energy source, surface radiation leads to heat diffusion from the midplane to the surface region. The associated reduction in pressure support leads to a readjustment towards a new hydrostatic equilibrium. In the typical temperature range of 10 to 10^3 K, such adjustment can lead to a *superadiabatic* structure in the vertical direction (see Ruden 1986). This structure is produced because the opacity, which is primarily due to dust grains, is a sufficiently strong increasing function of temperature. In the case of YSO disks, the cooler surface region has a lower opacity and cools more efficiently (Lin and Papaloizou 1980,1985; Lin 1981), although this condition is not generally satisfied in other accretion disks. The standard Schwarzschild criterion for convection can be written

$$\frac{d \log T}{d \log P} \geq \frac{\gamma - 1}{\gamma} \equiv \nabla_{\text{ad}} \quad (13)$$

where γ is the adiabatic exponent of the gas (see, e.g., Schwarzschild 1958). When the temperature gradient in the disk becomes superadiabatic, the disk becomes convectively unstable in the vertical direction.

C. Global Convective Pattern and Angular Momentum Transport

Once convection has become established in a circumstellar disk, a self-consistent cycle of disk accretion can occur. In this cycle, the convective

motions lead to turbulence. This turbulence leads to the production of eddies on a wide range of size scales, i.e., a cascade of eddies. On the smallest eddy scale, energy dissipation occurs through an effective viscosity. This viscosity, in turn, leads to energy generation in the disk and hence to disk accretion. The energy generation leads to steep vertical temperature gradients, which can be superadiabatic and therefore can support further convection. Thus, a self consistent cycle of convective instability can be maintained (see Fig. 7).

Figure 7. Schematic diagram of convective cell in a circumstellar disk (see text).

The role of convection in a disk is not limited to heat transport in the vertical direction. Convective eddies can induce mixing over a radial extent comparable to their own size. Through this mixing process, angular momentum is transferred. Convection also generates turbulence which causes dissipation of energy stored in differential rotation. Perhaps the simplest treatment for convection is to use the mixing-length prescription in which the eddy viscosity is assumed to be the product of the convective speed and an effective mixing length which is comparable to the size of the eddies (Lin and Papaloizou 1980). From such a treatment, we can build self-consistent models in which convection is responsible for (1) energy dissipation; (2) heat transport in the vertical direction; and (3) angular momentum and mass transport in the radial direction. Thus, energy dissipation is distributed from the midplane to the surface throughout the disk.

Notice, however, that the mixing-length model is based on an *ad hoc* prescription of eddy viscosity. In a convective disk, eddies with a variety of scales are generated. Similar to typical turbulent shear flows, the largest eddies often provide the dominant momentum transfer whereas the smallest eddies provide most of the energy dissipation in the disk. The scale of the largest convective eddies is comparable to the vertical scale of the entire convectively unstable zone which itself extends over a significant fraction of the thickness of the disk. On these large scales, global effects such as rotation

and radiative losses are important. Thus, convection must be examined with a global analysis. In an attempt to carry out such a global analysis, Cabot et al. (1987*a, b*) computed a vertically averaged effective viscosity which is derived from integrating the linear growth rate through various distances above the midplane of the disk. This growth rate varies greatly in the vertical direction and therefore cannot be attributed to any given eddy.

A more appropriate global treatment is to determine a unique growth rate (which is an eigenvalue) and its associated eigenfunction for each characteristic convective mode (Ruden et al. 1988; see Fig. 8).

Figure 8. Convective cell of eddies for an unstable convective mode in the protosolar nebula (figure adapted from Ruden et al. 1988).

These eigenfunctions extend over finite radial distances. In the thin-disk limit, the WKB approximation may be used to describe the radial dependence of temperature and density. These global linear stability analyses of axisymmetric perturbations indicate that:

1. Rotation and compressibility tend to reduce the growth rate of the disturbances; however, they cannot suppress the onset of convective instability in protostellar disks.
2. The growth rate is proportional to the square root of the radial wavenumber and is bounded by the maximum value of the Brunt-Väisälä frequency.
3. The maximum radial size of the eddies scales as the square root of the superadiabaticity times the size of the convective region.
4. Due to radiative losses, the short wavelength modes become overstable and only the fundamental and the first harmonic modes can grow effec-

tively (in these modes, the wavelength is comparable to the disk thickness).

5. Both even and odd modes exist, i.e., a single eddy may either be confined to one side of the disk or may thread through the midplane and have a characteristic scale comparable to the thickness of the entire disk.

Convective eddies can thus provide a relatively effective coupling between different parts of the disk and can induce both heat dissipation and angular momentum transport. The magnitude of the effective viscosity can be derived under the assumption that all of the gas within a radial wavelength mixes efficiently during the characteristic growth time scale. This estimate generally agrees well with that derived on the basis of the mixing-length model and yields an effective $\alpha \sim 10^{-2}$. For this value of α , the corresponding evolutionary time scale for the disk is $\sim 10^6$ yr and the mass accretion rate is 10^{-7} to $10^{-8} M_{\odot} \text{ yr}^{-1}$. The resulting intrinsic luminosity of the disk is fairly low, $L_D \leq 1 L_{\odot}$, and compares well with estimates of L_D from observations of boundary layers (see, e.g., Bertout et al. 1988). This calculation should be extended to include a global analysis of the initial linear growth of nonaxisymmetric disturbances and an analysis of the nonlinear regime where dissipative processes become important. The determination of the torque associated with growing nonaxisymmetric disturbances will provide a more rigorous estimate of the efficiency of angular momentum transport.

D. Suppression of Convection: Infall and Surface Heating

In order for convection to occur, the vertical gradient of temperature in the disk must be sufficiently large (superadiabatic); in particular, the central disk temperature must be sufficiently hotter than the disk surface. This temperature structure can be significantly modified by the boundary condition at the surface of the disk. In fact, any heating of the disk surface will tend to flatten the vertical temperature gradient and thereby suppress convection. In this section, we discuss two mechanisms that can heat the surface of the disk and can suppress convection: (1) disk heating through surface shocks from infalling material; and (2) disk heating by the stellar radiation field.

In the protostellar phase of evolution, infalling material falls onto the disk surface and dissipates its kinetic energy; this dissipation is achieved through a shock on the disk surface (see, e.g., Adams and Shu 1986). This shock heats the disk from its surface and thereby decreases the vertical temperature gradient; if the shock is sufficiently energetic, this heating from above can stabilize convection. If the infall rate onto the disk remains constant, shock dissipation near the surface can dominate the energy loss due to contraction towards the midplane and convection can be suppressed. However, when the infall rate is reduced, the superadiabatic gradient may be established as the surface heating becomes less important (Ruden 1986).

Surface heating due to radiation from the central star can also reduce the temperature gradient in the vertical direction in a manner similar to shock dis-

sipation associated with infall (Watanabe and Nakazawa 1988). In particular, convection may be stabilized for a relatively large stellar radiation field incident onto the surface of a disk with a relatively low surface density. A more general analysis (Bell et al. 1991) indicates that convection is suppressed only when the surface heating is sufficiently large to induce a blackbody temperature comparable to temperature near the midplane. This critical flux increases with the surface density of the disk because the opacity (and consequently the midplane temperature) also increases with the surface density.

In the limit where surface heating exceeds the critical flux required to stabilize convection, the subsequent evolution of the disk remains unclear (see the discussion in Lin 1989). Consider an axisymmetric perturbation in which one region of the disk has a slightly higher temperature. In that region, the disk thickness would increase and additional stellar radiation could be intercepted. Although the disk may be stable against convection, this relatively thick region of the disk would cast shadows on the outer disk and thereby reduce the surface heating for the exterior regions. A decrease in the incident stellar radiation in the shielded region can cause a reduction in the disk temperature. Consequently, the disk opacity is reduced and the cooling efficiency is increased. Although this process may not be thermally unstable, it may generate a large temperature gradient in the *radial* direction across the interface between the exposed inner hot region and the shielded outer cool regions. For perturbations with wavelengths comparable to or shorter than the thickness of the disk, the disk may become convectively unstable in the radial direction. Mixing in the radial direction would limit the magnitude of the radial temperature gradient. One possible consequence of these surface heating effects is the formation of "ripples" on the disk surface.

In the absence of infall and (strong) surface heating by the stellar radiation field, convective instabilities are expected to occur. However, these instabilities lead to accretion through the disk (see above) and reduce the disk mass, and the disk surface density. When the surface density in the disk becomes sufficiently small, the disk becomes optically thin and can no longer maintain vertical gradients of temperature. The disk thus becomes nearly isothermal, in the vertical direction, and convection again becomes suppressed.

E. Other Mechanisms for Angular Momentum Transport

In addition to the mechanisms for angular momentum transport outlined above, other possibilities exist. For example, if the magnetic field strength is large enough, magnetic torque can lead to the transport of angular momentum (see, e.g., Hoyle 1960; Hayashi 1981; Stepinsky and Levy 1990). One way to view magnetic effects is to define an effective magnetic viscosity (Hayashi 1981)

$$\nu_B \equiv \frac{B_r^2 \tau_B}{4\pi\rho} \quad (14)$$

where B_r is the radial component of the magnetic field, τ_B is the decay time of the field, and where ρ is the density. This magnetic viscosity drives disk evo-

lution in a manner which is analogous to the usual viscous evolution described above (see Sec. IV). On the other hand, if the magnetic field is relatively weak, i.e., if the energy density of the field is less than the thermal energy density, then a local axisymmetric shear instability can arise (Balbus and Hawley 1991; Hawley and Balbus 1991). This instability leads to turbulence in the disk and may provide a mechanism for angular momentum transport; further work is necessary to follow up these possibilities.

Magnetic fields may also play an important role in the generation of winds from YSOs (see Shu et al. 1988; Chapter by Königl and Ruden). In many wind models, the outflow is coupled to mass accretion through the disk; in addition, the associated magnetic fields tend to brake the rotation of the star and may expand the disk. The star/disk/wind interface is thus another important issue concerning the evolution of circumstellar disks.

In addition to the particular case of $m = 1$ self-gravitating modes (see Sec. III), other (higher m) modes and spiral density waves may also play a role in transporting angular momentum. Such effects have been studied by Larson (1984, 1989) and Spruit (1987); see Chapter by Morfill et al.

Tidal effects can also be important in the disks of YSOs. If planets form in the disk, they can clear out gaps in much the same way as moons of Saturn clear gaps in the rings (see, e.g., Lin and Papaloizou 1986*a, b*). As most stars are found in binary systems, binary companions should be present in many star/disk systems and can also transport angular momentum through the disk by tidal torques (Chapter by Bodenheimer et al.). These tidal effects are reviewed in the Chapter by Lin and Papaloizou.

V. DYNAMICAL EVOLUTION AND DISCUSSION

In this section, we discuss the various epochs of disk evolution. As the above sections concentrate on the specific topics of $m = 1$ instabilities and convective instabilities, we will also review other calculations related to the evolution of circumstellar disks.

A. Protostellar Disks and Disk Formation

The formation and evolution of protostellar disks are closely associated with the collapse of the protostellar cloud and the formation of the central star itself. The specific angular momentum of a typical protostellar cloud core is 10^{20} to 10^{21} cm² s⁻¹ (Goldsmith and Arquilla 1985). At the lower end of this range, the specific angular momentum of the cloud is comparable to that in our solar system today, whereas at the upper end, rotational effects would inhibit the collapse of the cloud at a size $\sim 10^{16}$ cm. Recently, numerical calculations have been carried out for both limits.

For a cloud with relatively low angular momentum, collapse calculations have been performed (Morfill et al. 1985) in two dimensions using an *ad hoc* α prescription (Shakura and Sunyaev 1973) for the angular momentum transport. Because the magnitude of viscosity is a function of temperature, the detailed

treatment of radiation transfer is important in determining the structure and evolution of the disk. Morfill et al. modeled the radiation transfer process with an Eddington approximation. The outcome of collapse was the formation of a central condensation surrounded by a disk. The energy dissipation associated with the formation and subsequent infall keeps the disk moderately hot. In a more comprehensive analysis, Bodenheimer et al. (1988) adopted a different numerical hydrodynamic scheme and modeled the radiative transport with a diffusion equation. Their results indicate the formation of a rapidly rotating central object which is surrounded by a relatively hot and geometrically thick disk spreading from 1 to 60 AU. The disk is essentially stable against axisymmetric gravitational instabilities.

The collapse of high angular momentum clouds can lead to the formation of more extended disks, which are likely to be optically thin. In such regions, the cooling time scale may be short compared with the dynamical time scale and the disk may be relatively cool. The combination of low temperature and a large distance from the central condensation (the star) provides favorable conditions for the growth of self-gravitating instabilities. Using a simple prescription for the effective torque induced by growing nonaxisymmetric perturbations (Lin and Pringle 1987), we can study the formation and evolution of an extended disk. In these computations, we also include turbulent transport of angular momentum (with an α prescription), but we assume that the turbulent viscosity is relatively small because convection is probably stabilized by the shock dissipation near the disk surface (see above). Radiative transfer for both the optically thin and thick limits are included. Finally, the difference in the specific angular momentum carried by the infalling and disk material is taken into account. In general, we find that nonaxisymmetric instability can induce efficient angular momentum transfer in the outer regions of the disk and regulate mass transfer through the disk; the associated mass accretion rate is $\sim 10^{-6}$ to $10^{-4} M_{\odot} \text{ yr}^{-1}$. The typical time scale for disk evolution is thus $\sim 10^5$ to 10^6 yr, which is comparable to the time scale of the infall phase. As a result, a substantial amount of material is likely to remain in the disk after the infall has been terminated.

In addition to the numerical results discussed above, analytical calculations have been performed for the collapse of rotating isothermal cloud cores (see, e.g., Terebey et al. 1984). These results have been used extensively as a basis for studying the formation of low-mass stars (see, e.g., Chapter by Shu et al.). In this rotating collapse scenario, the infall is nearly spherical outside a centrifugal radius R_C defined by

$$R_C \equiv \frac{G^3 M^3 \Omega^2}{16a^8} \quad (15)$$

where M is the mass of the central star/disk system, Ω is the initial rotation rate of the core, and where a is the isothermal sound speed of the core. Inside the radius R_C , the infall becomes highly aspherical. The infalling material with
