the highest specific angular momentum will encounter a centrifugal barrier at R_C and cannot fall to smaller radii; as a result, the radius R_C defines the outer radius of the disk (in the absence of angular momentum redistribution). Note that R_C grows with time, i.e., with mass M that is accumulating in the center of the collapse flow. The formation of the disk will occur when the centrifugal radius R_C becomes larger than the stellar radius R_* , which is nearly a constant in time (see Stahler et al. 1980). After the initial formation of the disk, most of the infalling material joins onto the disk rather than the star and the relative disk mass M_D/M grows with time (see also Cassen et al. [1985] for a more detailed review on this topic).

The calculations discussed above can be roughly summarized as follows. During the protostellar phase of evolution, the formation of a circumstellar disk is essentially unavoidable because of conservation of angular momentum. These protostellar disks are likely to be relatively massive; in particular, the relative disk mass M_D/M may be sufficiently large to sustain the growth of self-gravitating instabilities, especially the $m = 1$ modes considered in Sec. III above. The radius of the disk generally grows with time and is expected to be comparable to the size of our solar system, i.e., $R_D = 10$ to 100 AU, for much of the protostellar phase of evolution.

B. T Tauri Post-Infall Disks

We now consider the evolutionary phase after infall onto the disk has ended. During the early part of this stage, the disk mass may be large enough to continue to sustain self-gravitating modes; however, the disk mass must eventually become small enough that such modes are stabilized. The dynamics of the disk is then determined by the viscous diffusion process and can be analyzed by applying a simplified prescription for convectively induced turbulent viscosity (see Sec. IV above) in the diffusion equation; keep in mind, however, that other sources of viscosity are possible. In principle, the surface density distribution at the end of the infall stage may be used as the initial condition for the viscous diffusion phase. However, the evolution of the disk can also be computed with arbitrary initial conditions.

In the context of solar system formation, one interesting initial condition is the “minimum mass” nebula model (Cameron 1973; Hayashi 1981). In this model, the surface density distribution is derived by augmenting gas to the present mass distribution in the solar system based on the assumption that the protoplanetary disk had a solar composition and planetary formation is totally efficient at retaining all the heavy elements in the disk. Using the effective viscosity associated with convective viscosity, we find the evolution of the minimum-mass nebula with a physical dimension comparable to that of the present day solar nebula takes place on the time scale of $\sim 10^6$ yr (Lin and Papaloizou 1985). The temperature distribution resembles that deduced from the condensation temperature for various terrestrial planets and satellites (Lewis 1972), i.e., we obtain $T_D \sim r^{-3/4}$. At radii interior to the orbit of Mercury, the midplane temperature exceeds 2000 K, so that dust

grains will be mostly evaporated. Notice also that in protostellar models with Sun-like masses, the dust destruction front (i.e., the radius where dust grains are vaporized in the infalling envelope) is approximately 10^{12} cm, which is within the orbit of Mercury (Adams and Shu 1986).

For disks with moderate mass [i.e., $M_D/M_* = \mathcal{O}(0.1-1)$] and a surface density which decreases with radius (as expected), the outer regions of the disk will become optically thin. Observations of T Tauri disk systems show that the associated disks become optically thin for radii $r \geq 100$ AU (see Edwards et al. 1987; Adams et al. 1988, 1990). Theoretical models of the solar nebula become optically thin exterior to the orbit of Neptune and attain an isothermal vertical structure. In these optically thin regions, convection cannot occur and dust can settle towards the midplane. Even if some other local instabilities can occur, we do not expect the resulting turbulence to be sustained for an extended period. In the marginally optically thin region, the characteristic time scale for heat loss is comparable to, or shorter than, the orbital time scale of the disk. Energy transfer between eddies with different sizes occurs on the eddy turnover time scale, which is comparable to or longer than the orbital time scale. As thermal energy loss is thus *faster* than the kinetic energy transport of the eddies, the eddy motions become supersonic. Shocks can thus occur during eddy mixing and can lead to the decay of turbulence.

However, the absence of local turbulence may not imply the termination of disk evolution. Accompanying the decay of turbulence is the decline in mass diffusion and energy dissipation so that the disk temperature and optical depth decrease with the surface density. The effects of self gravity also increase with time. Eventually, the stability parameter Q can decrease to order unity and gravitational instability can lead to the growth of nonaxisymmetric disturbances and angular momentum transfer (Lin and Pringle 1990). In this regime, the evolutionary time scale is determined by the cooling time scale, because cooling is essential in maintaining a sufficiently low value for Q . In a relatively extended massive disk (i.e., $M_D \sim 0.1 M_\odot$ and $R_D \sim 100$ AU), when the temperature decreases to ~ 10 K, the cooling time scale at the disk edge exceeds 10^6 to 10^7 yr. However, the disk temperature cannot decrease below the temperature (~ 10 K) of the protostellar cloud. Thus, when the disk surface density decreases to a sufficiently small value, the effect of self gravity can no longer be important and the evolution of the disk must stop. A natural outcome for this process is the development of an extended, optically thin, circumstellar disk.

For the minimum-mass solar nebula model, the surface density of the disk is so low that self gravity becomes at best marginally important beyond the orbit of Neptune even when the disk temperature is 10 K. If the outer region is both optically thin and non self gravitating, no disk evolution can occur; this finding may be the reason why no major planet is found beyond the orbit of Neptune. In the inner region, the disk remains opaque and viscous evolution continues. As a result, some fraction of the disk material can be deposited in the outer disk region in order to conserve angular momentum.

C. Optically Thin Disks: The Naked T Tauri Phase

On the evolutionary time scale of typical T Tauri stars ($\tau \sim 10^6$ yr), approximately half of these objects become naked T Tauri stars, i.e., they lose any signature of a circumstellar disk (cf. Walter 1986). For the case of convectively driven turbulent viscosity, we can deduce the time scale for the disk to evolve into an optically thin system, i.e., $\tau \sim 10^8$ to 10^9 yr. Even with the assumption that some hypothetical transonic turbulence may be responsible for angular momentum transfer, the time scale for the disk to evolve into an optically thin state is still $> 10^7$ yr. These arguments imply that the disappearance of disk signatures (infrared and ultraviolet excesses) cannot be entirely due to viscous diffusion.

One possible mechanism for eliminating the ultraviolet and infrared excess from the disk is through dust settling. As discussed above, surface heating can stabilize the disk against convection (Watanabe and Nakazawa 1988) provided that the surface density is sufficiently low (Bell et al. 1991). During the evolution of the disk, the surface density of the disk continually decreases. For a minimum-mass nebula model, the surface density of the outer regions of the disk is reduced to a sufficiently low value such that the outer regions are stabilized after a few million years.

When the disk is stabilized, turbulence decays unless other instabilities can occur. In the absence of turbulence, dust can settle toward the midplane on the relatively short time scale of 10^3 to 10^4 yr (Hayashi et al. 1985). Once dust has settled to the midplane, the grains can either undergo gravitational instability to form kilometer-size planetesimals (Goldreich and Ward 1973) or coagulate rapidly (Weidenschilling 1984). These processes both cause the protoplanetary disk to become transparent so that it can no longer reprocess radiation from the central star. Furthermore, the lack of turbulent viscosity implies that no viscous dissipation can occur to heat the disk or to supply disk mass to the central star. Through this mechanism, radiative flux from the disk is significantly reduced while most of the disk gas is retained. The disk gas may be eventually eliminated on a somewhat longer time scale by (1) stellar wind ablation; (2) wind generated by the dissociation or ionization of disk gas by the incident solar radiation; and (3) disk-protoplanet tidal interaction. If naked T Tauri stars have no observable disk signatures because they are optically thin (for the reasons cited above), a clear prediction exists: these objects still have an appreciable amount of circumstellar gas with mass $\sim 10^{-2} M_{\odot}$. Further observations must be carried out to test this hypothesis.

VI. SUMMARY

In the last decade, a workable paradigm of star formation has emerged. In the paradigm, transport processes in circumstellar disks play an important role. In the earliest stages of evolution, the protostellar stage, the star and disk are still gaining mass from the surrounding infalling envelope. In this stage, the disk can have a mass comparable to that of the central star and gravitational

instabilities are likely to occur. Self-gravitating spiral modes with azimuthal wavenumber $m = 1$ are likely to dominate; these modes may lead to mass accretion through the disk and/or to the formation of binary companions within the disk. After the star/disk system becomes optically revealed (in the T Tauri phase of evolution), global self-gravitating instabilities decrease in importance as the disk mass decreases relative to that of the star. Once global gravitational instabilities have effectively shut off, the disk evolves viscously; however, the source of the viscosity remains undetermined. Angular momentum transfer and mass redistribution is induced by tidal torques associated with growing nonaxisymmetric perturbations in the self-gravitating outer regions of the disk. In the opaque inner regions of protoplanetary disks, convective instabilities provide one important mechanism for producing an effective viscosity. The amount of mass accretion through the disk is expected to decrease with time. In the later stages, the amount of luminosity generated in the disk itself becomes small compared to the amount of energy intercepted from the star (and reprocessed into the infrared), i.e., the disk becomes *passive*. Eventually, the disk becomes optically thin as the dust grains accumulate into larger bodies; the spectral appearance of the star/disk system then approaches that of an “ordinary” star, i.e., the infrared and ultraviolet excesses in the spectrum disappear. Finally, the remaining gas in the disk clears away through some sort of photoevaporation process. At this stage, the formation is complete and the star/disk system becomes a star/planetary system.

Although our understanding of circumstellar disks has improved greatly since the production of the *Protostars and Planets II* volume, much work remains to be done. The following areas of study are likely to be fruitful in the coming years:

1. Self-gravitating instabilities in circumstellar disks are likely to be important and may lead to disk accretion and/or the formation of binary companions. However, the present studies must be expanded to include both nonlinear and dissipative effects. In addition, the effects of the outer disk edge must be better understood.
2. Convective instabilities are likely to provide a source of viscosity for circumstellar disks and can therefore greatly affect their evolution. As convection, and hence the viscosity, can be turned off through various mechanisms (see above), future studies must determine the conditions under which convection can occur. Further studies of the global evolution of viscous disks, including nonlinear effects, should also be undertaken. In addition, models with realistic settling of dust grains need to be considered.
3. Other sources of viscosity and turbulence should also be considered. The effects of magnetic fields might be particularly rewarding.
4. Since energetic winds are ubiquitous phenomena and can produce a substantial back-reaction on circumstellar disks, the interface of the star, disk, and wind is another important area of study.

5. The circumstellar disks associated with forming stars provide the background state for the formation of planets. Now that the formation and evolution of circumstellar disks is becoming understood, studies of planet formation should be carried out for more general initial conditions, i.e., more typical circumstellar disks. In particular, planet formation should be studied in disk environments that are substantially more massive than the minimum-mass solar nebula.

ON THE TIDAL INTERACTION BETWEEN PROTOSTELLAR DISKS AND COMPANIONS

Formation of protoplanets and binary stars in a protostellar disk modifies the structure of the disk. Through tidal interactions, energy and angular momentum are transferred between the disk and protostellar or protoplanetary companion. Here, we summarize recent progress in theoretical investigations of the disk-companion tidal interaction. We show that low-mass protoplanets excite density waves at their Lindblad resonances and that these waves are likely to be dissipated locally. When a protoplanet acquires sufficient mass, its tidal torque induces the formation of a gap in the vicinity of its orbit. Gap formation leads to the termination of protoplanetary growth by accretion. For proto-Jupiter to attain its present mass, we require that (1) the primordial solar nebula is heated by viscous dissipation; (2) the viscous evolution time scale of the nebula is comparable to the age of typical T Tauri stars with circumstellar disks; and (3) the mass distribution in the nebula is comparable to that estimated from a minimum-mass nebula model. Tidal interaction between a disk and a binary star also leads to gap formation in the disk. Observations of binary T Tauri stars in a disk environment may provide important constraints on the origin of binary stars as well as on the nature of the companion-disk interaction.

I. INTRODUCTION

Recent observations indicate that a significant fraction of pre-main-sequence stars are deduced to have disks with masses in the range between 0.01 and $0.1 M_{\odot}$ and sizes from 10 to 100 AU (Strom et al. 1989a). Evidence for protoplanetary accretion disks comes from infrared and ultraviolet excesses which are interpreted as radiation from the disk and the accretion disk-star boundary layer, respectively (Adams et al. 1987; Shu et al. 1987a; Kenyon and Hartmann 1987). These observational data indicate that environments similar to those that led to the formation of the solar system may be common (see Chapter by Shu et al.). Theoretical investigation of these disks provides estimates on the physical conditions and evolutionary time scale in the disk and therefore imposes constraints on models of solar-system formation (Cameron 1985, 1988). For example, on the time scale ~ 1 Myr, a large fraction of

T Tauri stars lose any indication of the presence of a circumstellar disk (Walter 1987*a*). If protostellar disks viscously evolve on this time scale, the magnitude of effective viscosity needs to be much larger than that of molecular viscosity. One possible source of effective transport of angular momentum is convection driven turbulence (Lin and Papaloizou 1980, 1985; Chapter by Adams and Lin). From self consistent convective accretion disk models, we can deduce the temperature and density distribution near the present location of the planets (Ruden and Lin 1986).

To apply protoplanetary disk models to cosmogonical theory, it is important to note that protogiant planets must have been formed on a time scale comparable to or shorter than the viscous time scale of the disk. A similar formation time scale is needed for prototerrestrial planets as for protogiant planets as the latter proceed through the formation of solid cores, which have masses comparable to those of the terrestrial planets before acquiring their massive gaseous envelopes (Bodenheimer and Pollack 1986). One important task for a cosmogonical theory is to use this short formation time scale constraint to deduce the physical condition in the protostellar disks. In this chapter, we discuss the tidal interaction between a protoplanet and a protostellar disk and its implications for protogiant planetary formation.

Planetesimals coagulate through cohesive collisions (Safronov 1972). When the planetesimals acquire a few Earth masses, they begin to accrete nebula gas rapidly and become protogiant planets (Bodenheimer 1985). Through its tidal torque on the protostellar disk, a companion, such as a protoplanet or a binary protostar, can excite waves which carry angular momentum and energy. In the regions of the disk interior to the companion's orbit, the waves carry negative angular momentum and energy with respect to the local fluid. When the wave is dissipated, it deposits negative angular momentum and causes the disk material to drift inward. Similarly, in the regions of the disk exterior to the protoplanet, positive angular momentum is deposited and the disk material drifts outward. In Sec. II, we determine the rate of angular momentum exchange between a companion and the disk.

Companion-protostellar disk interaction can lead to modification in the disk structure. If tidally excited waves can propagate deep into the interior of the disk, the tidal influence of the companion is distributed over an extended region, whereas if these waves are dissipated in the close vicinity of the companion's orbit, the tidal effect is localized. In Sec. III, we discuss the response of a gaseous disk to the companion's tide under various physical conditions. Typical protostellar disks have thermally stratified vertical structure, in the sense that the gas temperature decreases with distance from the midplane. Differential propagation speed due to thermal stratification retards wavefronts and refraction transmits waves into the tenuous disk atmosphere. Consequently, wave propagation in the radial and vertical directions are linked. In Sec. IV we illustrate the propagation of density waves in a gaseous protostellar disk.

When the mass of the companion is sufficiently large, its tidal torque

may induce the formation of a gap in the vicinity of its orbit. There are two conditions for gap formation: the Roche radius of the companion must be comparable to or larger than the disk thickness and the rate of angular momentum transfer between the companion and the disk must exceed that in the disk due to viscous effects. In Sec. V, we illustrate these conditions, and in Sec. VI discuss the implication of gap formation on the growth of protoplanets in protostellar disks in Sec. VI.

After a protoplanet opens a gap in the vicinity of its orbit, mass growth of the protoplanet is terminated. However, its tidal interaction with the protoplanetary disk continues to operate until the disk material is dissipated. Such interaction causes the orbit of the protoplanet to evolve. If most of the interactions occur at the Lindblad resonance, there may be an imbalance between the exchange rate of energy versus angular momentum which would lead to an excitation of the protoplanet's orbital eccentricity. We determine the rate of change in the companion's orbital eccentricity in Sec. VII.

When gap formation first occurs, the amount of material cleared to either side of the gap is determined by the motion of the protoplanet. The disk responds by modifying the local surface density gradient such that the angular momentum transfer between the protoplanet and the interior regions of the disk is balanced by that between the protoplanet and the exterior regions of the disk. However, the disk interior to the protoplanet would be depleted on a viscous time scale whereas that exterior to the protoplanet retains its mass. This process could lead to substantial orbital migration for the protoplanet. In Sec. VIII, we illustrate the secular evolution of protoplanetary orbit and the disk structure.

Binary stars are very common and they are most likely to have formed in protostellar disks. In contrast to a protoplanet, the tidal effect of a binary with nearly equal mass ratio is widely distributed rather than concentrated near the Lindblad resonances on the disk. In Sec. IX, we determine the disk structure under the tidal influence of a binary star. Finally, in Sec. X, we outline some outstanding issues to be addressed in the future.

II. RATE OF ANGULAR MOMENTUM EXCHANGE FOR EXTREME MASS RATIO

The simplest derivation of the rate of tidally induced angular momentum transfer is based on an impulsive approximation in which the disk is composed of a collection of particles orbiting around a proto-Sun whose mass M is much larger than that of its companion M_p . In this limit, the tidal effect of the companion acts only during close encounters which deflect the orbit of a disk particle, assumed initially circular, by a small angle δ_e during a close passage such that

$$\cot^2(\delta_e/2) = u_e^4 \Delta^2 / G^2 M_p^2 \quad (1)$$

where u_e is the relative velocity which is counted positive if the relative motion is in the same sense as the binary, and $\Delta = |r_0 - r_c|$, where r_c and r_0 are

the radii of the unperturbed circular orbit of the disk particle and companion, respectively. The corresponding change in angular momentum of the particle is

$$\Delta h_e = -u_e(1 - \cos\delta_e)r_c. \quad (2)$$

If the unperturbed particle and the companion circulate around the proto-Sun with angular frequency Ω and ω respectively, $u_e = (\Omega - \omega)r_o$, so that

$$\Delta h_e = -\frac{2G^2M_p^2}{r_c^2(\Omega - \omega)^3\Delta^2}. \quad (3)$$

For the disk that is interior to the companion, $\Omega > \omega$, and Δh_e is negative corresponding to a loss of angular momentum from the disk to the companion. For an external disk, the transfer of angular momentum is from the companion to the disk. In addition to this angular momentum exchange, the particle is given some epicyclic motion so that in the absence of interactions, the subsequent encounter will be such that the particle is in an eccentric orbit. However, if we assume that the epicyclic motion of the particle is damped out by some internal dissipative process between successive encounters, the particle will return to a circular orbit. There will then be a net angular momentum transfer rate between the disk and the companion.

Because the time between encounters is $2\pi/|\Omega - \omega|$, the rate of angular momentum transfer becomes

$$\dot{h}_e = -\frac{G^2M_p^2|\Omega - \omega|}{\pi\Delta^2r_c^2(\Omega - \omega)^3}. \quad (4)$$

Using Taylor's expansion on $\Omega - \omega$ and working correct to first order in Δ , we can deduce the total rate of angular momentum change in an entire disk interior to the companions orbit to be

$$\dot{H}_T = \int_{\Delta_o}^{\infty} 2\pi\Sigma\dot{h}_e r_o d\Delta = -\frac{2G^2M_p^2\Sigma}{r_o(d\Omega/dr)_o^2} \int_{\Delta_o}^{\infty} \frac{d\Delta}{\Delta^4} = -\frac{8q^2\Sigma r_o^4\omega^2}{27} \left(\frac{r_o}{\Delta_o}\right)^3 \quad (5)$$

where $q \equiv M_p/M$ is the mass ratio, Σ is the surface density in the disk, assumed uniform in the interaction region, and Δ_o is the distance between the disk edge and the orbit of the companion. For an external disk, the same formula applies but the sign of \dot{H}_T is reversed.

The above result provides a simple evaluation of \dot{H}_T . However, it does not include the effect of the proto-Sun which causes the particle's orbit to curve prior to and after the impulsive encounters. For distant encounters in which Δ is larger than the Roche radius $r_R = (q/3)^{1/3}r_o$, the tidal effect of the proto-Sun is very important. This can be incorporated with a more sophisticated perturbation analysis of the particle orbit around the proto-Sun. Consider a particle which, in the absence of the companion, has a circular

orbit with a radius r_c and angular frequency Ω . We define the cylindrical polar coordinates of the particle based on the proto-Sun (r_p, ϕ_p) in an inertial frame to be such that $\phi_p = 0$ is the line joining the proto-Sun, its companion, and the particle on an unperturbed orbit at $t = 0$. The equations of motion for the particle are

$$\frac{d^2 r_p}{dt^2} - r_p \left(\frac{d\phi_p}{dt} \right)^2 = - \frac{\partial(\Psi - \psi_c)}{\partial r_p} \quad (6)$$

and

$$r_p^2 \frac{d^2 \phi_p}{dt^2} + 2 \frac{dr_p}{dt} \frac{d\phi_p}{dt} r_p = - \frac{\partial \psi_c}{\partial \phi_p} \quad (7)$$

where the potential of the proto-Sun and a companion in circular orbit are

$$\Psi = -GM/r_p \quad (8)$$

and

$$\psi_c = - \frac{GM_p}{[r_o^2 + r_p^2 - 2r_o r_p \cos(\phi_p - \omega t)]^{1/2}} + \frac{GM_p r_o \cos(\phi_p - \omega t)}{r_p^2}. \quad (9)$$

We determine the amount of angular momentum transfer from a particle to the companion as $\phi_p - \omega t$ goes from $-\pi/2$ to $\pi/2$. In the limit $M_p < M$, Eqs. (6) and (7) may be linearized in terms of variables $\delta_p = r_p - r_c$ and $\alpha_p = \phi_p - \Omega t$, with $\alpha_p = \dot{\alpha}_p = \delta_p = \dot{\delta}_p = 0$ initially, such that

$$\frac{d^2 \delta_p}{dt^2} + \Omega^2 \delta_p = S \quad (10)$$

and

$$r_c^2 \frac{d\alpha_p}{dt} + 2\Omega r_c \delta_p = \frac{\psi_c}{(\omega - \Omega)} \quad (11)$$

where $S = -(\partial \psi_c / \partial r) + 2\psi_c \Omega / [r_c(\omega - \Omega)]$ is evaluated for $r_p = r_c$ and $\phi_p = \Omega t$. Using a Fourier series expansion

$$S = \sum_{m=0}^{\infty} a_m \cos m(\omega - \Omega)t \quad (12)$$

the solution of Eq. (10) becomes

$$\delta_p = \sum_{m=0}^{\infty} \frac{a_m [\cos m(\omega - \Omega)t - A_m \cos(\Omega t + \epsilon_m)]}{[\Omega^2 - m^2(\omega - \Omega)^2]} \quad (13)$$

where $\epsilon_m = \pi \Omega / 2(\Omega - \omega) + m\pi/2$ and $A_m = 1$ for even m and $A_m = m(\omega - \Omega) / \Omega$ for odd m . In the limit that $|r_0 - r_c| \ll r_0$ but $m > 1$ such that $\xi = m|r_0 - r_c|/r_0$ is of order unity,

$$a_m = \frac{2GM_p r_0 \xi}{\pi r_0^2 |r_0 - r_c|} \left[K_1(\xi) + \frac{4}{3\xi} K_0(\xi) \right] \quad (14)$$

where K_0 and K_1 are modified Bessel functions (Goldreich and Tremaine 1982).

The angular momentum transfer to the companion is

$$\int_{-\pi/|2(\Omega-\omega)|}^{\pi/|2(\Omega-\omega)|} \frac{\partial \psi_c}{\partial \phi} dt = -\Delta h_e. \quad (15)$$

This must be evaluated to second order. After some algebra, one obtains

$$\Delta h_e = \frac{-1}{2(\Omega - \omega)} \left[\sum_m \frac{2\Omega a_m A_m \sin \epsilon_m}{[\Omega^2 - m^2(\omega - \Omega)^2]} \right]^2 \quad (16)$$

which differs only by a correction factor of $\frac{1}{2}$ from the corresponding previous expressions (Lin and Papaloizou 1979a).

If the disk is interior to the orbit of the companion, $\Omega > \omega$ and angular momentum is transferred to the companion. For a close encounter the major contribution to the sum comes from a few values of $m \sim m_0 = \Omega/(\Omega - \omega) = 2r_0/3|r_0 - r_c|$, where we can use a first-order Taylor expansion to evaluate $(\Omega - \omega)$. To perform the summation in Eq. (16) in the limit of a close encounter we assume that a_m is slowly varying with m so that it may be approximated as the constant value a_{m_0} . Using the results that for any w

$$\sum_{n=-\infty}^{n=\infty} \frac{(-1)^n}{(w^2 - 4n^2)} = \frac{\pi}{2w \sin(\pi w/2)} \quad (17)$$

and

$$\sum_{n=-\infty}^{n=\infty} \frac{(-1)^n (2n+1)}{w[w^2 - (2n+1)^2]} = \frac{-\pi}{2w \cos(\pi w/2)} \quad (18)$$

we may perform the summation in Eq. (16) with the result that to within a fractional error of order $1/m_0$,

$$\Delta h_e = \frac{-\pi^2}{2(\Omega - \omega)^3} (a_{m_0})^2 \quad (19)$$

or equivalently after using Eq. (14)

$$\Delta h_e = -\frac{64G^2 M_p^2 r_0}{243\omega^3 \Delta^5} \left[2K_0 \left(\frac{2}{3} \right) + K_1 \left(\frac{2}{3} \right) \right]^2 \quad (20)$$

(see also Julian and Toomre 1966; Goldreich and Tremaine 1982).

Equation (20) differs from Eq. (3) by a numerical factor of order unity and so one derives an expression for \dot{H}_T , which differs from that given by Eq. (5), by the same factor, namely

$$\dot{H}_T = -\frac{32q^2 \Sigma r_o^4 \omega^2}{243} \left(\frac{r_o}{\Delta_o} \right)^3 \left[2K_0 \left(\frac{2}{3} \right) + K_1 \left(\frac{2}{3} \right) \right]^2. \quad (21)$$

If the disk is viscous and in Keplerian rotation, there will be an outward flux of angular momentum at radius r given by

$$\dot{H}_v = 3\pi \Sigma \nu r^2 \Omega \quad (22)$$

where ν is the effective vertically averaged kinematic viscosity (Lynden-Bell and Pringle 1974). The angular momentum exchange between the disk and the companion is always such as to oppose the effect of viscosity. If for $r \sim r_0$, we have $\dot{H}_v < |\dot{H}_T|$, the companion's tidal effect is more effective in transporting angular momentum than the viscous process. In this case, the disk region in the vicinity of the companion's orbit may be depleted and a gap formed (Lin and Papaloizou 1979a). The physical process and implication for gap formation will be discussed in more detail in Secs. V and VI. Note that if a gap is formed as a result of tidal truncation, the width of the gap must be at least comparable to the companion's Roche radius so that $\Delta_o \sim r_R$. Thus, using Eqs. (5) and (21), the critical condition for gap formation becomes

$$q > 81\pi \nu / (8r_o^2 \omega) \quad (23)$$

such that the companion must have sufficient mass to induce gap formation in the disk.

The particle impulse approximation used above is simple to derive and can be adequately applied to particle disks such as planetary rings. However, caution in applying these results to gaseous disks has been urged by Lunine and Stevenson (1982). They have stressed the need to consider the detailed nature of the dissipative process, and have noted that the tidally induced disturbance may propagate throughout the disk, delocalizing the tidal torque, when the dissipation is very weak. They also noted that the formation of the gap changes the surface density profile, and, in turn, that could change the position of the Lindblad resonances where the tidal disturbances are launched. Greenberg (1982) has also emphasized the need for a proper consideration of the dissipative process. He suggested that the rate of tidally induced angular momentum transfer may be significantly reduced if the dissipation is weak. In the next section, we examine the linear propagation of a companion's tidal disturbances in a gaseous disk and the importance of dissipation in determining the angular momentum transfer rate.

III. RESPONSE OF A GASEOUS DISK TO THE COMPANION'S TIDE

In typical models of protoplanetary disks, the vertical scale height of the disk H_D is typically 0.05 to 0.1 times the distance to the proto-Sun (Lin and Papaloizou 1985). This scale height is comparable to the Roche radius of companions with mass in the range of 10^{-4} to $10^{-3} M_\odot$. When low-mass companions, such as protogiant planets, become sufficiently massive to open up a gap, the pressure scale height in the radial direction is approximately

r_R which is comparable to or smaller than that in the vertical direction H_D and cannot be neglected in describing the tidal interaction near the disk edge. The dominant contribution of the pressure effect in the radial direction is to delocalize the companion's tidal torque.

A. Basic Equations

The first step in the analysis of the tidal interaction between a companion and a gaseous disk is to determine the disk's structure. The structure and evolution of a general (not necessarily thin) gaseous disk can be deduced from the equations of fluid dynamics. The rate of change in density ρ is described by the continuity equation

$$\frac{\partial \rho}{\partial t} + \nabla \cdot \rho \mathbf{v} = 0. \quad (24)$$

The evolution of the velocity \mathbf{v} is determined by the momentum equation

$$\frac{D\mathbf{v}}{Dt} = -\frac{1}{\rho} \nabla p + \frac{1}{\rho} \nabla \underline{\underline{\sigma}} - \nabla(\Psi + \psi_c + \psi_d) \quad (25)$$

where p is the pressure. The material derivative D/Dt is composed of both the local time derivative $\partial/\partial t$ and the advective contribution $\mathbf{v} \cdot \nabla$. The stress tensor $\underline{\underline{\sigma}} = \sigma_{ij} = 2\rho v_s(e_{ij} - \Delta_d \delta_{ij}/3) + \rho v_b \Delta_d \delta_{ij}$, where v_s and v_b are the shear and bulk viscosity, the rate of strain tensor $e_{ij} = (\partial v_i/\partial x_j + \partial v_j/\partial x_i)/2$ and $\Delta_d = e_{ii}$. The gravitational potential due to the central object is Ψ , that due to an orbiting companion is ψ_c , and that due to the disk matter is ψ_d . The rate of change in thermal energy can be derived from the energy equation such that

$$C_v \rho \left[\frac{DT}{Dt} - (\Gamma_3 - 1) \frac{T}{\rho} \frac{D\rho}{Dt} \right] = D_v - \nabla \cdot \mathbf{F} \quad (26)$$

where C_v and Γ_3 are the specific heat and adiabatic index and \mathbf{F} is the total heat flux. The local rate of dissipation is given by

$$D_v = 2\rho v_s(e_{ij} - \Delta_d \delta_{ij}/3)(e_{ij} - \Delta_d \delta_{ij}/3) + \rho v_b \Delta_d^2. \quad (27)$$

Together with a viscosity prescription and an equation of motion, these basic equations describe completely the response of a disk due to the interplay between a companion's tidal torque, thermal effects, and viscous evolution.

To deduce the disk response to the tidal perturbation of the companion, it is convenient to adopt a thin disk approximation in which there is no vertical motion, and $\Sigma (\equiv \int_{-\infty}^{\infty} \rho dz)$, and $P (\equiv \int_{-\infty}^{\infty} p dz)$ are the surface density and vertically integrated pressure, respectively. In a nonrotating cylindrical coordinate system (r, ϕ, z) defined with the origin at the proto-Sun and z being the vertical coordinate, the radial component of the equation of motion is

$$\frac{\partial v_r}{\partial t} + v_r \frac{\partial v_r}{\partial r} + \frac{v_\phi}{r} \frac{\partial v_r}{\partial \phi} - \frac{v_\phi^2}{r} = -\frac{1}{\Sigma} \frac{\partial(P + q_v)}{\partial r} - \frac{\partial(\Psi + \psi_c + \psi_d)}{\partial r} \quad (28)$$

where v_r and v_ϕ are the radial and azimuthal components of velocity, and for our numerical work to be presented below, we use a pseudoviscous pressure q_v which enables the propagation of shock waves. The azimuthal component of the equation of motion in the flat disk model is

$$\frac{\partial v_\phi}{\partial t} + \frac{v_\phi}{r} \frac{\partial v_\phi}{\partial \phi} + v_r \frac{\partial v_\phi}{\partial r} + \frac{v_\phi v_r}{r} = -\frac{1}{r\Sigma} \frac{\partial(P + q_v)}{\partial \phi} - \frac{\partial(\psi_c + \psi_d)}{\partial r} + F_v \quad (29)$$

where

$$F_v = \frac{1}{\Sigma r^2} \frac{\partial}{\partial r} \left(v_s \Sigma r^3 \frac{\partial \Omega}{\partial r} \right). \quad (30)$$

The gravitational potential due to the disk material is

$$\psi_d = -G \iint \frac{\Sigma(r', \phi', t) r' dr' d\phi'}{[r^2 + r'^2 - 2rr' \cos(\phi - \phi')]^{1/2}}. \quad (31)$$

In Eqs. (28) and (29), the detailed treatment of an equation of state is not important. For illustrative purposes and computational convenience, a barotropic equation of state $P = P(\Sigma)$ is usually used and the local sound speed c is defined through $c^2 \equiv dP/d\Sigma$. Finally, the continuity equation becomes

$$\frac{\partial \Sigma}{\partial t} + \frac{1}{r} \frac{\partial}{\partial r} \Sigma r v_r + \frac{1}{r^2} \frac{\partial}{\partial \phi} \Sigma r v_\phi = 0. \quad (32)$$

The main motion in the disk is rotation in the azimuthal direction and its angular frequency can be deduced from Eq. (28) in the limit of negligible v_r , q , ψ_c and ψ_d such that

$$v_\phi^2/r = \Omega^2 r = \frac{1}{\Sigma_o} \frac{dP_o}{dr} + \frac{d\Psi}{dr} \quad (33)$$

where the subscript o denotes an unperturbed axisymmetric value. In the thin disk limit when the sound speed of the disk is very small, $\Omega^2 \sim GM/r^3$ which is the Keplerian rotation law. Using these equations, we calculate the response of the disk to the companion's tidal disturbance and the associated rate of angular momentum transfer.

B. Linear Calculations of Disk Response

In order to calculate the response of a gaseous disk and the propagation of disturbances induced therein by the presence of a companion, it is useful to carry out a linear analysis in which the nonaxisymmetric perturbations to the disk motion are assumed small. We linearize Eqs. (28) and (29) such that

$$\frac{\partial v'_r}{\partial t} + \Omega \frac{\partial v'_r}{\partial \phi} - 2\Omega v'_\phi = -\frac{\partial}{\partial r} \left(\frac{\Sigma' c^2}{\Sigma_o} \right) - \frac{\partial \psi_c}{\partial r} + F'_r \quad (34)$$

and

$$\frac{\partial v'_\phi}{\partial t} + \Omega \frac{\partial v'_\phi}{\partial \phi} + \frac{v'_r}{r} \frac{d(\Omega r^2)}{dr} = -\frac{1}{r} \frac{\partial}{\partial \phi} \left(\frac{\Sigma' c^2}{\Sigma_o} \right) - \frac{1}{r} \frac{\partial \psi_c}{\partial \phi} + F'_\phi. \quad (35)$$

In the above equations, perturbed quantities are denoted by a prime. In the unperturbed axisymmetric flow, $\Sigma = \Sigma_o$, $v_r = 0$ and $v_\phi = \Omega r$. Contributions arising from the viscous terms are included in F'_r and F'_ϕ . For most cases to be considered here, the contribution from self gravity is neglected. When the companion is in a circular orbit with orbital frequency ω , ψ_c is a function of ϕ and t only through the combination $\phi - \omega t$ and therefore the perturbed quantities are also functions of the same combination. Thus, $\partial/\partial t = -\omega \partial/\partial \phi$ and the equations of motion can be written

$$(\Omega - \omega) \frac{\partial v'_r}{\partial \phi} - 2\Omega v'_\phi = -\frac{\partial}{\partial r} \left(\frac{\Sigma' c^2}{\Sigma_o} \right) - \frac{\partial \psi_c}{\partial r} + F'_r \quad (36)$$

and

$$(\Omega - \omega) \frac{\partial v'_\phi}{\partial \phi} + \frac{v'_r}{r} \frac{d(\Omega r^2)}{dr} = -\frac{1}{r} \frac{\partial}{\partial \phi} \left(\frac{\Sigma' c^2}{\Sigma_o} \right) - \frac{1}{r} \frac{\partial \psi_c}{\partial \phi} + F'_\phi. \quad (37)$$

The perturbed continuity equation is

$$\frac{\partial \Sigma'}{\partial t} + \Omega \frac{\partial \Sigma'}{\partial \phi} = -\frac{1}{r} \left[\frac{\partial}{\partial r} (r v'_r \Sigma_o) + \frac{\partial}{\partial \phi} (\Sigma_o v'_\phi) \right] \quad (38)$$

which becomes

$$(\Omega - \omega) \frac{\partial \Sigma'}{\partial \phi} = -\frac{1}{r} \left[\frac{\partial}{\partial r} (r v'_r \Sigma_o) + \frac{\partial}{\partial \phi} (\Sigma_o v'_\phi) \right]. \quad (39)$$

One important quantity to be determined is the flux of angular momentum through a circle of constant radius

$$F_H = \int_0^{2\pi} \Sigma_o r^2 v'_r v'_\phi d\phi. \quad (40)$$

The lowest-order contribution to F_H is of second order in the perturbed variables. This is because the first-order terms average to zero. In a region where the direct forcing and hence ψ_c may be neglected, after some algebra (Papaloizou and Lin 1984), F_H may be expressed in terms of the radial Lagrangian displacement, ξ_r , such that

$$F_H = - \int_0^{2\pi} \Sigma' c^2 r \frac{\partial \xi_r}{\partial \phi} d\phi - \int_0^{2\pi} \Sigma_o r^2 \xi_r F'_\phi d\phi. \quad (41)$$

Using Eqs. (36), (37), (39) and (40), we can also derive

$$\begin{aligned} \frac{dF_H}{dr} = \frac{1}{(\omega - \Omega)} \left\{ \frac{d}{dr} \left[(\Omega - \omega) \int_0^{2\pi} \Sigma_o r^2 \xi_r F'_\phi d\phi \right] \right. \\ \left. + \int_0^{2\pi} (F'_r v'_r + F'_\phi v'_\phi) \Sigma_o r d\phi \right\}. \end{aligned} \quad (42)$$

To illustrate the direction of angular momentum flow, we consider the special case where $F'_\phi = 0$ but $F'_r = -kv'_r$, with k being a positive constant corresponding to a dissipative force (similar conclusions follow in more general cases) so that $dF_H/dr = -\epsilon_D/(\omega - \Omega)$ where $\epsilon_D = -\int_0^{2\pi} F'_r v'_r \Sigma_o r d\phi$ is the rate of energy dissipation per unit length which is positive. If the companion is interior to the disk, $\omega > \Omega$ and F_H decreases with r . Because F_H vanishes at large distances from the companion, F_H is positive close to the companion and the disk receives angular momentum. Similarly, the disk loses angular momentum when the companion is exterior to the disk. In both cases, there is an outward flux of angular momentum with $F_H > 0$.

To determine the magnitude of F_H as a function of r , we need to determine the disk response from the perturbed equation of motion. Note that in the absence of dissipation ($F'_r = F'_\phi = 0$), Eq. (42) implies F_H is constant and there is zero transfer of angular momentum. For computational convenience, we first consider the dissipation-free limit and incorporate the effect of dissipation at the end of this section. In the limit that $M_p < M$, it is convenient to expand ψ_c in Eqs. (28) and (29) into a Fourier series (Brouwer and Clemence 1961) where

$$\psi_c = \text{Re} \sum_{m=0}^{\infty} W_m \exp[im(\phi - \omega t)] \quad (43)$$

where for the case of extreme mass ratio

$$W_m = -\frac{GM_p}{\pi} \int_0^{2\pi} \frac{\cos m\phi d\phi}{(r_o^2 + r^2 - 2rr_o \cos \phi)^{1/2}} = -\frac{2GM_p}{\pi r_o} K_o \left(\frac{m\Delta}{r_o} \right) \quad (44)$$

where $\Delta = r - r_o$, and r_o is the orbital radius of the companion (Goldreich and Tremaine 1982). Equations (36) and (37) become

$$\frac{1}{\Sigma_o r} \frac{d}{dr} (\Sigma_o r \xi_{rm}) - \frac{2\Omega \xi_{rm}}{r(\Omega - \omega)} = \left[\frac{K_m}{r^2(\Omega - \omega)^2} - \frac{K_m}{c^2} \right] + \frac{W_m}{r^2(\Omega - \omega)^2} \quad (45)$$

and

$$\frac{dK_m}{dr} + \frac{2\Omega K_m}{r(\Omega - \omega)} = \xi_{rm} [m^2(\Omega - \omega)^2 - \Omega^2] - \frac{dW_m}{dr} - \frac{2\Omega W_m}{r(\Omega - \omega)}, \quad (46)$$

where $K_m = \Sigma'_m c^2 / \Sigma_o$, Σ'_m and ξ_{rm} are the coefficients in the Fourier expansion of Σ' and ξ_r , respectively.

The two linearized equations of motion may be combined to give a single second-order differential equation for ξ_{rm} from which the disk response to the companion's tide may be determined. For illustration purposes, let us consider the case in which the disk is tidally truncated and Σ_o vanishes near r_o . To avoid singularity, the boundary condition at the disk edge is

$$K_m = -\frac{\xi_{rm}}{\Sigma_o} \frac{dP_o}{dr}. \quad (47)$$

In the asymptotic limit far away from the companion, the general solution of Eqs. (45) and (46) can be obtained using a WKB approximation such that

$$\xi_{rm} = \frac{(\eta_1 e^{i\mu} + \eta_2 e^{-i\mu})}{\{\Sigma_o r c [m^2(\Omega - \omega)^2 - \Omega^2]^{1/2}\}^{1/2}} \quad (48)$$

where η_1 and η_2 are complex constants,

$$\mu = \int_{r_1}^r \frac{[m^2(\Omega - \omega)^2 - \Omega^2]^{1/2}}{c} dr \quad (49)$$

and r_1 is an arbitrary constant radial location chosen such that the WKB approximation is valid there. In addition r must be such that the WKB approximation is valid in the interval $[r_1, r]$. Equation (48) implies that waves are propagating away from and towards the companion with amplitudes η_1 and η_2 respectively. Inserting this solution into the expression (41), the flux of angular momentum carried by the waves is

$$F_H = \pi m (|\eta_1|^2 - |\eta_2|^2). \quad (50)$$

The limiting case $\eta_2 = 0$ corresponds to pure outward transport of angular momentum while $\eta_1 = \eta_2$ corresponds to zero transport. In general η_2 may be finite if there is some wave reflection at large distances from the location where the waves are launched. The ratio η_1/η_2 has to be determined from the boundary condition at large distances from the companion.

Equations (45) and (46) can be combined into a single second-order ordinary differential equation which can be solved by the method of variation of parameters. It turns out that F_H can be determined if the solution of the unforced equations ($W_m = 0$) that satisfies the correct boundary condition (47) is known (Papaloizou and Lin 1984). We denote ξ_{rm} for this solution by X_m . At large distances from the companion, say for $|r - r_o| > r_1$, this takes on the WKB form

$$X_m = (C e^{i\mu} + C^* e^{-i\mu}) / \{\Sigma_o r c [m^2(\Omega - \omega)^2 - \Omega^2]^{1/2}\}^{1/2} \quad (51)$$

where C is a complex constant which satisfies

$$|C|^2 = \frac{\Sigma_o r c^3}{4} \left[\frac{(dX_m/dr)^2}{|[m^2(\Omega - \omega)^2 - \Omega^2]^{1/2}|} + \frac{X_m^2 [m^2(\Omega - \omega)^2 - \Omega^2]^{1/2}}{c^2} \right]. \quad (52)$$

We then find that

$$F_H = \frac{\pi \eta f}{4|C|^2} \left| \int_{r_o}^{r_1} \Sigma_o r S_m X_m dr \right|^2 \quad (53)$$

where

$$f = \frac{(1 - y^2)}{(1 + y^2 - 2y \cos \chi)} \quad (54)$$

$$y = |\eta_2|/|\eta_1| \quad (55)$$

$$\chi = 2\arg(C) + \arg(\eta_2) - \arg(\eta_1) \quad (56)$$

$$S_m = \frac{d}{dr} \left(\frac{W_m \alpha}{c^2} \right) + \frac{2\Omega W_m \alpha}{r(\Omega - \omega)c^2} \quad (57)$$

and

$$\alpha = c^2 r^2 (\Omega - \omega)^2 / [c^2 - r^2 (\Omega - \omega)^2]. \quad (58)$$

The effect of distant boundary conditions is contained in the factor f through the phase argument χ . Equation (58) indicates that the asymptotic solution of X_m oscillates on a very small scale so that only a very slight change in the condition at large Δ can produce a large change in χ . The factor y is a measure of the strength of dissipation and we suppose $y < 1$. If $y = 0$, only outward transport of angular momentum is present which means that energy is dissipated before it can reach any distant boundary and be reflected. If $y = 1$, no dissipation takes place. In this case, f becomes infinite if $\cos \chi = 1$. This corresponds to a resonance and means that the orbital rotation frequency is equal to some free normal mode rotation frequency. The response is singular because there is no dissipation. In principle, if nonlinear effects are neglected, the magnitude of y and χ are determined by the size of the viscosity and details of very distant behavior. In practice, χ is so sensitive to small changes in distant conditions that we can take an average over 2π and replace f with $\int_0^{2\pi} f d\chi / 2\pi$. This corresponds to acknowledging that the disk and the companion are only slowly evolving, and calculating an average angular momentum transport over a range of disk-defining parameters or orbital frequencies. Physically, one requires that, as the system evolves, the full tidal response can be established, i.e., the time required to evolve χ through 2π be at least equal to the dissipation time scale associated with the tide. If we are considering a disk changing through viscous evolution, with viscosity as the dissipative agent acting on the tide, the above condition should be met even if the viscosity is small. Now

$$\frac{1}{2\pi} \int_0^{2\pi} f d\chi = 1, \quad (59)$$

independent of the size of y so that f in Eq. (53) can be replaced by unity. Thus, the net angular momentum flux carried by waves associated with a particular m value is

$$F_H = \frac{\pi m}{4|C|^2} \left| \int_{r_o}^{r_1} \Sigma_o r S_m X_m dr \right|^2 \equiv \frac{\pi m}{4|C|^2} \left| \int_{r_o}^{r_1} \frac{\Sigma_o r W_m K_m}{c^2} dr \right|^2. \quad (60)$$

Here the second equivalent form of the integral may be derived from Eqs. (45) and (46) (with $W_m \equiv 0$ and $\xi_{rm} \equiv X_m$) by integrating by parts under the assumption that the effect of the perturbing potential is negligible at the boundary most distant from the companion. To get the total angular momentum flux we must sum over m . We remark that Eq. (60) holds for any mass ratio and does not require the presence of a Lindblad resonance directly in the disk.

C. A Companion with Extreme Mass Ratio

To calculate the rate of angular momentum flux in a particular case, a specific equation of state and Σ_o distribution needs to be specified in order to evaluate X_m . For illustrative purposes, we adopt a polytropic equation of state

$$P = K \Sigma_o^{1+1/n} \quad (61)$$

and a disk model with a surface density profile which cuts off to avoid the companion

$$\Sigma = \Sigma_\infty (\tanh(\Delta - \Delta_o)/H_r)^n. \quad (62)$$

The characteristic radial scale length can be parameterized in terms of $H_r = (\frac{n}{\beta})^{1/2} c_\infty / \omega$ where c_∞ is the asymptotic sound speed and β is a constant. From Eq. (33) we obtain, for the case when the companion orbits inside the disk,

$$\frac{\Omega}{\omega} - 1 = \frac{H_r}{2r_o} \left(-3x + \frac{\beta}{\cosh^2(x - \delta)} \right) \quad (63)$$

with $x = \Delta/H_r$ and $\delta = \Delta_o/H_r$. Consequently the epicycle frequency becomes

$$\kappa^2 = \frac{2\Omega}{r} \frac{d(\Omega r^2)}{dr} = \omega^2 \left(1 - \frac{2\beta \tanh(x - \delta)}{\cosh^2(x - \delta)} \right) \quad (64)$$

such that the Rayleigh's stability criterion (which requires $\kappa^2 > 0$) is satisfied if the dimensionless constant $\beta < 3^{3/2}/4$ or equivalently,

$$H_r > 2n^{1/2}/3^{3/4} H_\infty \simeq H_\infty \quad (65)$$

where $H_\infty = c_\infty/\omega$ is the disk thickness; i.e., the characteristic density scale length in the radial direction cannot be less than the vertical disk scale height.

Figure 1. Excitation of waves in a gaseous disk. The variables X_m and Y_m are the values of $\xi_{r,m}$ (the perturbed displacement) and K_m (the perturbed surface density), respectively, in the homogeneous solutions of Eqs. (45) and (46) in the limit $W_m = 0$. These examples correspond to a perturber at approximately one vertical disk scale height away from the disk edge, where the surface density tails off on a similar scale length, ($H \equiv H_r$, $\lambda = mH/r_0$).

A similar conclusion may be obtained when the companion orbits exterior to the disk.

With the magnitude of n , β , and Δ_o/H_r specified, Eqs. (45) and (46) can be solved numerically and the results obtained therefrom indicate that the WKB approximation becomes reasonably good $2H_r$ into the disk (Fig. 1). The total angular momentum exchange rate can be deduced by summing F_H over m . Because, in the case of extreme mass ratio, most of the contribution comes from large m , m can be treated as a continuous variable so that

$$\dot{H}_T = \int_0^\infty F_H dm. \quad (66)$$

For illustration purposes, we adopt a particular case with $n = 1.5$ and $\beta = 1$ which corresponds to the disk thickness comparable to the gap width. The

discussion in Sec. IV show that $\beta \simeq 1$ during the epoch that the conditions for gap formation are marginally satisfied. Using the asymptotic value of X_m calculated as a function of m from Eqs. (45) and (46), and F_H from Eq. (60), Eq. (66) yields a maximum value for the total outward angular momentum flow given by

$$\dot{H}_T = 0.23q^2 \Sigma_\infty r_o^4 \omega^2 \left(\frac{r_o}{H_\infty} \right)^3. \quad (67)$$

This value applies independently of whether the disk orbits externally or internally to the disk and is very similar to the \dot{H}_T derived from the impulsive approximation given by Eq. (5), provided H_∞ and Δ_o are identified with each other.

The cold disk limit corresponds to the case where $\Delta_o/H_\infty \gg 1$. In this case, the torque decreases with Δ_o much as predicted by the impulse approximation in Eq. (5). The maximum value of the torque is attained when Δ_o is comparable to H_∞ . The latter in turn must satisfy $H_\infty \geq r_o q^{1/3}$ for the disk to lie exterior to the companions Roche lobe. Taking the lower limit, the viscous condition for gap formation derived from Eqs. (67) and (22) is

$$q > \frac{40\nu}{\omega r_o^2}. \quad (68)$$

This is very similar to the condition given by Eq. (23) derived from consideration of particle orbits. Note that when a gap is marginally formed, the maximum torque occurs when the edge of the disk around the protostar approaches the Roche lobe of the companion. In this case, from the reasoning that led to Eq. (65), a necessary condition to form a gap and avoid the violation of the Rayleigh stability criterion becomes $r_R \geq H_\infty$ or equivalently

$$q > (c_\infty/\omega r)^3. \quad (69)$$

Although the total rate of angular momentum transfer is independent of viscosity whether or not nonlinear effects operate, the extent of wave propagation is determined by the dissipation processes. From the dissipation-free results, we can estimate the condition for the tidally induced waves to reach a distance r_o before they are damped by some effective dissipation processes. We introduce an effective viscosity ν to parameterize the magnitude of viscosity. A wave with wavenumber $k \sim m\omega/c_\infty$ would decay by a factor $e^{-\nu k^2 t}$ after it has traveled for a time interval t . At a distance $\sim r_o$ from the companion, from the dispersion relation (to be given by Eq. 78 below) we may approximate the group velocity of the waves to be the sound speed. The appropriate value of $t \sim r_o/c_\infty$ so that the decay factor is $\sim e^{-\nu m^2 \omega^2 r_o/c_\infty^3}$. To reach r_o without large decay implies

$$\nu < \frac{c_\infty^3}{m^2 \omega^2 r_o}. \quad (70)$$

For important values of $m \sim r_o/H_\infty$ the above condition becomes

$$v/H_\infty^2 \omega < (H_\infty/r_o)^3.$$

In terms of the standard α -prescription (Shakura and Sunyaev 1973) in which $\nu = \alpha_D H_\infty^2 \omega$, waves are dissipated near the protoplanet if

$$\alpha_D > (H_\infty/r_o)^3. \quad (71)$$

Recent models of protostellar disks indicate that convection-driven turbulence may provide an effective viscosity with an $\alpha_D \sim 10^{-2}$ (Lin and Papaloizou 1985; Ruden et al. 1988; Chapter by Adams and Lin, and references therein) which suggests that tidally induced waves may be viscously dissipated in the vicinity where they are launched. In the following section, we show that even in the absence of any significant turbulent viscosity, tidally induced density waves cannot propagate over extended regions in the disk.

IV. PROPAGATION OF DENSITY WAVES EXCITED AT RESONANCES

When the companion's mass is very small compared with the central protostar, low order Lindblad resonances fall interior to the Roche radius of the protostar. If the disk is sufficiently extensive, so that it contains one or more of these resonances, density waves may be excited in their vicinity (Shu 1984). Density waves induced by such resonant tidal interactions have been observed by the voyager spacecraft in planetary rings (Cuzzi et al. 1984). The wave excited at these resonances carries both energy and angular momentum (Lynden-Bell and Kalnajs 1974). When the wave is dissipated, angular momentum is deposited in the fluid causing the disk material to evolve. If the waves can propagate deep into the interior region of the disk, the tidal influence of the satellite is distributed over an extended region whereas if these waves are dissipated in the close vicinity of the satellite's orbit, the tidal effect is localized. Thus, the propagation and dissipation of the waves determines the disk response to the companion's tidal field. In subsection IV.B, we examine how far the tidally induced waves can propagate in a protostellar disk.

A. Angular Momentum Flux at the Companion's Lindblad Resonances

Not all the resonances can be found in a disk. Consider the case where the companion is exterior to the disk. In the limit of a low mass companion and a geometrically thin disk, the disk's main motion is Keplerian rotation, $\Omega = (r_o/r)^{3/2} \omega$. In order for a low-order Lindblad resonance with $\omega/\Omega = (m-1)/m$ to fall inside the Roche lobe of the proto-Sun, we must have $q < 3\{1 - [(m-1)/m]^{2/3}\}^3$. For companions with $q > 0.3$, no low-order Lindblad resonances can be found inside the Roche radius of the proto-Sun.

Near the resonant radius r_s , the accumulated tidal effect can lead to an efficient angular momentum transfer. Several idealized cases have been analyzed in a variety of astrophysical contexts: gaseous disks with pressure only

(Goldreich and Tremaine 1978; Donner 1979), gaseous disks with viscosity only (Lin and Papaloizou 1979a), and particle disks with a low collision frequency (Franklin et al. 1980). In all cases excepting the last, an identical angular momentum flux is derived. Pressure and self gravity promote the propagation of the tidal disturbances whereas viscosity and nonlinear damping determine where the disturbance is damped and dissipated. To illustrate the derivation of the angular momentum flux, we present the analysis of the case of a disk with pressure but no viscosity which links with the more general calculations discussed above.

As the resonance is interior to the disk, Σ_0 and c are taken to be constant. In addition, we suppose the response varies on a small scale so that $d/dr \gg 1/r$, and $r^2(\Omega - \omega)^2 \gg c^2$. Then Eqs. (45) and (46) yield the following second-order ordinary differential equation.

$$-c^2 \frac{d^2 \xi_{rm}}{dr^2} = \xi_{rm} [m^2 (\Omega - \omega)^2 - \Omega^2] - \frac{dW_m}{dr} - \frac{2\Omega W_m}{r(\Omega - \omega)}. \quad (72)$$

To simplify further, we make a local expansion such that

$$[m^2 (\Omega - \omega)^2 - \Omega^2] = -Dx \quad (73)$$

where $x = r - r_s$ and

$$D = [3m^2 (\Omega - \omega) \omega / r]_{r=r_s} \quad (74)$$

may be approximated as constant.

In order to apply Eq. (60), we need to evaluate X_m . In this case, this is the solution of Eq. (72) (with $W_m = 0$) which is wavelike interior to an inner Lindblad resonance if appropriate, or exterior to an outer Lindblad resonance if that is appropriate, but which then decays exponentially on the other side of the appropriate resonance. This can be written in the form

$$X_m = \int_{-\infty}^{\infty} \exp i \left(kx + \frac{c^2 k^3}{3D} \right) \frac{dk}{|D|}. \quad (75)$$

This integral can be expanded asymptotically using the well known method of steepest descents and then by comparison with Eq. (51), one finds

$$|C| = \left(\frac{\pi \Sigma_0 r_s}{|D|} \right)^{1/2}. \quad (76)$$

If all quantities apart from X_m in the integral in Eq. (60) are taken to be constant and equal to their values at $r = r_s$, and the range extended to become $[-\infty, \infty]$, the integral may be evaluated analytically with the result

$$F_H = \left[\frac{\pi^2 \Sigma_0}{3\Omega \omega} \left(r \frac{dW_m}{dr} + 2 \frac{\Omega W_m}{(\Omega - \omega)} \right)^2 \right]_{r=r_s}. \quad (77)$$

This result is completely independent of viscosity provided the tidal disturbance induced by the resonant torque is completely dissipated. It gives the angular momentum flux as a result of resonance.

However, it is not strictly necessary for a resonance to be interior to the disk for it to produce an effect. Equation (75) shows that the scale of variation in the neighborhood of resonance is $\delta w \sim r_s [c/(r\Omega)]^{2/3}$. Therefore we would expect a strong virtual effect from a resonance as long as it was within a distance δw of the disk edge. In this way we would expect to account for the two-arm spiral features associated with the 2:1 inner Lindblad resonance often seen in the numerical calculations of disks in cataclysmic binaries, even though the resonance is outside the disk (see, e.g., Lin and Papaloizou 1979*a*, Whitehurst 1988*a, b*; Hirose and Osaki 1989). To calculate F_H in such cases one must solve for X_m numerically and then evaluate F_H using Eq. (60).

B. Waves Propagation and Dissipation in the Disk

We now examine the dissipation of the density waves excited at the Lindblad resonances. As these waves propagate away from the resonances, the tidal effect of the companion vanishes rapidly and the WKBJ approximation adequately describes the nature of wave propagation. In the absence of viscosity, these waves obey the standard dispersion equation (Lin and Shu 1964, 1968) such that

$$c^2 k^2 - 2\pi G \Sigma_o |k| + \kappa^2 - (m\Omega - m\omega)^2 = 0, \quad (78)$$

where k is the radial wavenumber. The effect of self gravity, which is contained in the second term of Eq. (78), allows the propagation of long waves between the Lindblad resonances (Lin and Lau 1979). In a non-self gravitating inviscid disk, for any wave to exist, we require that $m^2(\Omega - \omega)^2$ be bigger than $\kappa^2 (= \Omega^2)$; i.e., waves exist only interior to the inner Lindblad resonance for which $m(\Omega - \omega) = \Omega$ and exterior to the outer Lindblad resonance for which $m(\Omega - \omega) = -\Omega$.

The dispersion relation in (78) indicates that the wavelength decreases as a wave propagates inward from the inner Lindblad resonance. Linear solutions of the momentum Eqs. (45) and (46) indicate that the contrast between the waves' peaks and troughs also increases as waves propagate away from the locations where they are launched (Fig. 1 in Sec. III). From Eq. (48) one can show that Σ' increases as the fourth root of the distance from the resonance. This increase in Σ' with distance from the resonance is due to the conservation of wave action or the constancy of F_H with distance expressing conservation of angular momentum (Toomre 1969; Shu 1970). In the presence of viscous dissipation, the rate of dissipation may also increase as k increases. In the strongly viscous limit, propagation over a distance $\sim r_s/m$ from the Lindblad resonances occurs with a group velocity significantly less than the sound speed (in contrast to the situation considered in Sec. III.C). With a constant effective kinematic viscosity ν , the amplitude of the waves is significantly damped over

a distance

$$\Delta x \sim \left(\frac{c^3 r_s^{1/2}}{3vm^{1/2}\Omega^2} \right)^{2/3} \quad (79)$$

from the resonance (Goldreich and Tremaine 1978, 1980). In the weakly viscous limit (see Sec. III.C) when the propagation region extends to $\sim r_s$, the group velocity may be approximated as the sound speed and

$$\Delta x \sim \sqrt{\frac{c^3 r_s}{3vm^2\Omega\omega}}. \quad (80)$$

In the absence of viscosity, the waves will eventually become nonlinear when $|\Sigma'| \sim |\Sigma_o|$ (Cuzzi et al. 1981). Shock dissipation would lead to effective wave dissipation and angular momentum deposition (Lubow and Shu 1975; Shu 1976; Donner 1979; Shu et al. 1985*b*; Borderies et al. 1984*b*, 1986; Spruit 1987). Because density waves carry negative angular momentum in the disk interior to the companion, their dissipation would induce an inward migration of the disk gas. Similarly, nonlinear wave dissipation in the disk exterior to the companion would induce an outward migration.

If nonlinear waves propagate over a large region of the disk, the tidal effect of the companion could regulate the evolution of the entire disk (Larson 1989). To discuss this possibility, a self-similar, steady-state, but nonaxisymmetric disk model has been constructed (Spruit 1987, 1989*b*). This involves a nonlinear wave with zero pattern speed giving dissipation and angular momentum flow at shock discontinuities. The companion's tidal torque is not explicitly considered but must be thought of as ultimately responsible for the angular momentum which flows out of the system. For steady inviscid flow with no perturbing potential due to a companion, Eqs. (28) and (29) reduce to

$$v_r \frac{\partial v_r}{\partial r} + \frac{v_\phi}{r} \frac{\partial v_r}{\partial \phi} - \frac{v_\phi^2}{r} = -\frac{1}{\Sigma} \frac{\partial P}{\partial r} - \frac{GM}{r^2} \quad (81)$$

and

$$v_r \frac{\partial v_\phi}{\partial r} + \frac{v_\phi}{r} \frac{\partial v_\phi}{\partial \phi} + \frac{v_r v_\phi}{r} = -\frac{1}{r\Sigma} \frac{\partial P}{\partial \phi}. \quad (82)$$

The energy Eq. (27) reduces to

$$\Sigma T \left(v_r \frac{\partial S}{\partial r} + \frac{v_\phi}{r} \frac{\partial S}{\partial \phi} \right) + 2F_z = 0 \quad (83)$$

where S is the entropy at the midplane and F_z is the radiative flux in the vertical direction. Using a thin disk approximation, $F_z = 8\sigma T^4/(3\Sigma\kappa)$ and ideal equation of state and opacity $\kappa \propto \Sigma^{-1}$, Eqs. (81) to (83) have solutions of the form $v_r = r^{-1/2}f_r(\varphi)$, $v_\phi = r^{-1/2}f_\phi(\varphi)$, $P = r^{-5/2}f_p(\varphi)$, and $\Sigma = r^{-3/2}f_\rho(\varphi)$ where the similarity variable is $\varphi = \phi + B \ln r$ and

B is a constant which defines a logarithmic spiral where the streamlines converge and there is shock dissipation. Energy dissipation occurs across the shock front and the change in the flow variables across the shock front can be computed with the standard jump conditions (Shu et al. 1973; Larson 1990*b*). Two-dimensional numerical simulations for disk models in which the characteristic sound speed is a significant fraction of the Keplerian speed, lead to results which seem compatible with these semi-analytic calculations (Sawada et al. 1987; Spruit et al. 1987; Różyczka and Spruit 1989; Matsuda et al. 1989; Spruit 1989*b*).

The self similar solutions indicate the possibility that the companion's tidal disturbance may propagate and be dissipated over extended regions of the disk. However, the stability of the self-similar solutions remains uncertain. To distribute nonlinear dissipation and loss of wave action over the entire disk, a special temperature and density profile is needed which may not be generally realized. It is possible that when dissipation occurs, it would be localized in the region where the waves first become nonlinear (see Sec. V below).

C. Wave Refraction

The nonlinear development of density waves requires little or no dissipative damping of wave action as the waves undergo linear propagation in the disk. For waves propagating interior to the inner Lindblad resonance, $|k|$ increases rapidly as r decreases because Ω increases rapidly, and we have approximately

$$k^2 = (m^2 - 1)\Omega^2/c^2. \quad (84)$$

For sufficiently large values of m , the characteristic radial wavelength, $2\pi/|k|$, is comparable to or smaller than the disk's density scale height in the vertical direction, $H = 2^{1/2}c/\Omega$. In this case, wave propagation in the vertical direction can no longer be ignored. This effect is particularly important in a thermally stratified protostellar disk in which the propagation speed of the waves is a function of z because refraction of waves may turn the direction of propagation towards the vertical and cause an effective loss of wave action.

In order to examine the propagation of waves in a thermally stratified disk, a three-dimensional analysis is needed. This problem can be analyzed numerically with a linear numerical scheme (Lin et al. 1990*a*). In such a scheme, the equilibrium model may be arbitrarily chosen for computational convenience such that the flow velocity is $v = (0, \Omega r, 0)$ with $\Omega = (GM/r^3)^{1/2}$. In the equilibrium state, the z -component of the equation of motion reduces to

$$\frac{1}{\rho} \frac{\partial p}{\partial z} = -\Omega^2 z. \quad (85)$$

We are interested in studying wave propagation in a vertically stratified geometrically thin disk where there is the possibility of propagation through an

extended atmosphere. Such a structure may be obtained from a barotropic equation of state in which

$$p = c_{\infty}^2 \rho \left[1 + \left(\frac{An}{1+n} \right) \left(\frac{\rho}{\rho_c} \right)^{1/n} \right] \quad (86)$$

where the quantities A , n , and c_{∞} are constants. When the density at the midplane ρ_c is taken to be constant, the Keplerian rotation law is satisfied at the midplane. Equation (86) also implies

$$c^2 = \frac{dp}{d\rho} = c_{\infty}^2 \left[1 + A \left(\frac{\rho}{\rho_c} \right)^{1/n} \right]. \quad (87)$$

so that from Eq. (85) we have

$$A_n \left[1 - \left(\frac{\rho}{\rho_c} \right)^{1/n} \right] - \log \left(\frac{\rho}{\rho_c} \right) = \frac{z^2}{H^2} \quad (88)$$

where $H^2 \equiv 2c^2/\Omega^2$. Near the midplane, the gas is nearly polytropic with $c = (1+A)^{1/2}c_{\infty}$. Above H , the disk is isothermal with $c = c_{\infty}$. Provided the perturbation is modest in strength, wave propagation can be examined by using linearized fluid Eqs. (24) and (25) which, in a frame rotating with angular velocity Ω_p , are such that

$$\frac{\partial v'_r}{\partial t} + (\Omega - \Omega_p) \frac{\partial v'_r}{\partial \phi} - 2\Omega v'_\phi = -\frac{\partial W}{\partial r} + T_r \quad (89)$$

$$\frac{\partial v'_\phi}{\partial t} + (\Omega - \Omega_p) \frac{\partial v'_\phi}{\partial \phi} + \frac{\Omega v'_r}{2} = -\frac{1}{r} \frac{\partial W}{\partial \phi} + T_\phi \quad (90)$$

$$\frac{\partial v'_z}{\partial t} + (\Omega - \Omega_p) \frac{\partial v'_z}{\partial \phi} = -\frac{\partial W}{\partial z} + T_z \quad (91)$$

where

$$W \equiv \frac{p'}{\rho} = \frac{\rho'}{\rho} c^2,$$

T_r , T_ϕ and T_z are the external tidal forces per unit mass in the radial, azimuthal, and z directions, respectively. The linearized continuity equation gives

$$\frac{\partial W}{\partial t} + (\Omega - \Omega_p) \frac{\partial W}{\partial \phi} = -\frac{c^2}{\rho} \left[\frac{1}{r} \frac{\partial}{\partial r} (r \rho v_r) + \frac{\rho}{r} \frac{\partial v_\phi}{\partial \phi} + \frac{\partial}{\partial z} (\rho v_z) \right]. \quad (92)$$

Before looking into detailed numerical solutions of the linearized equations of motion (89) to (92), we demonstrate that in the absence of any external

force and dissipation, the angular momentum of the propagating wave is conserved. Consider wave-like disturbances which contain ϕ and t in the form

$$\phi - (\omega - \Omega_p)t \quad (93)$$

so that ω is the pattern speed measured in an inertial frame. It is convenient to introduce the Lagrangian displacement $\xi = (\xi_r, \xi_\phi, \xi_z)$ in terms of which the equations of motion (89–92) may be written as

$$(\Omega - \omega)^2 \frac{\partial^2 \xi_r}{\partial \phi^2} - 2\Omega(\Omega - \omega) \frac{\partial \xi_\phi}{\partial \phi} + 2r\Omega \frac{d\Omega}{dr} \xi_r = -\frac{\partial W}{\partial r} \quad (94)$$

$$(\Omega - \omega)^2 \frac{\partial^2 \xi_\phi}{\partial \phi^2} + 2\Omega(\Omega - \omega) \frac{\partial \xi_r}{\partial \phi} = -\frac{1}{r} \frac{\partial W}{\partial \phi} \quad (95)$$

and

$$(\Omega - \omega)^2 \frac{\partial^2 \xi_z}{\partial \phi^2} = -\frac{\partial W}{\partial z}. \quad (96)$$

For any ring-like internal region of volume v , when no external force acts, the rate of gain of angular momentum is given by

$$J = - \int_v \rho' \frac{\partial W}{\partial \phi} dv = 0 \quad (97)$$

and this of course must be identically zero.

From the continuity equation, we have

$$\rho' = -\nabla \cdot (\rho \xi) \quad (98)$$

so that

$$J = \int_v \nabla \cdot \left(\rho \xi \frac{\partial W}{\partial \phi} \right) dv + \int_v \left(\rho \frac{\partial \xi}{\partial \phi} \cdot \nabla W \right) dv = 0. \quad (99)$$

It is readily seen after using Eqs. (94–96) that the latter term vanishes on integration with respect to ϕ . Using the fact that

$$v_r = (\Omega - \omega) \frac{\partial \xi_r}{\partial \phi} \quad (100)$$

it follows from Eq. (90)

$$W = -r(\Omega - \omega) \left(v_\phi + \frac{1}{2} \Omega \xi_r \right). \quad (101)$$

Equation (99) may be recast, after integration with respect to ϕ , in the form of conservation law that

$$J = \int_v \left(\frac{1}{r} \frac{\partial}{\partial r} r F_r + \frac{\partial}{\partial z} F_z \right) r dr dz = 0 \quad (102)$$

where

$$F_r = \int_0^{2\pi} r \rho v_r v_\phi d\phi \quad (103)$$

and

$$F_z = \int_0^{2\pi} \rho v_z r (v_\phi + \frac{1}{2} \Omega \xi_r) d\phi \quad (104)$$

are the components of the angular momentum flux in the r and z direction.

Equation (102) indicates that if a wave component is transmitted to regions above the disk without reflection, then the component of the angular momentum flux in the radial direction should decrease as a disturbance propagates radially. One key issue is how far waves can propagate in the vertical direction. If we consider a disturbance moving vertically under the assumption that $\rho = \rho(z)$ and $W = W(z) \exp(im\phi)$ in Eqs. (94–96) (these assumptions can only be consistent if Ω is a constant so that which follows is only valid locally in r), we obtain the following equation for W

$$\frac{\partial}{\partial z} \left(\rho \frac{\partial W}{\partial z} \right) + \frac{m^2 W \rho \bar{\sigma}^2}{r^2 (\Omega^2 - \bar{\sigma}^2)} = - \left(\frac{\bar{\sigma}^2}{c^2} \rho W \right) \quad (105)$$

where $\bar{\sigma} = m(\Omega - \omega)$. If we set $W \equiv Q/\rho^{1/2}$, we find

$$\frac{\partial^2 Q}{\partial z^2} + Q \left[-\frac{\partial^2 \rho / \partial z^2}{2\rho} + \left(\frac{\partial \rho / \partial z}{2\rho} \right)^2 + \frac{\bar{\sigma}^2}{c^2} + \frac{m^2 \bar{\sigma}^2}{r^2 (\Omega^2 - \bar{\sigma}^2)} \right] = 0. \quad (106)$$

In the upper regions of the isothermal atmosphere of the disk, this takes the form of

$$\frac{\partial^2 Q}{\partial z^2} + Q \left[-\frac{\Omega^2}{2c_\infty^2} - \frac{\Omega^4 z^2}{4c_\infty^4} + \frac{\bar{\sigma}^2}{c_\infty^2} + \frac{m^2 \bar{\sigma}^2}{r^2 (\Omega^2 - \bar{\sigma}^2)} \right] = 0. \quad (107)$$

Equation (107) suggests that waves propagate vertically upwards until they are reflected at a level given, when $\Omega > \omega$, by

$$z_c^2 = \frac{4c_\infty^2}{\Omega^2} \left(m^2 - \frac{1}{2} \right) - \frac{4c_\infty^4 m^4}{\Omega^4 r^2 (m^2 - 1)}. \quad (108)$$

From this we see that for $m \sim r\Omega/c_\infty \sim r/H$, $z_c \sim r$. Thus for large m , we expect the wave energy to be readily lost through vertical propagation. At a sufficient distance above the midplane where the density is low, the wave amplitude becomes nonlinear and shock dissipation can lead to the deposition of energy and angular momentum into the disk (Murray and Lin 1991). However, for smaller m there may be a reflection before a sufficiently low density for shock formation to be attained. What happens in this case will be more sensitive to the details of the vertical structure. We present

some numerical results to illustrate the refraction of waves as they propagate through a thermally stratified disk.

In these numerical results, we set

$$T_r(r) = -\frac{m}{r_t} \left(\frac{r}{r_t} \right)^{(m-1)} \exp\{-i[(m-1)\Omega(r_t) - m\Omega_p]t + im\phi\}. \quad (109)$$

$$T_\phi = iT_r \quad \text{and} \quad T_z = 0. \quad (110)$$

In Eq. (109), the forcing frequency $m\omega$ (as seen in the inertial frame), is replaced by $(m-1)\Omega(r_t)$ and therefore $r = r_t$ corresponds to the inner Lindblad resonance of the companion (see Sec. IV.A). Both T_r and T_ϕ are independent of z and no forcing is imposed in the vertical direction so that the front of the excited wave should be initially perpendicular to the midplane and the propagation should therefore be in the radial direction near the location where the waves are launched. A useful quantity for analyzing the numerical results is

$$T(r) \equiv \int_{r_i}^r \pi r^2 dr \int_0^\infty \frac{\rho}{c^2} \text{Re}(W^* T_\phi) dz \quad (111)$$

which is the total rate of increase of angular momentum, due to external tidal forces, between r and r_i in that region of the disk above the midplane. Note that this quantity is negative for the calculations presented here. Because the companion orbits slower than the disk, the disk material loses angular momentum.

At a radius r , the angular momentum flowing in the radial direction is given by

$$J_r \equiv \text{Re} \int_0^\infty \pi r^2 \rho v_r v_\phi^* dz \quad (112)$$

and the angular momentum flowing normal to the surface given by $z = z(r)$, between r and r_i is given by

$$J_z(r) \equiv \text{Re} \int_{r_i}^r \pi r^2 \rho \left[v_z U^* - v_r v_\phi^* \left(\frac{dz(r)}{dr} \right) \right] dr \quad (113)$$

with

$$U \equiv v_\phi - \frac{i\Omega v_r}{2m(\Omega - \omega)} \quad (114)$$

where r_i is the radius of the inner boundary. From these two quantities, we can measure the efficiency of refraction.

For the numerical model presented here, dimensionless units for which $GM = 1$, $\Omega_p = 1$, $\rho_c = 1$, $c_\infty = 10^{-1.5}$, $A = 3$, and $n = 1.5$ are used. With these structural parameters, the sound speed near the midplane is twice that at the disk surface. Such a vertical structure corresponds to an optical depth of the order a few hundred which is typical of the expected optical depth for the protostellar disks. The inner and outer boundaries are set at

$r = r_i = 0.8$ and $r = r_o = 1.6$, respectively with radiative conditions for the inner boundary in the radial direction and surface boundary in the vertical direction. A reflection condition is used at the outer boundary in the radial direction. Reflection symmetry in the midplane is used so that W is an even function of z . For the perturbed quantities, $m = 5$ and $r_t = 1.55$, so that the inner Lindblad resonance is just inside the outer boundary of the main flow domain. To construct transient-free solutions, the external torque is switched on slowly and the asymptotic steady-state solution is presented below.

For the steady-state solutions, we plot the radial and vertical distribution of the real part of W , v_r , v_ϕ , and v_z (Fig. 2). In the steady-state solutions, all variables vary sinusoidally in azimuth so that the form of the radial and vertical distribution plots is independent of the azimuthal phase. The excited waves essentially propagate in the radial direction near the radius r_t where they are launched. As the waves propagate away from r_t , the retardation of the wave front at the larger values of z becomes more apparent. The sound speed decreases with z , and the differential speed of propagation induces a curvature in the wave front which leads to an upward propagation towards the disk surface. The refraction of the wave is also well demonstrated by the $v_z(r, z)$ plot. Near the midplane, v_z is relatively small and the wave propagates approximately radially. Near the disk surface, however, the amplitude of v_z increases considerably.

The characteristic radial wavelength near the inner Lindblad resonance, $r_t = 1.55$, is comparable to the disk radius and at $r \sim 0.8$ to 0.9 , it is reduced to one tenth the radius near the midplane and about half that near the disk surface. The midplane result is consistent with the expected wavelength from the dispersion relation. The fact that the wavelength is longer near the midplane compared to the surface, implies relatively fewer wave crests near the midplane.

We also plot the azimuthal variation of W at the midplane and near the disk surface as functions of r and ϕ (Fig. 3). The amplitude of W is not plotted to the same scale in these plots. The azimuthal extent in Fig. 3 is $2\pi/5$, W being periodic in ϕ with this period. The wavelength in the radial direction is smaller near the disk surface than at the midplane due to the lower sound speed. Near the midplane, the amplitude of the wave decreases with distance from the r_t where the wave is launched.

In Fig. 4, we also plot the angular momentum flow integral J_r with a dashed line, J_z with a dotted line, and the torque integral T with a solid line. Working outward from the inner boundary of the disk, J_z increases linearly with radius which is an indication that a nearly constant angular momentum flow rate per unit radius is being diverted vertically. Consequently, the angular momentum flux in the radial direction decreases linearly with distance from r_t . At the inner boundary there is a small amount of residual angular momentum flux which is transmitted through the inner edge in this particular case.

The torque integral $T(r)$ provides an indicator to the distribution of the angular momentum deposition rate in the disk. Our results indicate that most

Figure 2. Wave propagation pattern in the steady-state solution for a disk model in which $c_\infty = 10^{-1.5}$, $A = 3$ and $n = 1.5$. The real parts of perturbed quantities are plotted here. A resonant disturbance is imposed at $r = 1.55$. The quantities W , v_r , v_z and v_ϕ correspond to the perturbed surface density, radial, vertical, and azimuthal velocities.

Figure 3. Radial and azimuthal distribution of the perturbed surface density in the midplane (lower panel) and at the disk surface (upper panel). The azimuthal extent is $2\pi/5$ and the radial extent is identical to that in Fig. 2.

of the angular momentum is deposited into the disk near the inner Lindblad resonance where the characteristic wavelength is a significant fraction of the radius. From conservation of angular momentum, we expect

$$T(r_o) = J_z(r_o) - J_r(r_i) + J_r(r_o) \quad (115)$$

which is satisfied within 10% accuracy.

It is of interest to compare the total angular momentum transfer rate $|T(r_o)|$ with that expected from a two-dimensional cold disk. For a Keplerian disk, Eq. (77) gives for this case

$$|T(r_o)| = \frac{\pi^2 r^2 \Sigma m}{3\Omega^2(m-1)} \left(\frac{dW_m}{dr} + \frac{2mW_m}{r} \right)^2 \quad (116)$$

where in the above, only the surface density above the mid-plane should be used and the right-hand side is to be evaluated at the inner Lindblad resonance, with $|T_r| = dW_m/dr = mW_m/r$. A straightforward application of this result gives a value for $|T(r_o)|$ a factor of ~ 8 larger than that actually found in the

Figure 4. Evolution of total torque integral (upper panel) and the steady-state radial distribution of angular momentum flux $J_R(r)$ (dashed line) and $J_z(r)$ (dotted line) and the torque integral $T(r)$ (solid line) curves (lower panel). Note that the radial flux of angular momentum vanishes as waves propagate away from the location ($r = 1.55$) where a resonant disturbance is imposed.

calculation. However, we believe that this discrepancy can be explained by the fact that the resonance is very close to the outer boundary and the fact that the sound speed is finite. The latter effect causes the active region around resonance to have a width of order $H^{2/3}r^{1/3} \sim 0.1r$. Thus, the resonance must be regarded as being at the outer boundary. A simple calculation of the type done in Sec. III for the case when the resonance is precisely on the rigid outer boundary, shows that $|T(r_o)|$ should be reduced by a factor of ~ 3 . We further note that because of the finite resonance width, there is some uncertainty as to where the formula should be applied. If it is applied 10% farther in, the torque is reduced by a factor of 4. The formula is thus very sensitive to the radius of application. When several values of r_o and r_t are used, numerical

results show that $T(r_o)$ indeed increases with the distance between r_i and r_o as expected.

Numerical models with a variety of sound speeds, vertical thermal stratifications, and external torques have been computed (Lin et al. 1990*b*). These results indicate that the gradient of the sound speed in the vertical direction can induce tilting of the wave front as an excited wave propagates away from the region where it is launched. This leads to refraction which induces a propagation component in the direction normal to the plane of the disk. The wave carries energy and angular momentum as it propagates and so a flux of angular momentum is transmitted in both the radial and vertical directions.

In most astrophysical contexts such as interacting binary stars, the disk is optically thick. Then the temperature near the midplane is expected to be several times larger than that near the disk surface. Furthermore, the sound speed at the midplane is a small fraction of the local Keplerian velocity. Under these conditions, thermal stratification promotes efficient refraction as a wave propagates over a radial distance comparable to the vertical scale height from the region where it is tidally induced. Thus, in a vertically thin disk, tidally induced waves are localized in the region where they are launched and angular momentum transport by wave propagation is unlikely to be effective over extended regions of the disk.

The effect of refraction may be suppressed if the disk has an isothermal vertical structure or if the sound speed at the midplane is a significant fraction of the local Keplerian velocity. These conditions may be attained in protostellar disks when they are exposed to intense surface heating (Watanabe and Nagazawa 1988) or when they become optically thin or when there is infall onto the disk surface (Ruden 1986). In these cases, tidally induced waves may propagate over an extended region in the disk and angular momentum transport by wave propagation may be efficient. If the companion has a comparable mass to the proto-Sun so that Lindblad resonances are excluded from the Roche lobe of the proto-Sun, a strong wave-like response is possible only if the characteristic wavelength of the generated waves is comparable to the disk radius. But the dispersion relation indicates that the wavelength of a propagating wave is $\sim c/m\Omega$, and there is generally a wavelength mismatch. A large response is possible only if the sound speed is sufficiently large such that the characteristic scale height in the vertical direction is comparable to the disk radius (Sawada et al. 1986, 1987).

V. GAP FORMATION AND DISK STRUCTURE

The results in Sec. III indicate that the disk structure is regulated by the efficiency of density wave propagation and dissipation. Energy and angular momentum transferred from the companion is deposited into the disk through either viscous or nonlinear dissipation. Although the magnitude of the sound speed and hence the effective viscosity in protostellar disks remains uncertain, the results in Sec. IV indicate that even in the inviscid limit, refractory

effects inhibit significant radial wave propagation and induce effective dissipation through vertical losses. In this section, we present self-consistent two-dimensional numerical calculations to illustrate the nonlinear disk response to the companion's tide.

A. Numerical Methods

Several numerical schemes have been introduced to study companion-disk interactions. These include the sticky particle scheme (Lin and Pringle 1976; Lin and Papaloizou 1979*a, b*; Cameron 1979; Whitehurst 1988*a, b*, 1989; Hirose and Osaki 1989), smooth particle hydrodynamics (Miyama et al. 1984; Artymowicz et al. 1991), and finite difference methods (Prendergast and Burbidge 1968; Flannery 1975; Miki 1982; Matsuda et al. 1987; Różyczka and Spruit 1989). Although these schemes provide important information on global features of the disk such as total angular momentum flux and gap formation, they generally lack sufficient resolution for the investigation of resonant tidal interactions, linear wave propagation, and nonlinear wave dissipation especially when the companion has a low mass. To determine the fine structure of the disk, two versatile methods have been employed: a two-dimensional Lagrangian scheme (Lin and Papaloizou 1986*a*) and a two-dimensional second-order Lax-Wendroff scheme. The two-dimensional non-axisymmetric Lagrangian scheme was developed in order to calculate the disk structure in a steady state. In this scheme, the disk has one fixed rigid boundary at a disk radius which is far enough from the companion so that tidal effects are unimportant. At this location, the flow is assumed to be Keplerian. This condition introduces a viscous stress acting at the boundary such that it induces transfer angular momentum to the disk if the disk lies outside the boundary and remove angular momentum from the disk if it lies inside. The other boundary is assumed to be completely free so that it may move to a location close enough to the companion for its tidal effect to become important. An external companion removes angular momentum from the disk while an internal companion does the opposite. For a companion with a circular orbit, a steady-state solution may be attained in which the disk appears stationary in a frame corotating with the companion. In the inertial frame, the steady-state solutions are functions of ϕ and t through the combination of $\phi - \omega t$. To describe solutions of Eqs. (28) to (32), we introduce variable $\xi = \theta(\phi - \omega t)$ where $\theta = 1$ (-1) for a disk located interior (exterior) to the companion's orbit. The equations of motion then become

$$(\Omega - \omega)\theta \frac{\partial v_r}{\partial \xi} + v_r \frac{\partial v_r}{\partial r} - \frac{v_\phi^2}{r} = -\frac{1}{\Sigma} \frac{\partial(P + q_v)}{\partial r} - \frac{\partial \psi}{\partial r} \quad (117)$$

$$(\Omega - \omega)\theta \frac{\partial v_\phi}{\partial \xi} + v_r \frac{\partial v_\phi}{\partial r} + \frac{v_\phi v_r}{r} = -\frac{\theta}{\Sigma r} \frac{\partial(P + q_v)}{\partial \xi} - \frac{\theta}{r} \frac{\partial \psi}{\partial \xi} + F_v. \quad (118)$$

Only steady-state solutions of Eqs. (117) and (118) have physical meaning and they correspond to solutions that are periodic in ξ with period 2π .

To study the formation of gaps, an accurate treatment of the free boundary is essential. Because the location of the edge cannot be specified *a priori*, but must be determined in the course of solution, it is convenient to use a Lagrangian rather than a Eulerian description of the flow. Another advantage of the Lagrangian scheme is that by adjusting the initial mesh spacing, the spatial resolution may be improved greatly. In this scheme, the Lagrangian coordinate r is a function of ξ , which we treat as a time coordinate, and r_f the value of r at $\xi = 0$. The radial velocity is then given by

$$\left(\frac{\partial r}{\partial \xi}\right)_{r_f} = \frac{\theta v_r}{\Omega - \omega} \quad (119)$$

and the advective derivative becomes

$$\left(\frac{\partial}{\partial \xi}\right)_r + \frac{\theta v_r}{\Omega - \omega} \left(\frac{\partial}{\partial r}\right)_\xi \equiv \left(\frac{\partial}{\partial \xi}\right)_{r_f}. \quad (120)$$

The continuity Eq. (32) can be written

$$\left[\frac{\partial}{\partial \xi} \left(r \frac{\partial r}{\partial r_f} (\omega - \Omega) \Sigma\right)\right]_{r_f} = 0 \quad (121)$$

which implies the existence of a conserved Lagrangian mass element $\mu(r_f) = r(\omega - \Omega) \Sigma \partial r / \partial r_f$. After some algebra, Eqs. (117) and (118) become

$$\frac{\partial v_r}{\partial \xi} = \frac{\theta}{\Omega - \omega} \left[\frac{v_\phi^2}{r} - \left(\frac{\partial r_f}{\partial r}\right)^{-1} \left(\frac{1}{\Sigma} \frac{\partial (P + q_v)}{\partial r_f} + \frac{\partial \psi}{\partial r_f} \right) \right] \quad (122)$$

and

$$\frac{\partial}{\partial \xi} \left(\frac{v_\phi^2}{2} + \frac{v_r^2}{2} - r \omega v_\phi + \psi + H_\Sigma + \frac{q_v}{\Sigma} \right) = \theta r F_v - q_v \Sigma^{-2} \frac{\partial \Sigma}{\partial \xi} \quad (123)$$

respectively where

$$H_\Sigma(\Sigma) \equiv \int_0^\Sigma \frac{1}{\Sigma} \frac{dP}{d\Sigma} d\Sigma. \quad (124)$$

The four dependent variables r , Σ , v_r , and v_ϕ are obtained from the solutions of Eqs. (119) and (121–123). The numerical analysis is considered as posing an initial value problem with ξ playing the role of time, using standard finite difference techniques (Lin and Papaloizou 1986a). The solution is started from initial conditions chosen for convenience. It is then followed until it becomes periodic in ξ indicating that a physically meaningful solution has been obtained. For computational convenience, we adopt an equation of state

$$P(\Sigma) = c_o^2 \Sigma (\Sigma / \Sigma_o)^2 \quad (125)$$

where c_o and Σ_o are constants so that the sound speed $c = 3^{1/2} c_o \Sigma / \Sigma_o$. The constant Σ_o sets the surface density scale and may be taken, without loss of generality, to be unity. The maximum value of the surface density in the calculated profiles presented here is always close to Σ_o or equivalently unity. For shear viscosity we adopt $\nu_s = \nu_{so} \Sigma / (\Sigma + \Sigma_o)$, where ν_{so} is constant. The pseudoviscous pressure may be decomposed into two parts $q_v = q_1 + q_2$ where

$$q_1 = -\frac{\nu_{so} \Sigma^2}{(\Sigma + \Sigma_o)} \frac{\partial v_r}{\partial r} \quad (126)$$

and

$$q_2 = -a^2 (\Delta r)^2 \Sigma \left(\frac{\partial v_r}{\partial r} \right) \left(\left| \frac{\partial v_r}{\partial r} \right| - \frac{\partial v_r}{\partial r} \right). \quad (127)$$

The variable q_2 is introduced to handle strong shocks, Δr is the radial separation of two adjacent grid points and a^2 is a constant normally taken to be 2. These equations can be solved using a finite difference scheme with the time step restricted by the usual requirements for stability (Richtmeyer and Morton 1967). The initial surface density and width of each zone may be chosen to provide good resolution. These calculations are computed until the solution becomes periodic to within one part in 10^4 which, for typical models, occurs in a few hundred to a few thousand periods. The steady-state solution does not depend on the arbitrary choice of the initial surface-density distribution.

Although the periodic Lagrangian method is convenient to use, it is useful only in cases where periodic solutions exist. In order to verify that there is a tendency for the disk to evolve towards an equilibrium, we also computed the flow pattern with a two-step Lax-Wendroff scheme which is a second-order accuracy method that minimizes large numerical diffusion. This method is useful for computing-time-dependent behavior such as (1) evolution towards equilibrium disk structure; (2) disk response to a companion on an eccentric orbit; and (3) the evolution of a ring between two satellites.

B. Dynamical Equilibrium

The existence of periodic solution can be established with the fully time-dependent Lax-Wendroff method. For illustrative purposes, we adopt a model 1 in which $q = 10^{-2}$, $c_o = 0.04 \omega r_o$, and $\nu_{so} = \nu_{bo} = 10^{-5} \omega r_o^2$. This model is computed for more than 100 orbital periods when an asymptotic periodic solution is attained. The Σ distribution of model 1 (Fig. 5) is compared with that obtained from the periodic solution using the Lagrangian scheme in model 2 (Fig. 6). The model parameters have identical values in models 1 and 2. There are general agreement and many similarities between these two models: (1) strong density waves are excited near the 2:1 resonance (at $r \sim 0.6 r_o$); (2) the disk is tidally truncated just exterior to the 2:1 resonance; (3) density waves propagate well into small disk radii; and (4) the characteristic wavelengths in models 1 and 2 have similar radial dependence and magnitude. There are also some minor differences: (1) the amplitude of the waves in

Figure 5. Steady-state surface density distribution in model 1. The Lax-Wendroff scheme is used in this model. In this and subsequent figures, the position of the companion is located at $r = 1$ and $\xi = 0$ and the maximum value of the surface density plotted is close to unity in terms of the dimensionless units used in the text.

Figure 6. Steady-state surface density distribution in model 2. A periodic Lagrangian scheme is used in this and most of the subsequent models. The values of the physical model parameters used here are identical to those in model 1. The 2:1 (inner Lindblad) resonance is located at $r \approx 0.6$ where an $m = 2$ density wave is excited.

model 2 is less than in model 1. This difference is due to a slight difference in the equation of state; (2) the disk is slightly more extended in model 1 than in model 2 which may be attributed to the small numerical diffusion in the Lax-Wendroff scheme.

Figure 7. Steady-state surface density distribution in model 3. Wave propagation is enhanced by the large sound speed. There is wave reflection at the inner boundary. An $m = 4$ density wave is excited at the 4:3 resonance. Similarly, an $m = 3$ and an $m = 2$ wave is excited at the 3:2 and 2:1 resonances, respectively. In this and several subsequent figures, the azimuthal coordinate ϕ is identical to ξ in the text and units are adopted such that $\omega = r_o = 1$.

The results in Figs. 5 and 6 are also in good agreement with the analytic and numerical results presented in Sec. II–IV. With the parameters in models 1 and 2, both conditions [Eqs. (68) and (69)] for gap formation are satisfied. Indeed, the results in Figs. 5 and 6 show a tidally truncated disk structure. The model parameters in models 1 and 2 correspond to the weakly viscous limit. In agreement with criterion (70), the density wave propagates over an extended radial range as shown in Figs. 5 and 6. Applying the model parameters to Eq. (79), we find the damping length scale to be comparable to r_o as is found in models 1 and 2. The radial dependence of wavelength is also in good agreement with predictions made using the dispersion relation (78).

These comparisons indicate that when periodic solutions exist, the Lagrangian scheme can provide reliable results. Although the Lax-Wendroff method is a truly two-dimensional time-dependent scheme, it is very time consuming for numerical computation. Therefore, the Lagrangian scheme is used in the analysis of disk-companion tidal interactions presented below.

C. The Standard Model

In this and subsequent sections, we focus our discussion on cases where the companion's mass is much smaller than that of the central star. This calculation is particularly relevant to the formation of protoplanets. To illustrate disk response to the companion's tide, a standard model (model 3) is adopted in which $q = 10^{-3}$, $c_o = 0.1 \omega r_o$, and $v_{so} = v_{bo} = 1.5 \times 10^{-5} \omega r_o^2$. According to Eqs. (68) and (69), the mass of this companion is sufficiently large to marginally open a gap. These parameters are particularly relevant to the formation of Jupiter in the solar nebula.

Figure 8. Steady-state streamlines in model 3. The companion's perturbation is most intense at $\phi = 0$.

Surface Density Distribution. The equilibrium Σ distribution is plotted in Fig. 7. The outer edge of the disk approaches to within 2 Roche radii ($r_R \sim 0.1$) from the companion. A 4-arm spiral pattern is clearly visible near the outer edge of the disk. This pattern is excited by the 4:3 Lindblad resonance. Similarly 3- and 2-arm spiral waves are evident near the 3:2 and 2:1 Lindblad resonance. Although sound waves are excited at these resonances, that they can propagate throughout the disk is indicated by the fact that some reflection near the inner boundary is observed. Application of these model parameters to the discussion in Sec. IV indicate that waves can indeed propagate over a large radial extent. In particular, Eq. (78) indicates that deep inside the disk, the expected wavenumber is $k \sim m\omega/c_0$ and the condition for waves to propagate to the inner boundary is approximately that $[c_0/(r_0\omega)] > m^{2/3}(\nu_{s0}/r_0^2\omega)^{1/3}$. In the standard model, $\nu_{s0} = 10^{-5}\omega r_0^2$, this requires $c_0 > 0.02 \omega r_0$ which is satisfied for $m = 3$ or 4.

Streamlines and Shock Dissipation. The streamlines and non-Keplerian velocity vectors are plotted in Figs. 8 and 9. At the outer edge of the disk, the protoplanet's tide strongly perturbs the disk flow near $\xi = 0$. At later orbital phases, the amplitude of radial motion is damped by both viscosity and nonlinear shock dissipation. The streamlines depart strongly from sinusoidal form. In Fig. 10, the dimensionless shear gradient, $\Omega^* \equiv (r/\Omega)(\partial\Omega/\partial r)$ is plotted as a function of ξ for several streamlines. Note that although the shear is modified near $\xi = 0$, the protoplanet's perturbations are not sufficient to induce shear reversal. Nevertheless, $\kappa^2 = \Omega^2(4 + 2\Omega^*)$ is modified near the disk edge and the resonances become delocalized. Wave crests in the Σ distribution correspond to locations where the streamlines converge and shock. These shocks correspond to maxima in the dissipation due to the pseudoviscous pressure, $D_r = (q_v/\Sigma^2)(\partial\Sigma/\partial\xi)(\Omega - \omega)$ (see Fig. 11). At relatively small disk radii, tidal disturbances result from the effects of low-

Figure 9. Perturbed velocity field in model 3. The reference vector at the upper right corner represents $0.2 \omega r_o$ where ωr_o is the orbital velocity of the companion.

order Lindblad resonances and do not have strong phase dependence. The streamlines there thus take on a sinusoidal form.

D. Model Parameters

In a protoplanetary disk, a wide range of physical conditions may be possible. The three main model parameters are c_o , v_{so} , and q . Using a few models, we show below the disk response as a function of these parameters.

Sound Speed. The discussion in Sec. III indicates that gap formation in the disk is only possible if the Roche radius of the protoplanet is larger than the disk scale height H . Models with the same values of q and v_{so} but larger c_o do not lead to gap formation (see also the discussion in Sec. VI). In model 4, a cold disk is presented. We adopt $c_o = 10^{-3} r_o \omega$, and take all other parameters to be identical to those in model 3. The streamlines in Fig. 12 clearly indicate the presence of 2- and 3-arm spiral patterns near the 2:1 and 3:2 Lindblad resonances.

However, the Σ distribution (Fig. 13) shows that the tidally induced

Figure 11. Distribution of dissipation rate D_4 in model 3. The bulk dissipation rate attains local maxima at regions where the streamlines converge (compare to Fig. 9).

Figure 12. Steady-state streamlines in the corotating frame (counter-clockwise) of a companion which is located at $x = 1$ and $y = 0$.

density waves cannot propagate significantly from the location where they are launched.

Viscosity. In Sec. II, we showed that in the limit of large v_{so} , the rate of viscous transport of angular momentum dH_v/dt exceeds that due to the protoplanet's tide dH_T/dt so that gap formation is prevented. In Sec. VI, we deduce the critical value of v_{so} for gap formation. In the limit of small v_{so} , dH_v/dt may be small compared to the rate of angular momentum transfer that would occur if the disk includes Lindblad resonances. In this case, the disk may be tidally truncated at a Lindblad resonance. From Eqs. (22) and (60), an approximate condition for tidal truncation at a low-order Lindblad resonance is

$$2\pi v_s < q^2 r_o^2 \omega. \quad (128)$$

The physical parameters for model 5 are identical to those for model 4 except that $v_{so} = 10^{-7} r_o^2 \omega$ so that the condition for tidal truncation at the 2:1 Lindblad resonance is marginally satisfied. The Σ distribution (Fig. 14) indeed has a relatively sharp edge near the 2:1 Lindblad resonance.

Mass Ratio. In Sec. IX, we present disk structure in nearly equal-mass binaries. For protoplanets with a small q and thus a small r_R , the disk may include Lindblad resonances with values of m up to $(2/3)(r_o/r_R) \sim (2/3)q^{-1/3}$. In model 6, $q = 10^{-4}$, $c_o = 10^{-2} r_o \omega$, and $v_{so} = 10^{-7} r_o^2 \omega$ so that structures manifesting m as large as 10 may be produced in principle. The actual Σ

Figure 13. Steady-state surface density distribution in model 4. There is little wave propagation because the sound speed is low. Density waves are dissipated at the resonant locations where they are excited.

Figure 14. Steady-state surface density distribution in model 5. The disk is truncated at the 2:1 resonance because the viscosity is small. Models with even lower viscosity are also truncated at the 2:1 resonances.

distribution (Fig. 15) shows a $m = 8$ pattern. The smaller values of m seen are probably due to the fact that there is not enough material in the outer regions for the higher m resonances to be excited. At the disk edge, the streamlines depart significantly from a sinusoidal pattern. Viscous dissipation introduces an azimuthal dependence in the wave amplitude. There is no clear separation between the density waves which are excited at the several resonances within the disk. In fact, density waves propagate between resonances throughout the disk. This is due to a modest pressure effect which promotes wave propagation and slightly modifies the resonant locations. Despite the interference of density waves excited by different resonances, the wave pattern is dominated by local effects. At the inner edge of the disk ($r = 0.55$), there is a partial reflection of the density wave which is excited at the 2:1 resonance ($r \simeq 0.63$).

The small q models are useful to demonstrate that the gap width is also a

Figure 15. Steady-state surface density distribution in model 6 where $q = 10^{-4}$. The disk extends closer to the companion than in models where q is larger. Consequently high- m Lindblad resonances are excited.

Figure 16. Steady-state surface density distribution in model 7. The resonant zones are well separated due to the low sound speed. Waves are dissipated where they are excited.

function of c_o and v_{so} as well as q . Model 7 has identical parameters to model 6 but $c_o = 10^{-3} r_o \omega$. The size of the gap is a factor of 2 larger for the lower- c_o model 7 (Fig. 16) so that only $m = 4$ waves are seen in the disk. The waves are confined to the vicinity of the resonant locations where they are excited so different low-order resonances are clearly separated. Model 7 can be classified as a strongly viscous case as Eq. (79) implies that the dissipation length scale

is less than the separation of the resonances. We compute another model with identical parameters to model 7 but $\nu_{so} = 10^{-9} r_o^2 \omega$ so that $2\pi \nu_s < q^2 \omega r_o^2$. The disk is truncated at the 2:1 Lindblad resonance. In the absence of overlapping resonances and wave propagation, the disk edge is very sharp.

E. Circumcompanion Disks

The disk structure exterior to the protoplanet's orbit is essentially similar to that interior to it since, because of the symmetry that applies in these extreme mass ratio cases, the hydrodynamics of the disk flow is essentially identical. In model 8, $q = 10^{-3}$, $c_o = 5 \times 10^{-2} r_o \omega$, and $\nu_{so} = 10^{-5} r_o^2 \omega$. Near the inner edge of the outer disk, 2- and 1-arm spiral patterns are excited by the 3:2 and 2:1 outer Lindblad resonances (Fig. 17). In this relatively high sound speed case, the waves do not propagate very far from the gap edge. This occurs because the wave amplitude decreases as the wavelength decreases outward; this is also indicated by the dispersion relation (78). The gap attains a modest size which is about 2 to 3 r_R from the companion. Models with smaller viscosity attain larger gap because the viscous dissipation is distributed over extended regions of the disk.

Figure 17. Steady-state surface density distribution in circumbinary disk in model 8 where $q = 10^{-3}$.

F. Proto-Sun's Tidal Effects on Protoplanetary Disks

It is also of interest to consider the disk structure around the protoplanet where the "companion's" mass is much larger than that at the center of the disk (Lissauer and Cuzzi 1985). In model 9, $q = 10^3$, $\nu_{so} = 2 \times 10^{-5}$, and $c_o = 0.1$ which corresponds to a gaseous disk around proto-Jupiter. Streamlines in the outer region of the disk are very elongated (Fig. 18). The region near the protostar extends to $\sim 0.5 r_R$ whereas on the opposite side the disk is

strongly compressed. Density waves are not excited in the disk because the characteristic length scale for the protostar's tidal disturbance is comparable to the disk radius and much larger than the characteristic wavelength so that waves cannot be excited except near Lindblad resonances. In the disks around low-mass companions, the low-order Lindblad resonances are excluded.

Figure 18. Steady-state surface density profile in model 9. In this case, the companion is the proto-Sun whose mass is 10^3 larger than that of the protoplanet at the center of the disk.

In this model, the streamlines have eccentricities approaching ~ 0.15 (Fig. 19). The magnitude of v_r and v_ϕ are in units of $(GM_p/r_o)^{1/2}$ which is $[M_p/(M_p + M)]^{1/2}$ smaller than proto-Jupiter's orbital velocity. Nevertheless, they are sufficient to induce large compression in the streamlines. At $\xi \sim \pi$, streamlines converge with the material on them carrying differing specific angular momenta. In particular, material on outer streamlines has more specific angular momentum than material on inner streamlines. But material on outer streamlines undergoes a larger inward radial excursion than that on inner streamlines in order to produce convergence at periape. As specific angular momentum is approximately conserved during the excursion, the increase in v_ϕ for material on the outer streamlines is larger than that for material on the inner streamlines. Consequently, the local shear is significantly reduced and, for a limited range in ξ , even reversed. However, this flow pattern does not modify the outward direction of angular momentum flux when it is averaged over all phases. In models where the sound speed is much less than that adopted here, the compressional region becomes highly nonlinear and the shear reversal is more pronounced.

Figure 19. Perturbed velocities, radii and shear along five Lagrangian fluid elements in the outer regions of the circumplanetary disk. Note that at $\xi \sim \pi$ where the streamlines are near their perigee, the shear decreases and even changes sign. The eccentricity of the outermost streamlines is nearly 0.15.

VI. IMPLICATIONS FOR PROTOPLANETARY GROWTH

A. Necessary Conditions for Gap Formation

Protostellar disk-protoplanet interactions are very important in determining the final mass of the protoplanet. When the mass of the protoplanet is relatively small, its tidal influence is unlikely to perturb the disk structure strongly. The protoplanetary mass increases as it accretes gas from the disk. In Secs. II and III, we indicated that when a protogiant planet has acquired a sufficiently large mass, tidal effects will induce the formation of a gap in the vicinity of its orbit. Thereafter, mass growth of the protoplanet is essentially terminated. In this section, we examine the gap formation process and its implications for protoplanetary formation. These results are verified by a series of numerical computations based on the periodic Lagrangian scheme (see Fig. 20). In this series, $c_o = 10^{-2}\omega r_o$, and $10^{-4}\omega r_o^2 > \nu_{so} = \nu_{bo} > 10^{-7}\omega r_o^2$. In each case, radius and mass scale with the binary separation and the central star's mass, respectively, in such a way that the sound speed and viscosity are in units of ωr_o and ωr_o^2 , respectively. In most regions of the disk, $\Sigma \sim 1$. Models in which a gap is formed are marked with open circles and models in which a gap is overrun by viscous spreading are marked with filled dots. The results in Fig. 20

Figure 20. Viscous condition for gap formation. The 22 models have various values of q and $\nu_{so} = \nu_{bo} (= \nu)$. The sound speed for all models is $c_o = 10^{-2}$. The open circles represent models with gaps whereas filled circles represent models where gap formation is prevented. The critical relation for gap formation is $q \sim 40\nu_{so}$.

clearly delineate a critical line at $q \sim 40\nu_{so}$, which is in good agreement with the analytic approximation (68). A necessary condition for gap formation is determined by the gas pressure which induces wave propagation and modifies the epicyclic frequency κ . From the results in Sec. III, it is apparent that for a gap to exist, we need the radial scale length H_r at the edge of the gap to be greater than or comparable to the disk thickness H_∞ . If this condition is not satisfied, the radial pressure gradient at the boundary of the disk near the protoplanet would become sufficiently large to cause angular momentum to decrease with radius and κ to become imaginary. In this case, the disk edge near the gap would be dynamically unstable such that the disk flow would overrun the gap. The optimum torque occurs when the vertical and radial scale heights are equal to each other and to the distance between the disk edge and protoplanet. When a gap is first formed, the width of the gap must be larger than the Roche radius of the protoplanet; a necessary condition for gap formation is thus $r_R > H$ or $q > 3(H/r_o)^3$ as indicated by Eq. (69).

The analytic approximation to this necessary condition is also verified by numerical computations using the Lagrangian scheme for determining periodic solutions. The results for three mass ratios, $q=10^{-2}$, 10^{-3} , and 10^{-4} are plotted in Figs. 21, 22, and 23, respectively. In each case, models with

Figure 21. Thermal condition for gap formation. The 25 models have various values of c_o and ν_{s0} . The mass of the companion is $q = 10^{-2}$ in all cases. Note that the violation of the thermal condition prevents the gap formation in models with $c_o \geq 0.4$.

Figure 22. Thermal condition for gap formation for $q = 10^{-3}$. For $c_o \geq 0.3$, gap formation is no longer possible.

several values of c_o and ν_{s0} are used. These results indicate that gap formation is attainable only for $c_o < q^{1/3}$ which is in good agreement with the analytic approximation. For large values of c_o , gap formation is prevented for cases in which the condition for truncation based on torque comparisons is satisfied (i.e., cases with negligible ν_{s0}). In the low- c_o limit, this condition regulates gap formation independent of the value of c_o .

Figure 23. Thermal condition for gap formation for $q = 10^{-4}$. For $c_o \geq 0.2$, gap formation is prevented. The thermal condition for gap formation is that the Roche radius of the companion must exceed the disk thickness.

B. Implications for the Disk Structure

The above results indicate that gap formation is determined by the magnitude of viscosity as well as by the disk thickness, both of which are uncertain quantities. Let us consider the scenario in which the protoplanetary disk is not turbulent. In this case, viscosity is due to molecular processes and is negligible that only the necessary condition (69) is relevant. To avoid gap formation before a protoplanet has acquired a mass comparable to that of Jupiter, the disk scale height must be $\gtrsim (q/3)^{1/3} r_o = 0.1 r_o$.

In the absence of viscous dissipation, an isothermal vertical hydrostatic equilibrium may be maintained in the disk by surface heating from the central star such that $\rho = \rho_o \exp(-z^2/H^2)$ where $H = 2^{1/2} c/\omega = (2R_g T/\mu)^{1/2}/\omega$. Here ρ_o denotes the midplane density, T the temperature, R_g the gas constant, and μ the mean molecular weight. In the limit that the entire disk is optically thin, radiation from the central star with luminosity L , would heat dust in the disk to a temperature $T = 280(L/L_\odot)^{1/4}(r_o/1\text{ AU})^{-1/2}$ so that $H/r_o = 0.047(L/L_\odot)^{1/8}(r_o/1\text{ AU})^{1/4}$ (Hayashi et al. 1985). In reality, the temperature in the outer regions of the disk may be considerably lower than this value if the inner regions of the disk near the star are opaque. Therefore, unless the central star is much more luminous than typical T Tauri stars, the vertical scale height maintained by stellar radiation alone would not be able to prevent gap formation for protoplanets even with mass significantly less than the present mass of Jupiter. Thus, additional sources of heating are required to maintain

a large enough H/r_o that gap formation will be delayed until a protoplanet has acquired a mass comparable to that of Jupiter.

Viscous dissipation in the disk can provide a sufficiently high temperature but it requires an effective viscosity much larger than the molecular viscosity which is inconsistent with the assumption that the disk flow is laminar. To deduce the required magnitude of ν_s , we deduce the midplane disk temperature corresponding to conditions under which a gap could just form:

$$T_c \sim (q/3)^{2/3} \mu \omega^2 r_o^2 / R_g. \quad (129)$$

For Jupiter, this temperature is ~ 200 K which is comparable to the melting temperature of ice grains in a low-pressure environment. If this temperature is maintained by viscous dissipation in the disk, the standard thin-disk approximation (Shakura and Sunyaev 1973) indicates that the surface effective temperature would be

$$T_e^4 = 8 T_c^4 / (3 \kappa_c \Sigma). \quad (130)$$

Here the opacity in the midplane $\kappa_c = \kappa_o T_c^2$, where in cgs units $\kappa_o = 2 \times 10^{-4}$ is primarily due to ice grains. When a viscous protoplanetary disk is in thermal equilibrium such that the dissipation rate is balanced by the surface radiated flux,

$$2.25 \nu_s \Sigma \omega^2 = 2 \sigma T_e^4. \quad (131)$$

From the above equations, the magnitude of effective viscosity needed is found to be

$$\nu_s \sim \frac{64 \sigma \mu^2 \omega^2 r_o^4}{27 \kappa_o \Sigma^2 R_g^2} \left(\frac{q}{3} \right)^{\frac{4}{3}}. \quad (132)$$

We note that a decrease in the magnitude of κ_o , possibly due to grain coagulation (Pollack et al. 1985), would increase the required viscosity. During its evolution, most regions of the disk attain a quasi steady state (Lin and Bodenheimer 1982; Ruden and Lin 1986) such that the mass transfer rate is

$$\dot{m} \simeq 3\pi \Sigma \nu_s. \quad (133)$$

Taking $q = 10^{-3}$, at Jupiter's current location we obtain from Eq. (132) in cgs units

$$\nu_s \sim 0.1 \omega r_o^2 / \Sigma^2 \quad (134)$$

and then

$$\dot{m} \sim (10^{-6} / \Sigma) M_\odot \text{ yr}^{-1}. \quad (135)$$

The corresponding diffusion time scale is

$$\tau_d \sim r_o^2 / \nu_s \sim 10 \Sigma^2 \text{ yr}. \quad (136)$$

Adopting the value of Σ from the minimum-mass nebula model (Cameron 1973; Hayashi 1981), we find from Eqs. (134) to (136) $\nu_s / \omega r_o^2 \sim 10^{-5}$, $\dot{m} \sim 10^{-8}$

$M_{\odot} \text{ yr}^{-1}$, and $\tau \equiv \pi \Sigma r_o^2 / \dot{m} \sim 10^{5-6} \text{ yr}$. These results imply that $q \sim 40 v_s / \omega r_o^2$ and thus both the conditions (68) and (69) for gap formation are marginally satisfied in a minimum-mass nebula. According to these estimates, the diffusion time scale for a minimum mass nebula is relatively short and protoplanetary formation must proceed on a time scale $\sim 10^{5-6} \text{ yr}$. This time scale is comparable to the typical age of classical T Tauri stars with an observed signature of protostellar disks (Walter 1987a; Strom et al. 1989b).

The magnitude of effective viscosity estimated with Eq. (134) is much larger than the molecular viscosity. In typical astrophysical accretion disks, turbulent viscosity is usually invoked to account for efficient angular momentum transfer and energy dissipation. An often used prescription for turbulent viscosity is the *ad hoc* α -model (Pringle 1981), in which it is assumed that $v_s \sim \alpha cH$ despite the lack of rigorous demonstration of the presence of turbulence (Shakura and Sunyaev 1973). In terms of this prescription, the minimum-mass model implies $\alpha \sim 0.01$. Theoretical investigation has shown that protostellar disks are unstable against thermal convection in the vertical direction (see Chapter by Adams and Lin). Turbulence generated from this thermal convection may provide an effective viscosity with $\alpha \sim 10^{-2}$ (Ruden et al. 1988) which is consistent with the required viscosity (134) for the minimum-mass nebula. For an accretion rate of $\sim 10^{-8} M_{\odot} \text{ yr}^{-1}$, self-consistent convective accretion-disk models yield $H/r_o \sim 0.1$ at the present position of Jupiter (Lin and Papaloizou 1985). Using these models, the derived disk-temperature distribution is consistent with that inferred from the condensation temperature for various planets and satellites (Lewis 1972, 1974).

Despite the success of theoretical nebula models in satisfying the gap-formation conditions, there exist uncertainties in both the minimum mass nebula model and the self consistent convection model. For example, if the fractionation of heavy elements of the solar nebula and their subsequent accretion onto the protoplanets are relatively inefficient processes, the value of Σ inferred from the present mass of the planets would be larger than that deduced for the minimum mass nebula model. The corresponding viscosity is also smaller. The effective viscosity may also be less than that deduced from theoretical analyses if the viscous stress provided by the convective eddies is less than that estimated from the linear normal mode analysis and mixing-length model. In this case, the viscous condition (68) would be satisfied prior to the condition (69). However, gap formation cannot occur until $q > (H_{\infty}/r_o)^3$. We refer to gap formation in this case as weakly viscous disk truncation.

Strongly viscous disk truncation can occur if the thermal condition (69) is satisfied prior to the viscous condition (68). For example, in the self-gravitating outer regions (Toomre 1964) of protostellar disks where $\pi G \Sigma / (\omega c) \sim 1$ or $\Sigma \sim (M/\pi r_o^2)(H/r_o)$, the condition (69) implies a critical $\Sigma \sim q^{1/3} M_{\odot}/\pi r_o^2$ which corresponds to a disk mass $\sim 0.1 M_{\odot}$ for proto-Jupiter. When this condition is satisfied, angular momentum transfer by gravitational torques due to growing nonaxisymmetric perturbations (Larson 1984; Lin and Pringle

1987; Papaloizou and Lin 1989; Papaloizou and Savonije 1991) may be more efficient than effects arising from protoplanets such that no gap is formed until the protoplanet's mass becomes substantially larger than that of Jupiter. In the context of the solar nebula, the gravitational instability scenario seems unlikely unless planets in the solar system only acquired a small fraction of the total mass that resided in the primordial solar nebula (Cameron 1978*a*; Lin 1981*a*).

C. Growth of Protoplanet Planets

The short formation time scale inferred from the gap formation conditions places strong constraints on models of protoplanetary formation. The most probable scenario for protoplanetary formation is accretion onto solid cores (Bodenheimer 1985). The first stage of this process requires the formation of planetesimals (Safronov 1972; Cameron 1962, 1978*a*; Hayashi 1981). Surface density and temperature in the protoplanetary disk both decrease with time (Lin and Papaloizou 1985; Ruden and Lin 1986) leading to condensation and growth of dust particles. Dust particles segregate from the gaseous nebula and coagulate (Wasserberg 1985). Eventually, kilometer-size planetesimals form, either through gravitational instability (Goldreich and Ward 1973), or through continuing cohesive collisions (Weidenschilling 1987; also see Chapter by Weidenschilling and Cuzzi). Subsequently, the collisional evolution of low mass planetesimals results in the formation of Earth-mass prototerrestrial planets and protoplanetary cores (see Chapter by Lissauer and Stewart). The present estimates of the growth time scales for Earth-size planetesimals (Safronov and Ruzmaikina 1985; Hayashi et al. 1985) near Jupiter's orbit are ~ 10 to 100 Myr which is somewhat longer than the ~ 0.1 to 1 Myr protoplanet formation time scales deduced above. Detailed analysis of the expected kinematic properties of planetesimals (Wetherill and Stewart 1989) has shown that a relatively short growth time scale for Earth-sized planetesimals is possible if runaway coagulation occurs in which a few massive planetesimals grow much faster than the rest of the population.

When a protoplanetary core has attained $\sim 1 M_{\oplus}$, it begins to accrete a low-mass quasi-hydrostatic gaseous envelope (Mizuno et al. 1978; Mizuno and Nakazawa 1988). As the core continues to grow to 10 to 20 Earth masses, the hydrostatic equilibrium can no longer be maintained and the envelope collapses (Sekiya et al. 1987, 1988). We then have a situation approximating spherically symmetric accretion in which the gas accretion rate is

$$\dot{M}_p = 4\pi\rho_C r_C^2 \quad (137)$$

where r_C is the radius at the sonic point in the flow and ρ_C is the density there. For the isothermal Bondi solution,

$$r_C = GM_p/(2c^2) \quad (138)$$

where M_p is the protoplanet mass. The accretion rate then becomes

$$\dot{M}_p = \pi \exp(3/2) G^2 M_p^2 \rho_{\infty} / c^3 \quad (139)$$

where ρ_∞ is the ambient density. For a typical solar nebular model, the characteristic growth time scale near the present location of Jupiter is $\tau_g = M_p/\dot{M}_p \sim 10^5 (M_\oplus/M_p)$ yr. Provided that the coagulation time scale for Earth-mass cores is sufficiently rapid, a protoplanet could then accrete enough gas to become a giant planet on a time scale comparable to the viscous diffusion time scale of the protoplanetary disk.

During this early gas accretion phase, infall toward the protoplanet is essentially spherical because $r_C < r_R$. However, as a protogiant planet grows, r_C increases until it exceeds r_R or H . It turns out that as the protoplanet grows, the condition that $r_C = r_R$ is reached approximately simultaneously with the condition that $r_C = H$. The critical mass ratio for $r_C \sim r_R$ is $q \simeq (H/r_o)^3$. This is also the minimum mass ratio needed for gap formation. Subsequent protoplanetary growth and disk evolution depend on the viscosity in the disk. In the strongly viscous limit, gas accretion will continue until the viscous condition for gap formation is established when $q \sim 40\nu/\omega r_o^2$. During this final stage of gas accretion, $H < r_C$ implies that gas accretion proceeds primarily in the plane and $r_R < r_C$ indicates that the tidal effect of the central star regulates mass flow onto the protoplanet. Several numerical simulations of accretion in this strongly viscous limit have been carried out (Cameron 1979; Miki 1982; Sekiya and Miyama 1988a; Sekiya et al. 1988). These calculations have shown that as gas flows across the Roche lobe, a directly rotating circumplanetary disk is formed. This disk extends to a significant fraction of the protoplanet's Roche radius (see Fig. 18 in Sec. V.F) and is much larger than the final radius of the planet. Thus, the newly accreted material must lose more than 90 % of its original spin angular momentum if the giant planets and their satellite systems are to end up with their present spin and orbital angular momenta. Such angular momentum losses cannot be induced by the tidal field of the proto-Sun because such tides are ineffective near Jupiter's final radius which is $\sim 10^{-3} r_R$.

A more probable scenario for gap formation is that disk truncation occurs in the marginal or weakly viscous limits because little angular momentum loss may be needed. In this case, gap formation occurs while $r_C \leq r_R$ so that throughout the protoplanet's growth, gas accretion is essentially spherical. The details of gap formation in the disk and the final stages of protoplanetary accretion must be analyzed taking three-dimensional effects fully into account. Such analysis has yet to be carried out.

D. Termination of Protoplanetary Growth and Disk Clearing

After a protoplanet opens up a gap in the vicinity of its orbit, its mass growth is essentially terminated though energy and angular momentum continue to be exchanged between it and the disk. The orbital evolution of the protoplanet is thus locked to that of the disk. In the absence of continuous infall, Σ , c and ν decrease with time. The results in Sec. V showed that the width of the gap increases as c and ν decrease. For $q > 10^{-4}$, gas in the region between the inner and outer 2:1 Lindblad resonances may be expelled for modest values

of c and ν . Beyond the inner and outer 2:1 Lindblad resonances, there are no additional low-order orbital resonances and therefore the disk feels only a weak tidal effect from the protoplanet. Disk matter can accumulate in the neighborhood of the outer 2:1 Lindblad resonance and provide a favorable formation site for another protoplanet (see Sec. VIII).

Figure 24. Surface density distribution for a gaseous ring with two shepherding companions (model 10). The mass of both companions is $3 \times 10^{-3} M_{\odot}$. In the disk, $c_o = 0.04 \omega r_o$ and $\nu_{so} = 10^{-5}$. The companions have orbital radii 1 and 3, respectively. The plot is in the corotating frame of the outer companion at an epoch when both companions are at $\xi = 0$.

In a protoplanetary disk, several planets may be formed while there is still residual gas in the disk. Gaseous rings may be trapped between protoplanets in the same way that planetary rings are shepherded by guardian satellites (Goldreich and Tremaine 1979a). As the protoplanets' masses increase and Σ and c decrease, gaps around the protoplanets widen and the inner and outer edges of the trapped ring retreat toward the outermost Lindblad resonance of the inner protoplanet and the innermost Lindblad resonance of the outer planet. In the present solar system, the outermost Lindblad resonance of any given planet is exterior to the innermost Lindblad resonance of its neighboring outer planet. Consequently, for sufficiently small c and ν , the trapped ring may be squeezed.

To demonstrate the tidal interaction between a ring and two shepherding companions, we need to use the Lax-Wendroff scheme as a set of truly time-dependent, two-dimensional solutions is needed. In order to save computing time, models with massive protoplanets are computed. In each case, a gas ring is initially placed between two shepherding protoplanets with identical masses. In each model, $c_o = 0.04 \omega r_o$ and $\nu_{so} = \nu_{bo} = 10^{-5} \omega r_o^2$. The inner companion is placed at r_o and the outer planet is placed at $3r_o$ and $2r_o$ in models 10 and 11, respectively. In both models 10 and 11, $q = 3 \times 10^{-3}$. In model 10, the outermost Lindblad resonance of the inner planet is located at

Figure 25. Surface density distribution in model 11. All the parameters here are identical to model 10 (Fig. 24) except the orbital radius of the outer companion is 2. The spike at $\xi = 0$ near the outer edge of the disk is due to accretion onto the Roche volume of the outer companion. Its amplitude does not change with time.

a similar location as the innermost Lindblad resonance of the outer planet. In model 11, the outermost Lindblad resonance of the inner planet is outside the innermost Lindblad resonance of the outer planet. More massive protoplanets ($q = 0.01$) are examined in model 12 with the outer planet at $3r_o$. In each model, equilibrium is established in about a hundred inner planet's orbital periods. In Fig. 24, we plot the Σ distribution for model 10 in a frame corotating with the outer planet for the epoch at which both planets are located $\xi = 0$, where ξ here represents the azimuthal angle in the rotating frame. The analogous plot for model 11 is illustrated in Fig. 25. In this corotating frame, the azimuthal phase of the inner planet ξ_s changes on a synodic period and the disk structure in the inner part of the ring also evolves. In Fig. 26, the radial distribution of Σ at $\xi = 0$ ($\equiv \Sigma_o$) is plotted as a function of phase (ξ_s). The phase-dependent variation of Σ is much larger at small r than at large r because the outer region is predominantly under the influence of the outer planet with which the frame is corotating. The inner region of the ring is most strongly influenced by the inner planet and the variations there are due to the orbital phase change in this frame. This is best illustrated in Fig. 27 where the phase distribution of Σ at the inner boundary of the ring (Σ_i) is plotted against ξ_s .

The results in Sec. V show that the density waves excited at low-order Lindblad resonances which are in close vicinity to the protoplanet's orbit. In the low sound-speed limit, these waves are dissipated locally. The above results are in agreement with these qualitative expectations as the local ring structure is most affected by the nearest protoplanet. In comparison to

Figure 26. Surface density distribution at $\xi = 0$ as a function of the synodic phase ξ_s of the inner companion in model 10. Trailing density waves are excited near the inner companion.

model 10, the protoplanets are less separated in model 11 and the entire ring is consequently under strong tidal perturbation from both planets. The spike at the outer edge of the disk near $\xi = 0$ indicates accretion of gas into the Roche radius of the outer planet. The ring is modestly depleted and contains strongly nonlinear structures. Because of the strong perturbations, rings are unstable and Σ is rapidly depleted in models with smaller radial separation between the two shepherding protoplanets. In model 12 where the shepherding protoplanets are more massive, the ring is also strongly squeezed and it becomes unstable and is depleted on a relatively short time scale.

VII. ORBITAL ECCENTRICITIES

In addition to the above dynamical constraints, important clues on the structure and evolution of the solar nebula can be deduced from companion-disk interactions in the post gap formation epoch. In this section, we first show that tidally induced energy and angular momentum exchange between the disk and the companion can excite the growth of the companion's eccentricity. The small eccentricities of the planets today imply that Σ cannot much exceed the estimates in the minimum mass nebula model. The corresponding effective viscosity would imply a viscous evolution time scale ~ 1 Myr for Σ to be significantly depleted after a gap is formed.

When a companion with an initially circular orbit interacts with a disk, it is sometimes possible that an initially small eccentricity may be amplified through the tidal interaction. In order to discuss this issue, we consider the tidal interactions due to a companion that has an orbit with small eccentricity. We first consider the nature of the perturbing potential acting on an axisymmetric

Figure 27. Azimuthal distribution of surface density at the disk's inner boundary in model 10 ($r = 1.15$) as a function of ξ_s . The ridge marks the disk response to the inner companion's tidal disturbance.

disk centered on the primary protostar. We show that, to first order in the eccentricity, the tides can be considered to be produced by three independent companions in circular orbits with different frequencies. The tidal response can then be found by applying the theory developed above for systems with circular orbits to each component in turn and then superposing the results; this procedure will be valid in the linear regime. The rate of growth of orbital eccentricity can then be found by consideration of the orbital energy and angular momentum exchange rates associated with each tide.

The perturbing potential due to a companion in a nonrotating frame centered on the primary is

$$\psi_c = -\frac{GM_p}{[r^2 + r_p^2 - 2rr_p \cos(\phi - \Phi)]^{1/2}} + \frac{GM_p r \cos(\phi - \Phi)}{r_p^2}. \quad (140)$$

Here, r_p and Φ are the radius and angular coordinate of the companion, respectively. For an orbit with small eccentricity e , these are given to an adequate approximation by

$$r_p = r_o + er_o \cos(\omega t) \quad (141)$$

and

$$\Phi = \omega t - 2e \sin(\omega t) \quad (142)$$

where r_o is now the semimajor axis. We now expand ψ_c to first order in e and perform a Fourier analysis in ϕ with the result that

$$\psi_c = \sum_{m=0}^{\infty} W_m \cos[m(\phi - \omega t)] + \sum_{m=0}^{\infty} W_{1m} \cos[m(\phi - \omega_1 t)]$$

$$+ \sum_{m=0}^{\infty} W_{2m} \cos[m(\phi - \omega_2 t)] \quad (143)$$

where for a disk interior to the orbit

$$W_m = C_m(\epsilon)/r_o \quad (144)$$

$$W_{1m} = \frac{e}{2r_o} \left[-\epsilon C'_m(\epsilon) + (2m-1)C_m(\epsilon) \right] \quad (145)$$

and

$$W_{2m} = \frac{e}{2r_o} \left[-\epsilon C'_m(\epsilon) - (2m+1)C_m(\epsilon) \right]. \quad (146)$$

Here $\epsilon \equiv r/r_o$, $\omega_1 = \frac{(m+1)}{m}\omega$, and $\omega_2 = \frac{(m-1)}{m}\omega$, and the $C_m(\epsilon)$ are related to the Laplace coefficients.

For a disk exterior to the orbit the same formal expression for the potential holds but now

$$W_m = C_m(\epsilon^{-1})/r_o \quad (147)$$

$$W_{1m} = \frac{e}{2r_o} \left[\epsilon^{-1} C'_m(\epsilon^{-1}) + 2m C_m(\epsilon^{-1}) \right] \quad (148)$$

and

$$W_{2m} = \frac{e}{2r_o} \left[\epsilon^{-1} C'_m(\epsilon^{-1}) - 2m C_m(\epsilon^{-1}) \right]. \quad (149)$$

Sometimes when discussing an external disk it is convenient to use a coordinate system based on the center of mass of the binary system rather than that of the primary. If this is done, an expansion of the same formal type as that given above is obtained and the discussion given below also holds in this case.

Thus we see that for any $m > 0$ the tidal forcing can be considered to be produced by three companions in circular orbits with frequencies ω , ω_1 and ω_2 . The frequencies (ω_1) one obtains that are larger than ω are $2\omega, 3\omega/2, 4\omega/3, \dots$ for $m = 1, 2, 3, \dots$, respectively, while the frequencies (ω_2) smaller than ω are $\omega/2, 2\omega/3, 3\omega/4, \dots$ for $m = 2, 3, 4, \dots$, respectively. Axisymmetric forcing from terms with $m = 0$ is always weak and never resonant; in what follows it will be neglected. Both sets of frequencies (ω_1, ω_2) occur for internal and external disks. Because frequencies different from ω occur, in some cases, it is possible that disk material corotates with one of the tidal perturbations. One must then consider the effect of the corotation resonance on the response. This requires disk material orbiting with frequencies between 2ω and $\omega/2$ which is possible only for a fairly extreme mass ratio. Therefore effects arising from corotation resonances can generally be ignored for the binary star problem where the mass ratio is not extreme. However, they should be considered in the protoplanet problem. Goldreich and Tremaine (1979b, 1981) found that the effects of corotation resonances can dampen the eccentricity in a weakly perturbed disk. They also point out that a strong tidal interaction at the Lindblad resonances could lead to gap formation such that the region around the

corotation resonances is depleted as in the circular orbit case (see Sec. V). Consequently, eccentricity damping by the corotation resonances is rendered ineffective (also see Ward 1988). If there are gaps in the disk at corotation resonances, we should in principle consider the tidal response of more than one section for each m and this will be considered in what follows. However, in most cases one only gets a significant response from the section containing the appropriate Lindblad resonance.

We now consider the post gap formation epoch in which there are no corotation resonances, so that the theory given in Sec. III may be applied directly. This is correct in the binary star case and in the protoplanetary case if material is depleted at the Lindblad resonances appropriate to the circular orbit tide. In order to discuss the evolution of the eccentricity, we first note that for each m the terms in the tidal potential (140) proportional to e are the most important. The other term is of course the term that appears in the circular orbit case and this by itself cannot excite the eccentricity. We then evaluate the angular momentum exchange rate for each of the terms proportional to e independently, using the theory developed in Sec. III. We may, in fact, apply Eq. (53) directly, so obtaining an angular momentum flux for each m

$$F_{H1} = \frac{\pi m}{4|C_1|^2} \left| \int_{r_0}^{r_1} \Sigma_0 r S_{1m} X_{1m} dr \right|^2 \quad (150)$$

and

$$F_{H2} = \frac{\pi m}{4|C_2|^2} \left| \int_{r_0}^{r_1} \Sigma_0 r S_{2m} X_{2m} dr \right|^2. \quad (151)$$

Here F_{Hi} , C_i , S_{im} , and X_{im} for $i = 1, 2$ have the same meanings as F_H , C , S_m , and X_m , respectively as used in Sec. III but they apply to the situation where the forcing term is

$$\psi_c = W_{im} \cos[m(\phi - \omega_i t)]. \quad (152)$$

In order to evaluate the effect on the companion's orbit, we use the fact that a tidal wave in the disk proportional to $\cos[m(\phi - \omega_i t)]$ causes the binary orbit to evolve such that changes to its energy E and angular momentum J are related by

$$\frac{dE}{dt} = \omega_i \frac{dJ}{dt}. \quad (153)$$

Also we use the fact that correct to second order in eccentricity,

$$\frac{dE}{dt} - \omega \frac{dJ}{dt} = \omega \frac{G^{1/2} M M_p}{2\sqrt{(M + M_p)}} \frac{d(r_0^{1/2} e^2)}{dt}. \quad (154)$$

Only the effect of tidal perturbations proportional to e contribute to the left-hand side of the above equation so that we have for an interior disk

$$\frac{dE}{dt} - \omega \frac{dJ}{dt} = \omega \frac{G^{1/2} M M_p}{2\sqrt{(M + M_p)}} \frac{d(r_0^{1/2} e^2)}{dt} = \sum_m [(\omega_1 - \omega) F_{H1}]$$

$$+(\omega_2 - \omega)F_{H2}]. \quad (155)$$

For an external disk the signs of the terms on the right-hand side are reversed. Considering the effects of both an internal and external disk, we obtain after substituting the values of the ω_i

$$\frac{G^{1/2}MM_p}{2\sqrt{(M+M_p)}} \frac{d(r_o^{1/2}e^2)}{dt} = \sum_m \frac{1}{m} [F_{H1} - F_{H2}]_I + \sum_m \frac{1}{m} [F_{H2} - F_{H1}]_E \quad (156)$$

where the subscript I denotes the internal disk if it exists and the subscript E denotes the external disk if that exists. We now argue that the contributions from both the internal and external disk to the right-hand side of Eq. (156) are always positive.

In the protoplanetary case, when there is a gap, the F_{Hi} are only nonzero when appropriate Lindblad resonances occur in the disk. For high frequencies ω_1 , Lindblad resonances occur only in the internal disk, while for low frequencies ω_2 , Lindblad resonances occur only in the external disk. Thus the F_{H2} are zero in the inner disk and the F_{H1} are zero in the outer disk. It is then clear that

$$\frac{G^{1/2}MM_p}{2\sqrt{(M+M_p)}} \frac{d(r_o^{1/2}e^2)}{dt} > 0. \quad (157)$$

Therefore, for a slowly evolving disk and gap for which dr_o/dt may be neglected, we conclude that $de^2/dt > 0$. Thus in the absence of corotation resonances the eccentricity of the protoplanet grows. Similar conclusions can be obtained for tidal interaction between a binary system and an accretion disk (Artymowicz et al. 1991; also see Sec. IX).

The rate of eccentricity growth depends on the disk structure. In the high sound speed and marginal truncation limit, the disk is extended to the vicinity of the companion's radius. From Eq. (156) we find very approximately that for a gap with a width of ~ 2 Roche radii

$$\frac{1}{e^2} \frac{de^2}{dt} \sim \frac{q^{-1/3} M_N}{t_d M_\odot} \quad (158)$$

where $M_N = \pi \Sigma r_o^2$ is the characteristic disk mass and $t_d = 2\pi/\omega$ is the orbital period of the companion. Using a minimum mass nebula model, $de^2/dt \sim 10^{-4} \text{ yr}^{-1}$ for $e = 0.1$ at Jupiter's current location. Thus, on the evolution time scale of the disk, the orbits of protoplanets with mass comparable to Jupiter could become highly eccentric. A much slower rate of eccentricity increase may be attained in the weakly viscous and relatively cool limit where the disk is truncated near the 2:1 resonances (see numerical results in Sec. V). In this case, Eqs. (77) and (156) give very approximately

$$\frac{1}{e^2} \frac{de^2}{dt} \sim \frac{q}{t_d} \frac{M_N}{M_\odot} \quad (159)$$

Figure 28. Growth of companion's eccentricity in model 13. On the left panel, the instantaneous values of $\dot{\Gamma}_{EJ}$ are obtained from Eq. (160). When an equilibrium is achieved, the asymptotic values of $\dot{\Gamma}_{EJ}$ are plotted in the lower right panel. The time averaged value of $\langle \dot{\Gamma}_{EJ} \rangle$ (upper right panel) is derived from Eq. (161). Positive values of $\langle \dot{\Gamma}_{EJ} \rangle$ indicate eccentricity growth. The surface density distribution in model 13 is identical to that in model 1 (see Fig. 5).

so that proto-Jupiter's eccentricity would not increase significantly beyond its present value in < 1 Myr.

These results are verified with numerical computations. Because the potential of a companion in an eccentric orbit is time dependent, we use the Lax-Wendroff scheme. Other than the companion's eccentricity (0.1), model 13 has identical model parameters to model 1 (i.e., $q = 0.01$). The Σ distribution of the disk is essentially identical to that in Fig. 5, i.e., the disk is tidally truncated at the inner 2:1 resonance of the protoplanet. From the disk response, the value of

$$\dot{\Gamma}_{EJ} \equiv \frac{dE}{dt} - \omega \frac{dJ}{dt} \quad (160)$$

is computed and plotted as a function of time (Fig. 28). This result indicates that an equilibrium is essentially established at $t \sim 200$. Although the value of $\dot{\Gamma}_{EJ}$ has a phase dependence, when it is averaged over a sufficiently long time interval ΔT such that for some initial t_0 ,

$$\langle \dot{\Gamma}_{EJ} \rangle \equiv \frac{1}{\Delta T} \int_{t_0}^{t_0 + \Delta T} \dot{\Gamma}_{EJ} dt \quad (161)$$

a steady-state value independent of t_0 can be found. In the computations, Σ is of order unity so that Eqs. (155) and (156) would lead us to expect $\langle \dot{\Gamma}_{EJ} \rangle \sim 10^{-2} q^2 \omega^3 r_o^4 \sim 10^{-6} \omega^3 r_o^4$. This is in adequate agreement with the results shown in Fig. 28 which adopted units such that $r_o = \omega = 1$.

When tidal truncation occurs in the weakly viscous limit, the gap is relatively wide. However, in order to deplete a significant fraction of the disk mass in < 1 Myr so that a small eccentricity for proto-Jupiter may be sustained, a modest value ($\alpha \sim 10^{-2}$) of viscosity is needed. In addition, tidal interaction can also induce the growth of the inclination angle of protoplanets' orbits (Borderies et al. 1984a). The inclined protoplanets also excite density waves (Shu et al. 1983). The dynamical constraints that can be inferred from the present orbital inclinations of the planets are yet to be determined.

The mass deduced for protoplanetary disks around several T Tauri stars ranges from 10^{-2} to $10^{-1} M_\odot$ (Sargent and Beckwith 1987; Weintraub et al. 1989b; Adams et al. 1990; Beckwith et al. 1990; also see Chapters by Beckwith and Sargent and by Hartmann et al.). The above discussion indicates that giant planets formed in the relatively massive protostellar disks could have large orbital eccentricities. An interesting issue to investigate is that of the long-term stability of a system of planets with modest orbital eccentricities (see Chapter by Duncan and Quinn).

VIII. ORBITAL MIGRATION OF PROTOPLANETS

In the previous sections, we derived the tidal interaction between a protoplanet and the disk on the assumption of a constant r_o . However, angular momentum exchange can cause secular orbital evolution of the protoplanet's orbit (Goldreich and Tremaine 1980; Ward 1984). This orbital migration may also result in additional modification to the local disk structure.

A. Differential Torque

The discussion in Secs. II–IV indicates that angular momentum is transferred to a protoplanet from the disk interior to its orbit. Similarly, angular momentum is transferred from a protoplanet to the disk exterior to its orbit. Orbital migration of a protoplanet is induced by an imbalance in the losses and gains of angular momentum. For protoplanets with circular orbits, angular momentum flux is produced at the Lindblad resonances. The imbalance in the angular momentum exchange rate can be expressed as the sum of the differences between the torques, F_H^+ and F_H^- , at the outer and inner resonances, respectively, for each m

$$\Delta F_H = (F_H^+ - F_H^-). \quad (162)$$

The net rate of angular momentum gain of the protoplanet is then given by

$$\frac{dH}{dt} = - \sum_m \Delta F_H. \quad (163)$$

There are several cases where we would expect a nonzero ΔF_H . In a cold disk where the flow velocity is essentially Keplerian, a gradient in Σ according to Ward (1986) leads to

$$\Delta F_H = \frac{16}{9} m \Sigma q^2 \omega^2 r^4 \left[K_1 \left(\frac{2}{3} \right) + 2K_0 \left(\frac{2}{3} \right) \right]^2 \frac{d \ln \Sigma}{d \ln r}. \quad (164)$$

This differential torque calculation is valid only in the limit $\xi_c \equiv mc/r\Omega < 1$ and near the protoplanet where the relevant m is large this condition breaks down. For $\xi_c > 1$, the spacing between resonances becomes smaller than the disk thickness, the effects of the disk's vertical structure and its small deviation from Keplerian rotation must be taken into account. In addition coupling between different resonances may be induced by sound waves so that individual resonances can no longer be separated. In principle, a three-dimensional nonlinear analysis would be appropriate. However, some of the effects may be taken into account by multiplying each resonant contribution by a correction factor, $f_Q(\xi_c)$ which attains unity for $\xi_1 \ll 1$ and vanishes for some critical value $\xi_c \sim 1$ (Goldreich and Tremaine 1980; Ward 1989a). The total differential torque now becomes

$$\frac{dH}{dt} = - \sum_m f_Q(mc/r\omega) \Delta F_H. \quad (165)$$

A Σ gradient then leads to

$$\frac{dH}{dt} \simeq -5.6 \xi_1^2 q^2 \Sigma \Omega^2 r^4 \left(\frac{r\Omega}{c} \right)^2 \frac{d \ln \Sigma}{d \ln r}. \quad (166)$$

A pressure gradient in the disk can also contribute to ΔF_H . Equation (33) indicates that a modest sound speed in the disk changes the resonance locations. In an isothermal thin disk, the locations of high- m inner and outer Lindblad resonances become

$$r_s = r_o \left(1 \mp \frac{1}{m} + \frac{1}{2} \left(\frac{c}{r\Omega} \right)^2 \frac{d \ln \Sigma}{d \ln r} \right)^{2/3}. \quad (167)$$

The shift in the resonance locations introduces a difference between the protoplanet's distance to the inner and outer Lindblad resonances which then produces a torque imbalance leading to the angular momentum flux

$$\frac{dH}{dt} \simeq 5.19 \xi_1^4 q^2 \Sigma \Omega^2 r^4 \left(\frac{r\Omega}{c} \right)^2 \frac{d \ln \Sigma}{d \ln r}. \quad (168)$$

The results in Eqs. (166) and (168) should adequately approximate the magnitude of the differential torque induced by a protoplanet with a mass

large enough to have induced a gap. But there may be additional modifications due to asymmetries arising through the finite thickness of the disk and the correction functions. When there is no gap, the effects of material corotating with the protoplanet have to be taken into account. This requires a calculation which takes account of the disk's vertical structure which has yet to be performed.

B. Disk Response and Orbital Migration

The results in Eqs. (166) and (168) are obtained on the assumption that the Σ and pressure distribution are unperturbed by the protoplanet. In reality, Σ is actively modified by the protoplanet's tide and viscous stress. In the limit that the protoplanet does not strongly perturb the Keplerian flow, we integrate, in the azimuthal direction, Eq. (30) such that

$$\Sigma v_r \frac{d(r^2 \Omega)}{dr} = \frac{1}{r} \frac{\partial}{\partial r} \left(v_s \Sigma r^3 \frac{d\Omega}{dr} \right) + \Sigma \Lambda, \quad (169)$$

where Λ is the local injection rate of angular momentum per unit mass into the disk gas by the protoplanet's tidal torque. The radial dependence of Λ will be determined by the location where the density waves are dissipated rather than where they are excited. Conservation of total angular momentum implies that

$$\sum_m \Delta F_H = 2\pi \int_{r_{in}}^{r_{out}} \Lambda r \Sigma dr. \quad (170)$$

A protoplanet undergoes orbital migration such that

$$M_p \omega r_o \dot{r}_o / 2 = - \sum_m \Delta F_H. \quad (171)$$

The protoplanet's orbital evolution and disk response may be analyzed self consistently by choosing a prescription for Λ . The discussion in Secs. III and IV indicates that if v_s is relatively large, density waves are dissipated near the location where they are launched. If v_s is relatively small, nonlinear shocks and refraction effects may also lead to effective dissipation near the protoplanet. Thus, it is probably adequate to utilize the results derived from both the impulsive approximation and the resonant interaction calculation in Sec. II. Then

$$\Lambda = \text{sign}(r - r_o) \frac{1}{2\pi r_o \Sigma} \frac{d\dot{H}_T}{d\Delta_0} \quad (172)$$

where we can use Eq. (5) to evaluate $d\dot{H}_T/d\Delta_0$, with the result that

$$\Lambda = \text{sign}(r - r_o) f q^2 \omega^2 r_o^2 (r_o/|\Delta_0|)^4 \quad (173)$$

where $f = 4/9\pi$ is a constant of order unity. Equations (169), (171) and (173) coupled with the continuity equation

$$\frac{\partial \Sigma}{\partial t} + \frac{1}{r} \frac{\partial (r \Sigma v_r)}{\partial r} = 0 \quad (174)$$

and a viscosity prescription comprise a complete set of self-consistent equations from which the protoplanet's orbital migration and the disk's Σ evolution may be computed. Within the approximation scheme associated with the impulse approximation, we may replace r_0 by r and ω by Ω . To be consistent with the notation in some of our other work, we relabel $|\Delta_0|$, the distance to the protoplanet as $|\Delta_p|$.

Using these equations, Hourigan and Ward (1984) postulate that orbital migration may inhibit gap formation. Equations (169) and (173) indicate that the time scale for modifying an initially smooth Σ gradient is

$$\tau_{\text{grad}} \simeq \left| \frac{\partial \Sigma}{\partial r} / \frac{\partial^2 \Sigma}{\partial r \partial t} \right| \simeq \Omega \Delta_p^2 / \Lambda \simeq \left(\frac{M}{M_p} \right)^2 \left(\frac{\Delta_p}{r_o} \right)^6 \frac{1}{\omega}. \quad (175)$$

Equation (171) implies that the time scale for migrating across the gap, assuming a smooth background surface density, is

$$\tau_{\Delta} \simeq |\Delta_p / \dot{r}_o| \simeq \frac{M_p \omega}{\Lambda \Sigma} \frac{r_o}{|\Delta_p|} \simeq (M/M_p)(M/\Sigma r_o^2)(|\Delta_p|/r_o)^3 / \omega. \quad (176)$$

For $\tau_{\text{grad}} > \tau_{\Delta}$, the protoplanet drifts too fast to allow the disk to respond. Thus, there is a critical mass $M_c \sim \Sigma r_o^2 (\Delta_p/r_o)^3$ below which gap formation is inhibited by radial drift (Ward and Hourigan 1989). According to the results in Sec. III, the Rayleigh stability criterion requires $\Delta_p > H$ so that $M_c < (H/r_o)^3 \Sigma r_o^2 < (H/r_o)^3 M_{\odot}$. Thus, the prohibition of gap formation by tidal drift can only be realized in cases where the protoplanet's mass is already too small to satisfy the necessary condition for tidal truncation.

C. Self-Consistent Calculations

Because the disk does not have time to respond, Eqs. (166), (168) and (171) can be used to compute the evolution of protoplanets with $M_p < M_c$ once it is known how to make the modifications needed to account for neglected three-dimensional effects near the corotation radius. Simple estimates indicate that the characteristic drift time scale for resonant interaction between the disk and low-mass protoplanets is considerably shorter than that expected from hydrodynamic drag. But the drift time scale may be comparable to or longer than the viscous diffusion time scale of the disk gas so that low-mass protoplanets probably do not migrate over substantial radial distances prior to gas depletion in the disk.

For protoplanets with $M_p > M_c$, Eqs. (169), (171) and (173) are relevant. To apply these equations in accordance with the torque cutoff factor, $|\Delta_p|$ is taken to be the maximum of the disk thickness, c/Ω , or $|r - r_o|$. Note that this prescription does not prevent a discontinuous change of sign for Λ at r_o . Equations (169) and (171) can be solved for an arbitrary viscosity prescription. For example, according to both the simple self consistent convective model

Figure 29. Evolution of disk surface density and orbital migration of embedded protoplanet in model 14 with $r_o = 0.6$ initially. The time scale t is in terms of the diffusion time scale. Gap formation occurs early during the evolution and the companion migrates inward monotonically. Note also that the disk is spreading as a result of viscous diffusion.

and the α prescription $\nu_s = \nu_o(\Sigma/\Sigma_o)^2$ in a solar nebula (Lin and Papaloizou 1985).

For computational convenience, we can choose the unit of time to be the viscous diffusion time scale r_o^2/ν_o , where the unit of radius r_o is some suitably large radius, and the unit of Σ is Σ_o . Each model is then defined by two parameters, $A \equiv \omega r_o^2 q^2/3\nu_o$ which measures the ratio of viscous and orbital time scales, and $B \equiv 3\pi\Sigma_o r_o^2/M_p$ which measures the ratio of disk mass to protoplanet mass. The magnitudes of A and B can be easily estimated for any solar nebula model. For example, by adopting the assumption that the protostellar disk had a solar composition and that most of the volatile material in the disk was not accreted by the planets, we can determine a lower limit on the mass of the nebula to be $\sim 0.02 M_\odot$ (Cameron 1962). For a protogiant planet with a Jupiter mass, $B \sim 10$. According to self-consistent convective disk models (Lin and Papaloizou 1980), $\nu_s \sim 10^{-5} \omega r_o^2$ so that $A \sim 10^{-3}$. Based on these estimates, we computed a series of models with $10^{-4} > A > 10^{-2}$ and $10^2 > B > 0.1$ (Lin and Papaloizou 1986b).

It is of interest to examine the protoplanet's orbital migration under a variety of initial conditions. For illustrative purpose, we show in Figs. 29–31 the evolution for an arbitrarily chosen model 14 with $A = 10^{-3}$ and $B = 20$. At $t = 0$, $\Sigma = 1$ at $r < 1$ and 0 at $r > 1$ in the disk. Three initial protoplanetary positions 0.6, 0.7 and 0.8 are chosen. These results indicate that the protoplanet opens up a gap in the disk shortly after the onset of the calculation. After an initial transitory stage, Σ , near the protoplanet's orbital position, adjusts continually so that the angular momentum transferred from

the inner disk region to the protoplanet is approximately balanced by that transferred from the protoplanet to the exterior disk region. This has the effect that the protoplanet's orbital evolution ultimately occurs on the disk's viscous diffusion time scale.

Figure 30. Evolution of disk surface density and orbital evolution of embedded protoplanet in model 14 with $r_p = 0.7$ initially. During the early stage of the evolution when the disk mass inside is greater than that outside to the protoplanet's orbit, the protoplanet migrates outward. At later stages, the surface density in the inner region is depleted due to accretion. Angular momentum removal from the protoplanet by the external disk becomes more efficient than the angular momentum supply from the interior disk so that the protoplanet migrates inward.

A comparison of different models also indicates that the protoplanet's orbital evolution is sensitive to the location of the protoplanet with respect to the mass distribution of the disk. If a protoplanet is located in the inner regions of the disk, it evolves towards the center on a local viscous evolution time scale. A protoplanet may be induced to evolve into the Sun if its mass is much less than that of the disk exterior to its orbit. If a protoplanet is located in the outer regions of the disk, it generally migrates outward on the viscous diffusion time scale of the outer disk region which is generally longer than that of the inner region. However, a protoplanet cannot double its distance from the Sun unless the disk mass interior to the protoplanet far exceeds that exterior to it and that of the protoplanet. In the intermediate region, the protoplanet first moves outward and then inward following a similar pattern to a local fluid element. The initial outward migration is induced by the absorption of angular momentum from the inner parts of the disk. As the inner region is depleted, the location of maximum viscous stress moves outward (Lynden-Bell and Pringle 1974). When the protoplanet's loss of angular momentum to the outer region cannot be replenished, it migrates inward. Throughout its evolution, the protoplanet maintains a strong tidal coupling with the disk. This is well

illustrated by the relative position of the protoplanet in the gap and the Σ distribution. Note that the protoplanet is slightly closer to the inner edge of the gap (Fig. 30) because Σ adjacent to the gap is slightly larger in the inner region. Despite the lack of mass transfer through the gap, the two regions of the disk are dynamically connected by the protoplanet's tidal torque. Note that in the exterior regions of the disk, Σ attains a local maximum value at the outer Lindblad resonance of the protoplanet. This disk structure provides a favorable location for the formation of a subsequent protoplanet which is consistent with the presently observed orbital distribution of the planets.

Figure 31. Evolution of disk surface density and orbital evolution of embedded protoplanet in model 14 with $r_o = 0.8$ initially. Throughout the calculation, the rate of angular momentum transfer to the protoplanet from the disk interior to its orbit exceeds that from the protoplanet to the disk exterior to its orbit. Consequently, the companion migrates outward monotonically.

In Fig. 32, the protoplanet's position $r_p (= r_o)$ is plotted as a function of time for models 15 and 16 which have the same value of A but $B = 5$ and 80, respectively. These values of B represent a relatively low-mass model and a modestly massive solar-nebula model, respectively. Model 15 showed that in the low-disk-mass limit, the protoplanet regulates the structure of the disk but does not undergo significant orbital migration. In model 16 where the disk mass is relatively high, the protoplanet's orbital evolution is regulated by the disk's viscous evolution. From these results, we speculate that the disk mass exterior to proto-Jupiter's orbit did not exceed $\sim 0.1 M_\odot$, otherwise Jupiter's orbit would have evolved into the Sun as the inner regions of the disk were depleted in < 0.1 to 1 Myr. It is also unlikely that the disk mass interior to Jupiter's orbit exceeded that exterior to its orbit by $\sim 0.1 M_\odot$, otherwise Jupiter's outward motion would have led to resonant capture of protoplanets and asteroids at its outer Lindblad resonance. The results in Sec. VII provide stronger limits on the disk mass as it is shown that modest radial migration would lead to a significant orbital eccentricity for the protoplanets. The small orbital eccentricity of the planets today implies that the mass of the nebula is

Figure 32. Orbital migration of the protoplanet in models 15 (left panel) and 16 (right panel) where $A = 10^{-3}$ and $B = 5$ and 80 , respectively. The labels a, b, and c represent three initial values for $r_o = 0.6, 0.7, 0.8$, respectively.

probably comparable to that deduced from the minimum mass nebula model.

IX. BINARY STAR-DISK INTERACTION

In addition to protoplanet-disk interaction, the above discussion can also be applied to binary star-disk interaction. Such interaction is most likely to occur during the formation of binary stars. In the past few years, several binary T Tauri stars have been observed (see Chapter by Bodenheimer et al.). These binary stars probably formed in a disk environment (Adams et al. 1989; Shu et al. 1990). In some binary T Tauri stars, infrared excesses have been observed and interpreted as evidence for protostellar disks (Mathieu et al. 1991). It is therefore timely to investigate tidal interactions between a binary star and an accretion disk. Such interactions are commonly observed in interacting binary stars in the post-main-sequence phase such as cataclysmic variables (Warner 1976; Robinson 1976; Wade and Ward 1985).

Unlike the star-planet configuration, low-order Lindblad resonances are excluded from the Roche lobe of both components of a binary system with modest mass ratio. Nevertheless, low order resonances may have a virtual

effect on disk structure because of their finite width. One task here is to determine the range of mass ratios for which coherent density waves are excited. Because the tidal perturbation of the companion is strong, the disk response is expected to be nonlinear. We will also evaluate the validity of extrapolating results based on linear approximations. The same numerical techniques used in Secs. V–VIII are ideally suited to these problems.

A. The Standard Model

To illustrate the disk response to a binary star, a standard model (model 16) is adopted in which $q = 1$, $c_0 = 10^{-2}$, and $v_{s0} = 10^{-5}$. Most of the following discussion will be centered on the response of an interior disk the inner boundary of which is set at $r = 0.25$. We refer to the star with the disk as the primary star and its companion as the secondary star.

Figure 33. Steady-state surface density distribution in model 16 in which $q = 1$, $c_0 = 10^{-2}$ and $v_{s0} = 10^{-5}$. Although the 2:1 resonance is excluded from the disk, the effect of virtual resonance regulates the $m = 2$ structure in the outer region of the disk.

Surface Density Distribution. The equilibrium Σ distribution is plotted in Fig. 33. The outer edge of the disk is an off-center ellipse with the major axis perpendicular to the line joining the two stars. The apoaapse of the outer edge is ~ 0.3 which is about half of the Roche radius of the primary. Although no Lindblad resonances are inside the disk, some influence of the lowest-order 2:1 resonances is implied by the presence of a low amplitude $m = 2$ response in the outer regions of the disk. In contrast to the disk response to a protoplanet's tidal torque (e.g., Fig. 6), Σ decreases monotonically with radius without any clear evidence of waves being excited. This is because the characteristic wavelength of the companion's tidal disturbance is comparable

with the disk radius which is much larger than the disk thickness, which produces an “impedance mismatch” in the absence of resonance. This is in contrast to some numerical computations (Matsuda et al. 1987) for thick disks where the sound speed is a large fraction of the Keplerian speed and waves may be excited.

Streamline Eccentricity and Shear Reversal. The streamlines of the flow depart significantly from those of a Keplerian pattern. The outer radius of the disk forms an asymmetric $m = 2$ pattern corotating with the binary star (left panel Fig. 38 below). The disk radius attains a maximum at $\xi \sim \pm\pi/2$ and a minimum at $\xi \sim \pi$. In the outer regions of the disk, the streamline eccentricity is approximately 0.1. The outermost streamlines extend slightly beyond the maximum nonintercepting periodic orbits (Paczynski 1977). Those orbits are computed for noninteracting particles whereas gas pressure prevents the crossing of streamlines.

Figure 34. Perturbed velocities and shear of five Lagrangian fluid elements in model 16. The local shear vanishes at $\xi = \pi$ where the streamlines approach to their perigee. The eccentricity of the streamlines exceeds 0.1.

In Fig. 34, we plot the orbital radius, v_r , v_ϕ and $\Omega^* \equiv (r/\Omega)(\partial\Omega/\partial r)$ as functions of ξ . Near $\xi = \pm\pi/2$, the streamlines in the outer regions of the disk are most radially extended and have essentially uniform specific angular momentum ($\Omega^* \sim -2$). Although the epicyclic frequency κ essentially vanishes near $\xi = 0$, Rayleigh's stability criterion is not violated. The variations

in r and V_ϕ indicate that the specific angular momentum on each streamline is essentially conserved. As streamlines converge toward their perigee at $\xi \sim \pi$, the local shear vanishes (i.e., $\Omega^* \sim 0$) and reverses as is shown in Fig. 19 (Sec. V.F) where $q = 10^3$. Nevertheless, the total angular momentum luminosity remains in the outward direction when the flux is integrated over all phases (Borderies et al. 1982, 1983). The radial velocity in the outer regions of the disk varies with azimuth approximately sinusoidally with an amplitude ~ 0.1 of the expected local Keplerian velocity. The azimuthal velocity varies similarly but with half the amplitude. These large amplitude variations imply that caution must be applied when using Doppler imaging techniques to map the disk structure and deduce the binary orbital properties (Marsh and Horne 1990*a, b*; Marsh et al. 1988; Hessman and Hopp 1990). In eclipsing interactive binaries, these velocity variations may be directly observed from the evolution of emission line profiles (Young et al. 1981; Marsh et al. 1987).

Figure 35. Amplitude of the perturbed velocities and surface density distribution at four orbital phases near $\xi = 0, \pi/2$, and $3\pi/2$. The values of the perturbed velocities are normalized to the local Keplerian velocity. These amplitudes exceed 10%.

The velocity variations also strongly modify the surface density profile in such ways that Σ decreases more rapidly with radius during the compression phase ($\phi \simeq \pi$) than during the rarification phase ($\phi \simeq \pm\pi/2$) (Fig. 35). At $\phi \sim 0$, the characteristic surface density scale height is $\sim 10^{-2}$ and the pressure gra-

dient provides an outward force per unit mass such that $|(1/\Sigma)(\partial \Sigma c^2/\partial r)| \sim 10^{-2} GM/r^2$. This is insufficient to change Ω significantly, but can strongly modify κ in this case. Also plotted in Fig. 35 are $\Delta v_r \equiv v_r(r/GM)^{1/2}$ and $\Delta v_\phi \equiv v_\phi(r/GM)^{1/2} - 1$. During some phases, Δv_r exceeds 0.1.

Figure 36. The distribution of viscous shear dissipation in model 16. Tidal disturbances do not introduce significant departure from the Keplerian values.

Dissipation Pattern. The modest departure from Keplerian flow in the outer regions of the disk slightly modifies the dissipation rate per unit area $D_\xi = \Sigma v_s r^2 (d\Omega/dr)^2$ from that of an isolated accretion disk where $D_K = 9\Sigma v_s \Omega^2/4$. These changes are brought about by both the variation in the shear and the Σ dependence of the viscosity. With the prescription adopted here, the reduction in the shear in the compressed regions (at $\xi \simeq \pi$) is compensated by a slight increase in the viscosity. Consequently, the D_ξ distribution differs little from D_K apart from the absence of dissipation in the gap (Fig. 36). The relatively small departure of D_ξ from D_K is because the tidal torque of the companion is distributed throughout the disk. In the absence of Lindblad resonances, the characteristic length scale of the tidal forcing is comparable to the disk radius. In addition, wave propagation may further diffuse the tidal disturbances. Azimuthal variations would be larger if ν increases more rapidly with Σ . We note that other than a dip at the relevant wavelength, the spectrum of a disk which is truncated by a binary is essentially identical to that of a disk which is unperturbed. This expectation is in agreement with observations of the binary T Tauri system GW Ori (Mathieu et al. 1991).

B. Model Parameters

Disk Temperature and Sound Speed. The size and structure of the outer disk is relatively insensitive to changes in the magnitude of the sound speed. In model 17, $c_0 = 0.08$ and all other parameters are identical to those in model 16. The Σ distribution in this case (Fig. 37) is essentially the same

as that in model 16. Similarly, the stream lines (right panel, Fig. 38) do not undergo significant changes. Despite a relatively large sound speed, the characteristic wavelength is an order of magnitude less than the disk radius so no coherent response to the companion's tidal effect is found. The results in Sec. IV indicate that a large sound speed also promotes the propagation of

Figure 37. Steady-state surface density distribution in model 17 where $c_o = 0.08$. Despite the large sound speed, density waves are not excited and the disk structure in this case resembles that in model 16 (Fig. 33).

Figure 38. Streamlines for model 16 (left component) and 17 (right component) in a corotating frame of the binary.

Figure 39. Steady-state surface density distribution for model 18 where the viscosity is high and sound speed is modest. The apogee of the streamlines reaches $0.39 r_o$ and the eccentricity is large (≥ 0.15).

tidal disturbances throughout the disk. With a much larger sound speed, it may also become possible for the disk to undergo a coherent response (Matsuda et al. 1989). However, in this limit, it becomes inappropriate to use the standard vertically averaged approximation for the equation of motion.

Viscosity. In the limit of low sound speed and high viscosity, most of the tidal disturbance is dissipated close to the location where it is excited. Thus at each radius, angular momentum flux induced by the companion's tidal torque is balanced by that due to viscous stress. With an increase in the magnitude of viscosity, the viscous transport of angular momentum becomes more efficient and the disk expands in radius. In model 18, we adopt the same parameters as in model 16 except $\nu_{s0} = 5 \times 10^{-5}$, a value 5 times bigger than that in model 16. The disk size increases by $\sim 30\%$ (Fig. 39). For some phases, the streamlines expand beyond the Roche radius (right-hand panel, Fig. 43 below). At the outermost regions of the disk, the eccentricity of the streamlines becomes ~ 0.2 and the shear is significantly reduced from its Keplerian value (Fig. 40). Although shear reversal occurs during some phases, the average value of the shear continues to correspond to an outward viscous transport of angular momentum.

The values of effective viscosity we have adopted here are much larger than what can be accounted for by molecular process; the physical process usually invoked to explain this excess is turbulence. In a turbulent disk, a relatively large viscosity may require a relatively large sound speed. The above results are not strongly altered if the sound speed is only a factor of 2 larger than in model 18. However, if the value of α in the α -prescription of turbulent viscosity is small and a large sound speed is thus needed for even a modest magnitude of viscosity, large gas pressure may efficiently induce wave propagation and redistribution of tidal disturbances over extended regions of

Figure 40. Perturbed velocities and shear of five Lagrangian fluid elements in the outer regions of the disk in model 18. Over most orbital phases, the local shear is significantly reduced from the Keplerian value.

the disk. In model 19, we adopt $v_{s0} = 5 \times 10^{-5}$ and $c_0 = 0.08$. In this case, the Σ distribution (Fig. 41) is similar to that of model 17 despite the fact that the viscosity is a factor of five larger. The size of the disk is smaller than that of model 18 (left-hand panel, Fig. 43), but the outermost streamlines in this smaller disk have eccentricity ~ 0.1 (Fig. 42). The dissipation pattern is much more smoothly distributed over the entire disk.

These theoretical results can be tested with observational data in the context of post-main-sequence cataclysmic variable stars. These systems are semi-detached close binaries in which the companion fills its Roche volume and transfers mass onto the accretion disk around the primary star (Warner 1976). In some cases, the orbital plane of the binary is essentially in the line of sight and the disk is eclipsed periodically. In these systems, the duration of the disk eclipse increases significantly during outbursts (Smak 1984). The most likely cause for these outbursts is thermal instability in the disk (Meyer and Meyer-Hofmeister 1981; Faulkner et al. 1983; Lin et al. 1985). During the onset of thermal instability, both c_s and ν increase. Because viscous transport of angular momentum increases with ν , the disk expands. As the disk fills the Roche volume, tidal transport increases rapidly with disk size (Papaloizou and Pringle 1977). A new equilibrium may thus be established with a larger disk (Smak 1984). Such a scenario is consistent with the results in models

Figure 41. Surface density distribution in model 19 which has the same viscosity as model 18 but much larger sound speed. Tidal disturbances are transmitted throughout the disk although no coherent waves are excited. Consequently, they are easily dissipated near the inner disk region.

16–19 where $\alpha \sim 0.1 - 1$.

Mass Ratio. In models 20–23, a range of mass ratios are considered where $q = 0.1, 0.3, 3$ and 10 . The sound speed and viscosity in these models are identical to those in model 16. In all these models, the disk extends to a significant fraction of the Roche lobe such that the streamlines in the outermost regions of the disk have eccentricity > 0.1 . The Σ distribution of models 20 and 21 shows a $m = 2$ response with the elongated axis perpendicular to the line joining the centers of the binary. Such a disk pattern indicates that the flow is under the influence of the inner Lindblad resonance. Such a pattern is observed even for $q = 1$. Although, for $q > 0.2$, the inner Lindblad resonance is not contained in the primary's Roche volume, it appears that because the resonance can be thought of as having a finite width, it still has a strong influence on the disk flow (Figs. 44 and 45). However, for $q > 1$, the Lindblad resonances are sufficiently remote from the disk that their finite width is insufficient for them to regulate the flow at the outer regions of the disk (Figs. 46–48). The disk structure in these cases are very similar to that for model 9 in which the companion's mass is 10^3 that of the gravitating object at the center of the disk.

C. External Disks and Width of Gap

The above models indicate that tidal truncation is a natural consequence of binary-star formation in a disk. This phenomenon can be observed as a dip in the power-law continuum spectrum from the disk. The range of wavelength for the dip is determined by the width of the gap which can be determined from the structure of both the inner and outer disks. Calculations based

Figure 42. Perturbed velocities and shear of five Lagrangian fluid elements in the outer regions of the disk in model 19. The flow pattern is different to both model 17 and 18. The large viscosity and sound speed remove the azimuthal symmetry about $\xi = \pi$.

on sticky particle hydrodynamics (Lin and Papaloizou 1979*b*) and smoothed particle hydrodynamics (Artymowicz 1990) show that the inner edge of a circumbinary disk is typically a 2-binary separation from the center of mass. The models presented in this chapter show that the width of the gap may be dependent on the thermal and viscous structure of the disk. In model 24, we use the Lagrangian scheme to determine the structure of a circumbinary disk which has the identical structure property as model 16, i.e., $v_{s0} = 10^{-5}$ and $c_0 = 10^{-2}$. In this case, the inner edge of the disk extends to a 2-binary separation from the center of mass. For the viscosity prescription, the inner edge of the disk retreats to larger values for disks with higher sound speed. However, other parameters being fixed, the inner edge moves to smaller values for disks with larger viscosity. These properties are consistent with similar behavior for the inner disk.

D. The Companion's Orbital Eccentricity

In Sec. VII, we showed that the orbital eccentricity of a protoplanetary companion grows in the post gap formation epoch. This eccentricity growth is driven by energy and angular momentum transfer at the Lindblad resonances. In binary stars with comparable masses, for Lindblad resonances associated

Figure 43. Streamlines for models 18 (right panel) and 19 (left panel) in a rotating frame. Note that the disk in model 18 is extended to the Roche surface. The disk size determined from eclipsed observation for model 18 is considerably larger than for models 16, 17 and 19. Although viscosity in models 18 and 19 are identical, the disk size is smaller for model 19 because the large sound speed promotes the distribution of tidal disturbance well into the inner regions of the disk.

Figure 44. Steady-state surface density distribution in model 20 where $q = 0.1$.

Figure 45. Steady-state surface density distribution in model 21 where $q = 0.3$.

Figure 46. Steady-state surface density distribution in model 22 where $q = 3$. Note that the flow in the outer regions of the disk has an $m = 1$ pattern which is different from the $m = 2$ response for disks in systems with $q \leq 1$.

with the ω_1 terms to occur in the inner disk, we require disk material with $\Omega \geq 3\omega$ (see discussion in Sec. VII). For Lindblad resonances associated with the ω_2 terms to occur in the outer disk, there needs to be finite amount of disk material with $\Omega \leq \omega/3$. Equality here corresponds to 3:1 resonances and such a resonance can exist inside the Roche lobe of the primary only for $q \leq 0.3$. Therefore, we would expect the tidal response to the terms proportional to the eccentricity to be dominated by either the presence in the disk of, or the virtual effect through the finite width of the 3:1 resonance even for moderately high mass ratios.

More generally, because of an impedance mismatch, an inner disk re-

Figure 47. Steady-state surface density distribution in model 23 where $q = 10$. The flow pattern is similar to model 9 where $q = 10^3$ (Fig. 18). The local surface density maximum at $\xi = \pi$ is due to the pressure gradient as streamlines converge near their perigee.

Figure 48. Steady-state surface density distribution of a circumbinary disk in model 24 where $q = 1$, $c_o = 10^{-2}$ and $v_{so} = 10^{-5}$. For binaries with identical q , the size of the gap increases with c_o and decreases with v_{so} .

sponds poorly to the low ω_2 frequencies as compared to the higher ω_1 frequencies. Similarly, an outer disk responds poorly to the higher-frequency ω_1 terms as compared to the lower-frequency ω_2 terms. Thus just as for the

protoplanet case, we expect

$$\frac{G^{1/2} M M_p}{2\sqrt{(M + M_p)}} \frac{d(r_0^{1/2} e^2)}{dt} > 0. \quad (177)$$

Therefore, if either $dr_0/dt < 0$, which would occur if there was an external disk alone, or r_0 is very slowly changing as would occur either in a disk-gap situation or in an interacting binary system, we expect $de^2/dt > 0$. In all of these cases, because the F_{Hi} are proportional to e^2 , the eccentricity grows exponentially on a time scale roughly equal to the ratio of the orbital angular momentum to the tidally induced angular momentum flow rate, calculated as if e were of order unity. This time scale is independent of, and can be much smaller than, the viscous evolution time of the disk-gap configuration so that eccentricities can grow within the lifetime of the system. However, we should stress the limitations of the above discussion. Because in the linear approximation, we have neglected the interaction of the tides induced by terms proportional to e with the circular orbit tides and have assumed that material was depleted at the Lindblad resonances associated with the circular orbit tides. In order to relax these assumptions it is necessary to do nonlinear time-dependent calculations of disk structure with an eccentric binary orbit. We have performed such calculations with the Lax-Wendroff scheme. The results obtained for these cases are similar to that in Fig. 26 (Sec. VI.D). These results are also in qualitative agreement with numerical simulations of binary star-disk interaction using a smoothed particle hydrodynamics scheme (Artymowicz et al. 1991).

E. Eccentric Disks

It has been suggested that the accretion disks associated with the SU Ursa Majoris subgroup of cataclysmic binaries might be eccentric (Whitehurst 1989; Hirose and Osaki 1989). Such behavior may result from possible excitation of parametric instabilities associated with 3:1 resonances in the disk. The disk is then made to appear eccentric through the presence of an $m = 1$ mode. A similar process may operate in planetary rings (Goldreich and Tremaine 1980).

To understand the proposed instability mechanism we consider a simplified model of a disk which is initially stationary when viewed from a reference frame corotating with the binary with a circular orbit which has period $2\pi/\omega$. We treat the disk as an axisymmetric and initially inviscid object being forced tidally by the nonaxisymmetric potential ψ_c . This tidal potential is supposed to have a negligible effect on the initial steady state which is approximated as axisymmetric, but is retained when linear perturbations are considered. We consider such a perturbation associated with a Lagrangian displacement $\xi \exp(i\sigma t)$. This can be found from an equation of the general form

$$\mathcal{O}(\sigma)\xi = -(\xi \cdot \nabla) \nabla \psi_c \quad (178)$$

which may be considered as giving the response to the perturbing potential given on the right-hand side exactly in the same way as in Sec. III.B. Here \mathcal{O} is a generalised linear operator, the detailed form of which is not needed to illustrate the instability.

Parametric instability occurs when two normal modes with different m in the axisymmetric disk have nearly the same eigenfrequency. These are uncoupled in the axisymmetric limit when ψ_c is neglected but become coupled and may interact unstably when it is included. To show this we look for a solution when $|\psi_c|$ is small of the form in cylindrical coordinates

$$\xi = a_1 \xi_1(r) \exp(im_1 \phi) + a_2 \xi_2(r) \exp(im_2 \phi) \quad (179)$$

where a_1 and a_2 are constants and ξ_1 and ξ_2 give the radial parts of the eigenfunctions for the axisymmetric disk associated with azimuthal mode numbers m_1 and m_2 , respectively. In order to give an eccentric disk, we require m_1 or m_2 to be 1. To obtain an equation for σ , we substitute the above specified form of ξ into Eq. (178) noting that differentiating with respect to ϕ is equivalent to multiplying by an appropriate value of m . We then multiply by $\Sigma \xi_k^* \exp(-im_k \phi)$, ($k = 1, 2$) and integrate over the disk so obtaining two linear equations for a_k , ($k = 1, 2$). Setting the determinant of the coefficients to zero then gives an equation for σ in the form

$$|\mathcal{O}_{i,j} + \mathcal{P}_{i,j}| = 0 \quad (180)$$

where

$$\mathcal{O}_{ij} = \delta_{ij} \int_{\text{disk}} \Sigma \xi_i^* \cdot \mathcal{O}(\sigma) \xi_j r dr d\phi \quad (181)$$

with δ_{ij} being the Kronecker delta, and

$$\mathcal{P}_{i,j} = \int_{\text{disk}} \exp[i(m_j - m_i)\phi] \Sigma \xi_i^* \cdot (\xi_j \cdot \nabla) \nabla \psi_c r dr d\phi. \quad (182)$$

The cross terms $\mathcal{O}_{i,j}$, $i \neq j$, are zero because of the orthogonality of modes with different m regardless of axially symmetric weight. Without loss of generality, we may assume that when ψ_c is Fourier analyzed in azimuth, there is no axisymmetric ($m = 0$) component. Then the diagonal elements \mathcal{P}_{ii} will be zero. In addition, we always have $\mathcal{P}_{ij} = \mathcal{P}_{ji}^*$. We suppose that the ξ_i , $i = 1, 2$ are eigenmodes of the axisymmetric disk with the same eigenvalue σ_0 , (but note that the assumption of strict equality here is not essential to the analysis), so that $\mathcal{O}_{ii}(\sigma_0) = 0$. For σ close to σ_0 , we adopt the first order Taylor expansion

$$\mathcal{O}_{i,i}(\sigma) = B_{ii}(\sigma - \sigma_0) \quad (183)$$

where

$$B_{ii} = \left[\frac{\partial}{\partial \sigma} (\mathcal{O}_{ii}(\sigma)) \right]_{\sigma=\sigma_0}. \quad (184)$$

Evaluating the determinant to find σ then gives

$$B_{11}B_{22}(\sigma - \sigma_0)^2 = |\mathcal{P}_{12}|^2. \quad (185)$$

From this we see that instability occurs if B_{11} and B_{22} are of opposite sign. This means that the modes have opposite signs of energy and angular momentum as measured in the rotating frame. If friction were applied to reduce the Lagrangian displacement to zero in this frame the positive energy mode would decay and the negative energy mode would grow. The parametric instability then occurs because of the interaction of positive and negative energy modes. To ensure that the modes have opposite signs of energy, m_1 and m_2 must be of opposite sign so that the modes which have the same eigenfrequency, propagate in opposite directions when viewed from the rotating frame. Also, we require that the modes are in fact coupled through the tidal potential which therefore must contain a nonzero Fourier component with $m = m_1 - m_2$.

The resonance condition that both modes must have $\sigma = \sigma_0$ in the axisymmetric disk can be evaluated by noting that in a thin disk that if there is to be significant spatial overlap of the modes, their inner/outer Lindblad resonances must coincide. Applying the dispersion relation (78) with $\sigma_0 \equiv -m\omega$, $k = 0$ and m set equal to m_1 and m_2 , respectively we get

$$[\sigma_0 + m_i(\Omega - \omega)] = \pm\kappa, i = 1, 2 \quad (186)$$

where ω has been subtracted from the gas angular velocity because we are in a rotating frame. If we take m_1 to be positive with the + alternative and m_2 to be negative with the - alternative, elimination of σ_0 leads to the condition that at the Lindblad resonance

$$\Omega - \frac{2\kappa}{(|m_2| + m_1)} = \omega. \quad (187)$$

For an eccentric disk, we must take $m_1 = 1$, then the smallest possible value of $|m_2|$ is 2. Then in a Keplerian disk, we require that at the Lindblad resonance, $\Omega = 3\omega$. Thus there needs to be a 3:1 resonance in the disk. In a slender planetary ring, larger values of $|m_2|$ are needed to satisfy the parametric resonance condition inside it.

The instability as described here requires two coherent modes in the unperturbed axisymmetric disk. However, because the instability occurs as the result of the interaction of positive and negative energy modes it is likely that only the $m = 1$ mode needs to have reasonable coherence. The excited $m_2 = -2$ disturbance may not need to be in the form of a normal mode. It could be a wave taking away energy and angular momentum, the excitation of which causes the $m_1 = 1$ mode to grow. We remark that in the inertial frame the $m_1 = 1$ mode rotates with a prograde pattern speed equal to $\Omega - \kappa$ evaluated at the 3:1 resonance.

It is unclear whether realistic models of disks in close binary systems allow a parametric instability of the type described above to occur. There is some evidence for the effect in particle simulations (Whitehurst 1989; Hirose and Osaki 1989). However, attempts to find the effect using the finite difference codes described here have so far been unsuccessful. It may be that conditions for the instability to occur are sensitive to the disk model.

X. SUMMARY

We briefly recapitulate the main conclusions and discuss some outstanding uncertainties.

A. Disk Response

A companion around a protostar exerts tidal torque on the disk. For a low-mass companion such as a protoplanet, density waves are excited at Lindblad resonances. These waves carry an energy and an angular momentum flux which are determined entirely by the gravitational force of the companion; they are independent of physical conditions in the disk. For a disk under the tidal influence of a companion with either a comparable mass (such as a binary T Tauri system) or a much larger mass (such as disk around a protoplanet), the Lindblad resonances are excluded from both the disk and the Roche lobe which contains the disk. In this case, unless the disk is geometrically thick, an impedance mismatch between the natural length scale of the tidal field and the characteristic wavelength in the disk prevents the excitation of density waves.

The propagation and dissipation of tidal disturbances is determined primarily by the thermal and viscous properties of the disk. In a non-self-gravitating disk, tidal disturbances propagate away from the companion at essentially the sound speed. In a vertically thermally stratified disk, refraction induces wavefront retardation and wave propagation into the disk atmosphere. Nonlinear dissipation in the tenuous disk atmosphere then leads to effective loss of wave action, a local deposition of the wave's angular momentum and reduction in the thermal stratification of the vertical structure. Thus, refraction may be a self-limited process (Larson 1990*b*). A natural next step of theoretical investigation is to carry out a self-consistent nonlinear analysis of wave propagation in a disk with a modest thickness. In addition to sound waves, internal and Alfvén waves may also be excited (Vishniac et al. 1991). The propagation speeds of these waves increase with the distances from the midplane and thus they may be focused toward the midplane. At large radii, the disk's self gravity may become important such that the characteristic wavelength becomes large compared with the disk thickness and the vertical thermal stratification may only negligibly impede wave propagation. The propagation and nonlinear dissipation of these waves needs to be further investigated.

Surface heating of the disk by nonlinear dissipation and irradiation can effectively eliminate the vertical temperature gradient in the disk. In an isothermal disk where the refraction effect is ineffective, density waves can propagate with little or no loss of wave action. As waves propagate inward from the inner Lindblad resonances, their wavelength decreases and amplitude increases. At large distances from the Lindblad resonances, these waves may either be dissipated viscously or become nonlinear leading to a local deposition of angular momentum. Energy dissipation then modifies the temperature distribution in the disk which may further modify the wave propagation speed and the condition for nonlinear dissipation. Self-consistent investigation of this issue is underway.

B. Implications for Protoplanetary Formation

Tidal interaction between a protoplanet and the protoplanetary disk is particularly important during the late stages of protoplanetary formation. The flux of tidally induced angular momentum transfer is determined by the mass of the protoplanet. When the protoplanet's mass becomes sufficiently large, it can induce gap formation in the vicinity of its orbit. Thereafter, gas in the disk can no longer flow through its orbit; a protoplanet's growth by accretion is terminated. There are two conditions for gap formation: (1) the mass ratio between the protostar and the protoplanet must exceed about 10^{-2} the effective Reynolds number so that the angular momentum flux induced by the companion's tidal torque exceeds that due to viscous stress; and (2) the Roche radius of the protoplanet must not exceed the vertical density scale height in the disk so that the flow near the truncated edges of the disk is stable. Discussions in Sec. VI imply that if gap formation terminates protoplanetary growth, a protoplanet can only acquire the present mass of Jupiter (1) if the disk is heated by turbulent viscosity; (2) if the mass of the disk is comparable to that estimated from the minimum-mass nebula scenario; and (3) if the viscous evolution time scale of the disk is ~ 0.1 to 1 Myr. With milliarsecond resolution, we should be able to resolve the spiral dissipation pattern induced by this protoplanet-disk interaction as far away as the Orion star-forming regions.

The actual gap-formation process determines not only the mass but also the spin angular momentum of a protoplanet. The remarkably low spin angular momentum of Jupiter and its satellites suggest that most of proto-Jupiter's mass is acquired through nearly spherical accretion rather than through mass transfer from the protoplanetary disk through Lagrangian points. This scenario is feasible if the gap formation is regulated by the second criterion. Such a condition requires the disk temperature near Jupiter to be relatively high ($H/r_o \sim 0.1$) and viscosity to be relatively low ($\alpha < 0.1$). The implication here is that a three-dimensional scheme must be used to analyze the secular evolution of the disk during the final stages of protoplanetary growth when the protoplanet acquires most of its final mass. Such a calculation is a natural next step in studying protoplanetary growth.

A lower limit for α may be obtained from the orbital properties of the protoplanet. After a gap is formed, gas is expelled from regions around the Lindblad resonances associated with the circular orbit tide, which are also located at corotation resonances when the orbit has a slight eccentricity. The disk and the protoplanet then continue their interaction only through the Lindblad resonances. For disk regions interior to a protoplanet's slightly eccentric orbit, energy is transferred from the disk to the protoplanet at a faster rate than that required to keep it in a circular orbit consistent with the amount of angular momentum transferred. This results in the growth of the protoplanet's orbital eccentricity. Interaction between a protoplanet and an external disk also amplifies the protoplanet's orbital eccentricity. The rate of eccentricity growth is determined by the disk's surface density. In order to restrain the protoplanetary orbits from attaining eccentricities greater than their present observed value, a solar nebula with a mass comparable to that in the minimum-mass-nebula model must have had an evolutionary time scale comparable to or shorter than ~ 1 Myr. This implies that $\alpha \geq 10^{-2}$. For a relatively low-mass protoplanet, the orbital eccentricity will grow until its orbit undergoes an excursion which takes it beyond the gap region. Subsequent nonlinear interactions remain uncertain and require further investigation. Another important issue to be investigated is the growth of the orbital inclination of protoplanets.

C. The Companion's Orbital Evolution

An important element in deducing physical conditions in the solar nebula is the assumption that both the terrestrial and giant planets are formed in the vicinity of their present orbits. However, tidal interaction between the disk and protoplanets can lead to orbital migration. For protogiant planets, after their mass becomes large enough to induce gap formation, their orbital migration is locked to the viscous evolution of the disk. If the disk is very massive, a protoplanet can migrate over a large radial extent. Such orbital migration would, however, lead to very large orbital eccentricities. The small observed eccentricity of the giant planets today implies that they are unlikely to have participated in large-scale radial migration and the mass of the nebula must thus be relatively low. These constraints, however, do not apply to prototerrestrial planets and protogiant planetary cores. The Roche radius of these bodies is smaller than the vertical scale height of the disk and gap formation will not occur. Nevertheless, these bodies participate in tidal interactions with the disk. Surface density gradients and velocity differences between the protoplanets and the gas can lead to nonvanishing differential tidal torques and thus to radial orbital migration. However, analyses of these processes remain uncertain because they are carried out with a thin disk approximation. A more appropriate analysis requires the investigation of wave excitation and propagation in three dimensions.

D. Binary Star-Disk Interaction

A large fraction of stars in the Galaxy are members of binary or multiple-star systems (Abt 1983). One of the most exciting recent observational results has been the discovery of binary T Tauri stars with circumbinary disks (Mathieu et al. 1991; Chapter by Bodenheimer et al.). Binary star-disk tidal interactions are similar to protoplanet-disk interactions in that they induce energy and angular momentum transfer. In binaries with nearly equal masses, density waves may not be excited because the Lindblad resonances are excluded from both the disk and the Roche lobe which contains the disk. Nevertheless, the finite width of Lindblad resonances permits the virtual effect of the resonances to be present. These effects promote eccentricity growth. Consequently, unless the residual disk mass in the vicinity of the binary is relatively small, binary T Tauri stars should acquire large orbital eccentricities on a time scale comparable to or less than the typical age of T Tauri stars (Artymowicz et al. 1991).

The rate of eccentricity growth may be reduced if the binary induces a sufficiently large gap near its orbit. Because tidal effects are large, both conditions for gap formation will generally be satisfied in circumbinary disks unless the disk's mass in the vicinity of the binary is comparable to the mass of the binary. The width of the gap is determined by the local sound speed and viscosity in the disk. Hot and inviscid disks have wide gaps whereas relatively cool and viscous disks have narrow gaps. A relatively wide gap would significantly reduce the effect of virtual resonances. The width of the gap should be directly observable as a dip in the disk spectrum (Mathieu et al. 1991).

The disk response to the companion's tidal disturbance remains a controversial issue. The results of some calculations show the excitation of self-similar density waves (Matsuda et al. 1989). Other calculations based on sticky particle schemes suggest the possible excitation of parametric resonances at 3:1 resonances (Whitehurst 1989; Hirose and Osaki 1989). Despite our efforts to reproduce these results, neither response is found with either the Lax-Wendroff scheme or the Lagrangian periodic scheme for disks with appropriate sound speeds and viscosities. Another interesting feature of these calculations is the strong nonlinear behavior of the streamlines near the outer edge of the disk. For eclipsing cataclysmic variable stars, the flow pattern of these streamlines can be observed directly using Doppler imaging techniques (Marsh and Horne 1990*a, b*). During the quiescent state when the disk is optically thin, the existence of the self-similar nonlinear wave dissipation may also be tested directly from observed temperature distribution in the disk (Horne 1985; Wood et al. 1986, 1989*a*). Thus, observations of post-main-sequence interacting binary systems may thus provide valuable clues to the formation of binaries in a disk environment.

EVOLUTIONARY TIME SCALES FOR CIRCUMSTELLAR DISKS ASSOCIATED WITH INTERMEDIATE- AND SOLAR-TYPE STARS

STEPHEN E. STROM, SUZAN EDWARDS and
MICHAEL F. SKRUTSKIE
University of Massachusetts

Sensitive infrared and millimeter-continuum measurements provide the basis for diagnosing the frequency with which disks are formed around solar-type and intermediate-mass stars, and the time scales for disk evolution. Optically thick disks in regions sampled by excess emission at $\lambda \leq 10 \mu\text{m}$ are found around 30% to 50% of young ($t < 3$ Myr) stars of all masses ($M < 3 M_{\odot}$); such disks are also found around young, higher-mass stars but with unknown frequency. Nearly all stars with optically thick disks have disk masses comparable to or greater than the minimum-mass solar nebula. Disk sizes range from $\simeq 10$ to $\simeq 1000$ AU. Hence, disks of solar system size, and of masses at least that of a minimum-mass nebula appear to form around a significant fraction of stars with $M < 3 M_{\odot}$. Disks survive as massive optically thick structures extending nearly to the stellar surface for times ranging from $t < 3$ Myr to $t \simeq 10$ Myr around solar-type pre-main-sequence stars; no optically thick disks have been identified around solar-type stars with ages $t \geq 30$ Myr. The survival times for disks surrounding more massive stars may be shorter. Evidence of infrared excess emission consistent with emission arising in optically thin disks is found for stars of all masses. These disks are presumably the descendants of objects originally surrounded by massive, optically thick disks. The presence of micron-size dust grains in optically thin disks requires that such grains be continuously supplied to the disk, possibly from (1) massive outer disk regions; (2) collisions among larger grains or planetesimals; or (3) evaporation of cometesimals. Disks with apparent “inner holes” have been discovered. These are most likely structures in transition between massive, optically thick disks that extend inward to the stellar surface, and disks that are optically thin throughout. The presence of an inner hole probably requires that the inner regions of a disk be isolated from the outer regions, and may indicate the formation of a Jupiter mass planet. The discussion of disk properties summarized in this review rests entirely on observations of micron-size dust embedded in circumstellar disks. Possible observations aimed at detecting the dominant component of primordial solar nebulae, the gas, are reviewed and discussed briefly.

I. INTRODUCTION

The formation of circumstellar disks appears to be a natural, if not inevitable, consequence of the process which gives birth to stars. Observations of young, optically visible pre-main-sequence (PMS) stars show that many solar-type

Figure 1. Spectral energy distributions for a selection of Herbig Ae/Be stars (top) and T Tauri stars (bottom). Superposed on this figure are spectral energy distributions for unreddened B5 (top) and K0 stars (bottom). The millimeter-continuum points plotted are from Beckwith et al. (1990) for the T Tauri stars, and from unpublished data obtained at the Cal Tech Submillimeter Observatory by Edwards, Strom and Keene. Note that the shapes of the excess emission above photospheric levels at $\lambda > 2.2 \mu\text{m}$ are similar for both young intermediate-mass and solar-type pre-main-sequence stars. We conclude that massive, optically thick disks of similar characteristics surround young solar-type and intermediate-mass stars.

($0.2 < M/M_{\odot} < 1.5$) and intermediate-mass ($1.5 < M/M_{\odot} < 10$) stars are surrounded by disks of solar-system dimension with masses comparable to or greater than the “minimum-mass solar nebula”^a (Adams et al. 1989,1990; Edwards et al. 1987; Strom et al. 1989d; Strom et al. 1989; Skrutskie et al. 1990; Beckwith et al. 1990) as evidenced by:

1. Broad forbidden line profiles, which diagnose outflowing gas driven by

^a The minimum-mass for the solar nebulae, $M_{\text{mm}} \simeq 0.01 M_{\odot}$, is computed from the total mass of the planets, adjusting for the difference in chemical composition between the planets and the interstellar medium.

PMS stars and show only *blueshifted* components; no redshifted emission is observed. The receding gas in the outflow is presumed to be occulted by an *optically thick disk* of dimension about 10 AU to hundreds of AU (see, e.g., Appenzeller et al. 1984; Edwards et al. 1987; Hamann and Persson 1989; Cabrit et al. 1990).

2. Infrared, submillimeter, and millimeter-continuum radiation in excess of photospheric levels which finds most straightforward interpretation in terms of emission arising in circumstellar disks (Myers et al. 1987; Adams et al. 1987; Kenyon and Hartmann 1987; Chapters by Edwards et al. and by Hartmann et al.). Such excesses (see Fig. 1) arise both from photospheric radiation absorbed and re-radiated by circumstellar dust grains ("reprocessing"), and from heating of circumstellar gas and dust via accretion (see Lynden-Bell and Pringle 1974; Kenyon and Hartmann 1987; Adams et al. 1987; Bertout et al. 1988; Bertout 1989).

For most solar-type PMS stars surrounded by optically thick disks, the masses deduced from modeling infrared and mm spectra lie in the range $0.01 < M_{\text{disk}}/M_{\odot} < 0.1$ (Beckwith et al. 1990), while sizes range from 10 AU to 1000 AU (Edwards et al. 1987; Adams et al. 1990). The range of masses and sizes for disks surrounding young intermediate mass stars is not as well established because systematic surveys of infrared and mm-continuum spectral energy distributions and forbidden line profiles are currently lacking.

No main-sequence stars exhibit strong infrared excess emission characteristic of the massive, optically thick disks which surround many stars during earlier evolutionary phases. Hence, the mass of disk material in the form of small dust grains must decrease with time. The observation of infrared and millimeter-continuum emission arising in massive, optically thick disks surrounding young PMS stars of all masses, combined with the absence of such signatures among their older stellar counterparts provides the basis for establishing time scales for disk evolution from studies of intermediate-age stars. Such time scales provide an astronomical constraint on the time available for building large grains and possibly planetesimals.

The goals of this contribution are the following:

1. To determine the frequency with which massive, optically thick disks (with mass in the form of *distributed* micron-size dust and orbiting gas greater than that of the minimum-mass solar nebula, M_{mm}) form around solar-type and intermediate mass stars. Our strategy will be to develop criteria for diagnosing massive, optically thick disks, and to determine the fraction of young, optically visible stars surrounded by such disks. Because some disks may evolve on time scales short compared to the time required for stars to emerge from optically opaque protostellar cores, this fraction will represent a *lower limit* to the fraction of all stars which form disks massive enough to make planetary systems similar to our own.
2. To determine the range of *survival times* for massive, optically thick

disks by determining the fraction of stars surrounded by such disks as a function of stellar age. Our discussion of the frequency of disk occurrence and the time scales for disk evolution will rest exclusively on observations of emission from distributed circumstellar *dust*. Establishing time scales for the evolution of the *gas* component of disks is essential, but technically far more difficult at present.

3. To establish the existence of the probable descendants of massive, optically thick disks: *optically thin* dust disks, perhaps analogous to the structures surrounding Vega and β Pictoris (Aumann et al. 1984; Gillett 1986; Backman and Gillett 1987; Chapter by Backman and Paresce). The mass in *distributed* material (as opposed to dust and gas which have been assembled into larger grains, planetesimals, or planets) will be small ($M_d < M_{mm}$). Such disks are best detected at present from high precision infrared observations capable of measuring small excess emission above photospheric levels. We shall argue that optically thin disks must represent secondary structures, continuously replenished by small grains produced either *in situ* via collisions between large grains or planetesimals (see Gillett 1986; Backman and Gillett 1987; Chapter by Backman and Paresce), or supplied from material (e.g., small grains and cometesimals) stored in outer regions of the disk and introduced into the inner disk via Poynting-Robertson drag or gravitational scattering. If planetesimal collisions are the dominant source of dust replenishment, then measurement of optical depths for disks surrounding stars sampling a wide range of ages will provide a measure of the rate of dust production via collisions as a function of stellar age, and thus an astronomical constraint on the time scale(s) for assembling planetesimals into larger bodies.
4. To establish the existence of structures in transition between those which are optically thick from the stellar surface outward, and those which are optically thin throughout. Observational practicalities force us to search for transition structures in which the inner disk regions have cleared and are optically thin (the absence of warm dust in the inner regions will result in small near-infrared excesses), while the outer disk regions remain optically thick (the presence of cool dust in the outer regions will produce large far-infrared excesses). We shall argue that this type of transition structure may require that the inner and outer disks be isolated, and that the formation of a giant planet represents a natural mechanism for ensuring that material from the outer disk is prevented from entering the inner disk. So interpreted, the ages of these systems would provide upper limits to the time scale for building a giant planet. Their number, relative to the number of stars surrounded by optically thick disks, would provide an estimate of the time required following giant planet formation for gas and small dust grains in the initially optically thick inner disk regions to be accreted by the star.
5. To review current efforts and future prospects for measuring the gas

content of disks and discuss their implications for constraining the time scale for building gas-rich planets.

II. OBSERVATIONAL CRITERIA FOR DIAGNOSING DISK PROPERTIES

Direct determinations of disk masses depend on modeling of far-infrared, sub-millimeter and millimeter-continuum excesses arising in circumstellar disks (Beckwith et al. 1990; Adams et al. 1990). Submillimeter and millimeter-continuum measurements are particularly critical because at wavelengths $\lambda \leq 100 \mu\text{m}$, disks are usually optically opaque (see below); flux measurements below $100 \mu\text{m}$ are therefore insensitive to the disk mass. Unfortunately, mass determinations are thus far available for a relatively small and not completely representative sample of PMS stars (Beckwith et al. 1990; Chapter by Beckwith and Sargent). However, examination of the frequency distribution of disk masses derived for solar-type stars by Beckwith et al. (1990) reveals that virtually all disks with masses $M \geq M_{mm}$ have optical depths $\tau \geq 1$ as inferred from measurements of excess infrared emission at wavelengths $\lambda \leq 10 \mu\text{m}$. This result is not surprising because if a disk has (1) a mass $M_d = 0.01 M_\odot = M_{mm}$; (2) a radius of 50 AU; (3) a gas/dust ratio and a grain size distribution characteristic of the interstellar medium; and (4) dust grains which are distributed uniformly throughout the disk, then the disk will have an optical depth, $\tau(\lambda) \sim 1$ at $100 \mu\text{m}$, and will be optically thick at all wavelengths $\lambda \leq 100 \mu\text{m}$ (for an assumed grain emissivity $\simeq \lambda^{-1}$ for $\lambda > 1 \mu\text{m}$). Disks with $M_d < M_{mm}$ will have correspondingly smaller optical depths at all wavelengths. Hence, it is possible to use estimates of disk optical depth inferred from near- and mid-infrared excesses as a surrogate means of identifying disks having masses in distributed material $M_d \geq M_{mm}$. Such measurements are available for large samples of stars covering a wide range in age and mass.

Different wavelength regimes probe the optical depth in different regions of the disk, as the equilibrium dust temperature falls with increasing distance from the star. For example, in an optically thick reprocessing disk surrounding a star with luminosity $L_* = 1 L_\odot$, the dominant contribution to the observed fluxes at $100 \mu\text{m}$, $10 \mu\text{m}$ and $2 \mu\text{m}$ arises from dust located at radial distances of ~ 4 AU, 0.2 AU and 0.04 AU, respectively. Given observations of sufficient sensitivity, the observed infrared excess relative to the photospheric flux can determine whether the disk is optically thick or thin at a radius corresponding to the wavelength of observation. Figure 2a shows the computed spectral energy distribution for a “typical” solar-type PMS star of spectral type M0 in Taurus-Auriga, and the spectral energy distribution for such a star surrounded by a perfectly flat, optically thick reprocessing disk viewed at inclination angles, $i = 0^\circ$ (pole-on) and $i = 80^\circ$; Fig. 2b shows the corresponding stellar, and star-plus-disk spectral energy distributions for a main-sequence A0 star at the same distance. Accretion and disk “flaring” can increase the observed

infrared spectral energy distribution above the solid line (Kenyon and Hartmann 1987); inclination effects reduce the observed disk contribution from its maximum for pole-on stars, by a factor $\sim \cos(i)$.

In the following discussion, we will consider stars showing excess emission falling below the expected emission for a flat, optically thick disk viewed at $i = 80^\circ$ at a given wavelength λ to be *candidates* for objects surrounded by disks that are *optically thin* at those radii which dominate contributions to the observed flux at λ . Among a large sample of such candidates, 1/6 may in fact be optically thick disks viewed at $i > 80^\circ$. We shall consider stars showing excess emission falling above this level as *candidates* for objects surrounded by *optically thick* disks, recognizing that among a large sample of such candidates, we could include some optically thin disks with $0.2 < \tau < 1$ (if such disks exist).

By using the observed infrared excess radiation to infer the radial variation of disk optical depths, we can define 3 disk classes:

1. Optically thick disks: if $\tau(\lambda) \geq 1$ for all wavelengths $\lambda \leq 100 \mu\text{m}$, the radial surface density distribution of dust is *consistent* with that of a nebula with $M_{\text{disk}} \geq M_{\text{mm}}$ extending to the stellar photosphere.
2. Optically thin disks: in practice, observations will reveal two categories of stars: (1) those in which there are no infrared excesses above photospheric levels to within observational uncertainties; and (2) those that show small excesses consistent with $\tau \ll 1$. Stars in category (1) either were never surrounded by disks or were surrounded by disks which were quickly ($t \ll 1$ Myr) disrupted or have evolved over longer times to a point where the mass of distributed material is too small to detect. We will argue (see below) that disks in category (2) must represent structures in which small dust grains are continuously supplied to the inner disk regions probed by infrared observations at $\lambda \leq 100 \mu\text{m}$.
3. Transition disks: if for $\lambda < 100 \mu\text{m}$, $\tau(\lambda) \geq 1$ at wavelengths λ longer than some wavelength, λ_0 , and $\tau(\lambda) \ll 1$ for $\lambda \leq \lambda_0$, then we conclude that such a disk lacks "warm" distributed dust (diagnosed by small excess emission at $\lambda < \lambda_0$) in its inner regions, but is surrounded by an optically thick outer disk (inferred from the observed infrared excess at $\lambda > \lambda_0$). The "hole" in the inner disk regions could result from: (1) more rapid assembly of small grains into larger bodies in the inner disk, where the shorter dynamical time scales may hasten the agglomeration process; or (2) accretion of material in the inner disk following the formation of a giant planet which isolates the inner and outer disk regions (S. Ruden, personal communication). If disk optical depths in the inner regions are high, while those in the outer regions are low, we would conclude that either such disks initially had small radii, or that assembly of dust grains into larger bodies may have begun first in the outer disk regions. In practice (see below) the current sensitivity of long-wavelength ($\lambda \geq 25 \mu\text{m}$) infrared measurements precludes detection of this class of transition structure.

Figure 2. (a) A plot of the spectral energy distribution for a "diskless" M0 star (dark solid line) of radius $3 R_{\odot}$, and an M0 star surrounded by a flat reprocessing disk viewed at inclinations $i = 0^{\circ}$ (pole-on; light dotted line) and $i = 80^{\circ}$ (light dashed line). Superposed on this plot are the 5σ limiting fluxes which can be achieved in an integration time of 1 hr on the 3-m diameter IRTF at wavelengths $\lambda \leq 10 \mu\text{m}$, along with the limits reached by the IRAS for $\lambda \geq 12 \mu\text{m}$ for such a star observed at the distance of the nearby ($d = 150 \text{ pc}$) Taurus-Auriga complex. (b) Identical to (a) except for an A0 main-sequence star.

Classification of disks into these categories depends critically upon the ability of infrared measurements to distinguish between optically thin and optically thick disks. We indicate in Fig. 2 the 5σ sensitivity limits for groundbased IRTF ($1.6\ \mu\text{m} \leq \lambda \leq 10\ \mu\text{m}$; assuming 1 hr integration) and IRAS measurements for a "typical" solar-type PMS star in Taurus-Auriga ($d = 150\ \text{pc}$). The IRAS sensitivity limits lie near or *above* the level of excess radiation expected from a flat reprocessing disk, and well above the limit required to detect stellar photospheric emission. Hence IRAS measurements cannot, in general, reveal weak infrared excesses arising in optically thin disks surrounding solar-type PMS stars in Taurus-Auriga. Diagnosis of optically thin regions in disks surrounding PMS stars in nearby star-forming regions must therefore depend primarily on groundbased measurements at wavelengths $\lambda \leq 10\ \mu\text{m}$. IRAS measurements are however, capable of detecting excess radiation at $\lambda \geq 12\ \mu\text{m}$ from many optically thick disks surrounding known solar-type PMS stars in this region. For stars with photospheric luminosities $L_* > 100\ L_\odot$ and located within $\sim 200\ \text{pc}$, IRAS measurements are sufficiently sensitive at $12\ \mu\text{m}$ and $25\ \mu\text{m}$ to permit detection of emission from all optically thick, and some optically thin disks.

Let us define a quantitative measure of the infrared excess at a given wavelength X as $\Delta X = \log_{10}[F(X)_0/F(X)_*]$. Here, $F(X)_0$ is the observed flux for a PMS star corrected for interstellar reddening, while $F(X)_*$ is the photospheric flux predicted for a disk-free star of spectral type identical to the PMS star. Thus ΔK and ΔN , for example, represent the logarithm of the ratio of the observed flux to the flux expected from the PMS star photosphere at $2.2\ \mu\text{m}$ and $10\ \mu\text{m}$, respectively (see Strom et al. 1989*d*). For the discussion that follows, we choose the excess infrared radiation at $2.2\ \mu\text{m}$ and $10\ \mu\text{m}$ as diagnostic of the state of the inner disk, because $10\ \mu\text{m}$ is the longest wavelength where achievable sensitivity permits the detection of typical stellar photospheres of solar-type PMS stars in Taurus-Auriga, and $2.2\ \mu\text{m}$ is the shortest wavelength where an optically thick reprocessing disk contributes more than 30% of the total flux in such stars.

Candidate *optically thick* disks will be those with ΔK and ΔN values which exceed the critical values ΔK_c and ΔN_c , listed in Table I for a flat, optically thick reprocessing disk viewed at an inclination $i = 80^\circ$; candidate *optically thin* disks will be those having ΔK and ΔN values *smaller* than these critical values. For a central star of luminosity $L_* = 1\ L_\odot$, the $2.2\ \mu\text{m}$ and $10\ \mu\text{m}$ radiation will arise from small grains located in disk regions centered at distances $r < 1\ \text{AU}$, and thus diagnoses the optical depth in the inner terrestrial planet region; these distances will scale as $L_*^{1/2}$.

III. FREQUENCY OF OPTICALLY THICK DISK OCCURENCE AMONG YOUNG STARS

A. Solar-Type Stars

Strom et al. (1989*d*) and Skrutskie et al. (1990) have recently compiled infrared fluxes for a sample of 83 solar-type PMS stars in Taurus-Auriga; most stars in this sample are spectral types between K0 and M5. We make use of these flux values along with their estimates of the expected level of photospheric radiation to compute ΔK and ΔN values based either on $10\mu\text{m}$ fluxes measured at the NASA IRTF, or on IRAS $12\mu\text{m}$ fluxes. In Fig. 3, we plot the frequency distribution of ages among the stars in the Strom et al. sample. Ages derived from comparing the location of these stars in the HR diagram with computed pre-main-sequence evolutionary tracks; the uncertainties in such ages may exceed ± 0.5 dex in some cases (see Kenyon and Hartmann 1990; Hartmann and Kenyon 1990). We also indicate the locations of stars with $\Delta K \geq 0.2$ dex (the critical value, ΔK_c , for a F0-type star, separating candidate optically thick from optically thin disks at $2.2\mu\text{m}$; see Table I) and note that 22/48 stars with ages $t < 3$ Myr are surrounded by optically thick disks as judged from ΔK ; the corresponding fraction as judged from $\Delta N \geq 0.8$ dex is 28/37 for the smaller subset of stars having adequate N -band or IRAS measurements.

TABLE I
Predicted Excess Emission From Flat Reprocessing Disks
Viewed at Inclinations $i = 80^\circ$ and 0°

Spectral Type	ΔK_c (dex)	ΔN_c (dex)	ΔK_c (dex)	ΔN_c (dex)
	$i = 80^\circ$		$i = 0^\circ$	
B0	0.78	1.83	1.48	2.59
B3	0.49	1.45	1.11	2.20
B5	0.38	1.27	1.95	2.01
A0	0.25	1.05	0.74	1.78
F0	0.16	1.84	0.55	1.55
G0	0.12	0.73	0.46	1.43
K0	0.10	0.67	0.40	1.35
M0	0.06	0.52	0.28	1.16

We thus conclude that approximately 50% of all young ($t < 3$ Myr) solar-type stars are currently surrounded by disks that are optically thick at $r < 1$ AU. Although the mass contained within 1 AU represents a small fraction of the total mass in a minimum-mass nebula, nearly all PMS stars in our sample with optically thick *inner* disks appear to have masses in the range $0.01 < M/M_\odot < 0.1$ as judged from the recent millimeter-continuum measurements of Beckwith et al. (1990). [We note that the sample of solar-type PMS stars in Taurus-Auriga is incompletely known, particularly among “weak

Figure 3. The observed frequency distribution of derived ages for the sample of stars in the Taurus-Auriga complex compiled by Strom et al. (1989a). We separate the sample into two categories: (1) stars with $\Delta K \geq 0.2$ dex (the condition for a candidate optically thick disk surrounding a G0 star in those regions contributing to the $2.2 \mu\text{m}$ flux; see Table I), the locations of which are indicated by the hatched region; and (2) stars with $\Delta K < 0.2$ dex. We draw two conclusions from this figure: (i) \sim half of all *known* solar-type stars in Taurus-Auriga with ages $t < 3$ Myr are surrounded by optically thick disks; (ii) as judged from ΔK , the survival time of optically thick disks ranges from $t < 3$ Myr to $t \sim 10$ Myr; few disks survive as infrared-detectable entities at ages in excess of 10 Myr.

emission" T Tauri stars (WTTS) heretofore detected primarily by X-ray observations. These stars, in general, do not show signatures of optically thick disk emission (Walter et al. 1988; Strom et al. 1989d; Chapter by Montmerle et al.).]

To ensure that in most cases ΔK and ΔN provide consistent diagnostics of disk optical depth, we plot ΔN against ΔK (Fig. 4); the uncertainty in ΔN and ΔK is estimated to be ± 0.10 dex. This figure reveals that for a sample of 51 stars having both ΔK and ΔN values, the large majority, 39/51, are selected as candidate optically thick or optically thin disks based on *both* ΔN and ΔK . Figure 4 also reveals that the sample stars fall in two clearly separated regions: the domain occupied by optically thick disks ($\Delta N > 0.8$ dex), and the domain occupied by candidate optically thin disks. The group of objects with $\Delta N > 0.8$ dex is dominated by "classical" T Tauri stars. Their location in the ΔN - ΔK plane finds ready explanation if all such T Tauri stars are surrounded by optically thick disks heated by a combination of radiation from the central star and accretion. Stars in our sample with $\Delta N < 0.8$ dex and $\Delta K < 0.2$ dex are dominated by weak emission T Tauri stars (WTTS; see Walter et al. 1988; Strom et al. 1989a; Chapter by Montmerle et al.). From the

Figure 4. A plot of ΔN against ΔK , the logarithmic ratios of observed to photospheric fluxes at $10\ \mu\text{m}$ and $2.2\ \mu\text{m}$, respectively, for all stars in the Strom et al. (1989) and Skrutskie et al. (1990) samples for which adequate ($>3\sigma$) estimates of these quantities are available. Note that systematic errors in determining ΔK and ΔN are estimated to be $\sim\pm 0.1$ dex. The sample stars fall in two domains separated by a gap. We superpose on this figure the loci defined by (1) flat reprocessing disks viewed at inclination angles ranging from $i = 0^\circ$ (pole-on) to $i = 60^\circ$; (2) two flared reprocessing disks viewed over the same range of inclination angles; the disk scale height h varies with radial distance r , as $r^{9/8}$ (middle dotted line), and $r^{5/4}$ (top dotted line); and (3) slightly flared ($h \sim r^{9/8}$ accretion disks with mass accretion rates ranging from 10^{-8} (leftmost star symbol), to 10^{-7} (middle star symbol), to $10^{-6}\ M_\odot\text{yr}^{-1}$. These model disks are assumed to surround a star of type M0, typical of the solar-type PMS population in Taurus-Auriga. The two circled points denote the locations of the candidate "transition" cases V819 Tau and DI Tau.

above arguments, these stars must be surrounded by optically thin inner disks. The paucity of stars with ΔN values between 0.3 and 0.8 argues strongly that (1) the majority of stars with $\Delta N < 0.2$ dex represent optically thin disks rather than the extrema (disks viewed nearly equator-on) in a continuum of optically thick disks ($\Delta N > 0.8$ dex) viewed at differing inclinations; and (2) the transition between disks with $\tau \geq 1$ and $\tau \ll 1$ must be rapid as there are few disks with infrared excesses consistent with disks having intermediate ($0.2 < \tau < 1$) optical depths (see the Chapter by Edwards et al.). This result provides strong *ex post facto* confirmation of the practical utility of our criteria for selecting optically thick and optically thin disks.

It is also noteworthy that nearly all solar-type PMS stars selected to have massive, optically thick disks (with both ΔK and ΔN exceeding ΔK_c and ΔN_c , respectively) also show evidence of (1) boundary layer emission diagnosed by excess ultraviolet and optical continuum emission, and indicative of accretion of disk material onto the surface of the star; and (2) broad H α

emission and forbidden line profiles (Chapter by Edwards et al.; Hartigan et al. 1990a), indicative of energetic winds. Disks with smaller excesses generally show neither measurable optical veiling, nor energetic wind signatures.

B. Intermediate-Mass Stars

Observations of a group of stars known as Herbig Ae/Be stars provide convincing evidence that some intermediate-mass stars with $M > 1.5 M_{\odot}$ are surrounded by massive, optically thick disks during early evolutionary phases.^b These stars were selected (Herbig 1960) on the basis of (a) spectral type (type A or earlier); (b) strong H α emission (a characteristic shared with solar-type PMS stars of the T Tauri class); and (c) close association with molecular cloud material as evidenced by their illumination of reflection nebulae. Strom et al. (1972) and Finkenzeller and Mundt (1984) located these stars in the HR diagram and found them to be PMS stars with ages in the range 0.2 to 1 Myr, and with masses $1.5 < M/M_{\odot} < 10$. Values of ΔK and ΔN for Herbig Ae/Be stars derived from the observations of Strom et al. (1972), Lorenzetti et al. (1983) and from the IRAS *Point Source Catalog*, are consistent in a large majority of cases with emission arising from massive, optically thick disks. Unfortunately, the fraction of the population of young ($t < 1$ Myr) stars with $M > 1.5 M_{\odot}$ represented by stars selected with Herbig's criteria is unknown. Hence, the infrared properties of Herbig Ae/Be stars establishes the *existence*, but not the *frequency* with which massive, optically thick disks form around stars in this mass range.

The disk occurrence frequency for intermediate stars must rest at present on estimates of disk optical depth in the inner disk provided by the $2.2 \mu\text{m}$ excess, ΔK , in two well-studied young clusters: (a) the Orion Nebula cluster (Walker 1969; Penston 1973; McNamara 1976); and (b) NGC 2264 (Walker 1956; Warner et al. 1977); both clusters contain stars with ages ranging from 1 to 10 Myr. There are as yet no surveys which permit optical depth estimates based on ΔN for representative samples of young, intermediate-mass stars.

We estimate ΔK values for intermediate-mass stars in Orion and NGC 2264 from the reddening-corrected ($V - K$) color index $\equiv 2.5 \log[F(2.2 \mu\text{m})/F(0.55 \mu\text{m})]$. Reference to Fig. 2b shows that for an optically thick reprocessing disk, the flux at V ($0.55 \mu\text{m}$) is dominated by the stellar photosphere, while at K ($2.2 \mu\text{m}$) the flux is dominated by disk emission. Hence, the difference between the reddening-corrected ($V - K$) index and

^b Perhaps the most persuasive arguments are provided by (1) the similarity of Ae/Be star infrared spectral energy distributions to those of solar-type PMS stars believed to be surrounded by disks (see Fig. 1); and (2) the recent millimeter-continuum observations obtained at the Caltech Submillimeter Observatory by Strom et al. (1990, unpublished). The observed millimeter-continuum fluxes lead to mass estimates of ~ 0.1 to $1 M_{\odot}$ for the objects included in their sample. Were the gas and dust corresponding to this mass distributed in a spherical envelope of radius 500 AU, the optical depth at $0.55 \mu\text{m}$ would be ~ 100 if $M(\text{env}) \sim 0.1 M_{\odot}$. By confining the material to a relatively flattened disk, one can produce the same mm-continuum fluxes while preserving an optically thin line of sight to the star at most viewing angles.

the $(V-K)$ color for a standard star of identical spectral type, will yield $\Delta K \sim [(V-K)_0 - (V-K)_{\text{std}}]/2.5$. Stars with $\Delta K \geq \Delta K_c$ (see Table I) appropriate to their spectral type are considered candidates for systems surrounded by optically thick disks.

Ages for individual stars are estimated from their location in the HR diagram relative to computed pre-main-sequence evolutionary tracks (Iben and Talbot 1966). In practice, such determinations are possible only for objects that have yet to reach the main sequence: stars with mass $M \leq 3 M_\odot$ in these clusters. For proper motion members (probability $\geq 80\%$) of these clusters in the mass range $1.5 \leq M/M_\odot \leq 3$, having ages $t < 3$ Myr, we find that in Orion, the fraction of stars with optically thick disks as judged from ΔK is 9/23 (Penston [1973] sample), and 10/19 (McNamara [1976] sample); in NGC 2264, the corresponding fraction is 7/18 (Warner et al. [1977] sample). Hence the frequency with which massive, optically thick disks are found among young stars of mass $1.5 < M/M_\odot < 3$ may be comparable to that characterizing solar-type stars of similar age.

Both clusters contain PMS stars with masses $M < 3 M_\odot$, and ages as small as $t \sim 1$ Myr as judged by their location in the HR diagram relative to computed evolutionary tracks. While age determinations are impossible for more massive stars (because they have reached the main sequence), it is likely that at least some of these stars have ages comparable to those of the youngest PMS stars ($t \sim 1$ Myr). Nevertheless none of the 11 stars in NGC 2264 with $M > 3 M_\odot$ and nominal ages $t \geq 1$ Myr have ΔK values signifying the presence of optically thick disks (neither the McNamara nor Penston sample in Orion include a significant number of main-sequence B stars). However, the presumed precursors of these stars, Herbig Be stars with masses $M > 3 M_\odot$ and ages $t < 1$ Myr, show evidence for massive, optically thick disks. Thus, the *survival time* for massive optically thick disks may be short for stars in this mass range. Observations of a much larger sample of B stars in young clusters is clearly desirable in order to confirm this result.

IV. SURVIVAL TIME SCALES FOR OPTICALLY THICK DISKS

The range of survival times for massive, optically thick disks is derived from the range of ages over which such disks are detected around young stars. The presence of optically thick disks is diagnosed from the magnitude of the observed infrared excesses (Fig. 2; Table I). Ages are estimated from the observed location of such stars in the HR diagram relative to computed PMS evolutionary tracks. Such ages, particularly for classical T Tauri stars, should be treated with caution, because the effects of infall and accretion have not been incorporated into currently available pre-main-sequence evolutionary tracks (see Hartmann and Kenyon 1990; Kenyon and Hartmann 1990); ages for weak line T Tauri stars in which accretion has ceased may be more reliable.

A. Solar-Type Stars

The information required to estimate the range in survival times for optically thick disks is also provided in Fig. 3. We interpret this histogram as follows: if *all* solar-type PMS stars are surrounded initially by optically thick disks, then by an age $t \sim 3$ Myr, $\sim 50\%$ of these disks have been accreted, disrupted or have begun to form larger bodies. Candidate optically thick disks (as judged from ΔK) are found around only 1/11 stars in our sample older than 10 Myr. Hence, we conclude that few disks survive as optically thick structures for ages much in excess of 10 Myr.

Strong confirmation of this limit on survival times is provided by unpublished near-infrared observations (J. Stauffer and R. Joyce, personal communication) of 15 main-sequence G stars in the α Perseii cluster (age ~ 30 to 50 Myr). None of these stars exhibits a near-infrared excess ΔK , consistent with emission arising in an optically thick disk.

Note that our discussion of disk survival time relies exclusively upon ΔK estimates; in principle, similar estimates could be made from ΔN and mm-continuum excesses. Unfortunately, while the sample of stars with $10\ \mu\text{m}$ measurements of precision adequate to distinguish between excess emission arising in optically thick and optically thin disks includes a large fraction (90%) of known solar-type PMS stars in Taurus-Auriga with ages $t < 3$ Myr, more than 55% of those stars with ages $t > 3$ Myr lack such measurements. A similar under-representation of older PMS stars is found among the Beckwith et al. (1990) sample of millimeter-continuum measurements. Hence, at present we can only estimate the range in times over which disks remain optically thick in their innermost regions ($r < 1$ AU). We emphasize as well that infrared and millimeter-continuum measurements probe only emission arising from circumstellar dust; *gas* survival times should not be inferred from these observations.

B. Intermediate-Mass Stars

At present, no comprehensive studies yielding ΔK , ΔN , or mm-continuum excesses are available for intermediate mass stars having a wide range of ages. Quantitative estimates of disk survival times must thus await observations of infrared spectral energy distributions for B, A and F stars in clusters and associations sampling a broad range of ages: for example, NGC 6611 (age ~ 1 to 3 Myr; distance ~ 2 kpc), Sco-Cen (age ~ 7 to 10 Myr; $d = 150$ pc) and α Per (age ~ 30 to 50 Myr; $d = 140$ pc), in addition to the Orion and NGC 2264 clusters already discussed, would be good candidates for study.

Qualitatively, however, the observation of massive, optically thick disks among Herbig Be stars with ages $t < 1$ Myr and masses $M > 3 M_{\odot}$, combined with the apparent lack of massive disks surrounding B stars in NGC 2264 (with ages ~ 1 to 3 Myr) suggests that disk survival times for stars with $M > 3 M_{\odot}$ may be considerably shorter ($t < 1$ Myr) than the values characterizing solar-type stars (~ 3 to 10 Myr).

V. OPTICALLY THIN DISKS

Candidate optically thin disks will show infrared emission which lies below the excess emission produced by a flat, optically thick reprocessing disk, but above photospheric emission (see Fig. 2; Table I). Recent observations provide persuasive evidence that such disks surround both solar-type and intermediate-mass stars.

A. Young Solar-Type Stars

Dutkevitch et al. (in preparation) carried out a series of observations of solar-type PMS stars in Taurus-Auriga aimed at determining infrared excesses as small as 5% above photospheric levels. Their technique involves *simultaneous* measurement of stellar fluxes over the wavelength range 1.2 to 4.6 μm , and thus avoids the uncertainties ($\sim \pm 0.1$ dex) inherent in extant estimates of excess disk radiation based on more heterogeneous data sets obtained at different times for these photometrically variable objects (see Strom et al. 1989d; Skrutskie et al. 1990). Reference to Fig. 2 shows that for a typical solar type PMS star, the flux at 1.2 μm is dominated by photospheric emission, while the flux at $\lambda \geq 2.2 \mu\text{m}$ has a significant (2.2 μm) or dominant (4.6 μm) contribution from the disk. Hence, accurate estimates of the quantities ΔK (2.2 μm), ΔL (3.5 μm), ΔM (4.6 μm) can be derived from reddening-corrected color excesses $(J-X)_0$, as follows: $\Delta X \sim [(J-X)_0 - (J-X)_{\text{std}}]/2.5$, where $(J-X)_{\text{std}}$ is the color index for a standard star of identical spectral type.

The Dutkevitch et al. sample is selected from the set of stars in Skrutskie et al. (1990) with tabulated ΔK and ΔN values which fall near the critical values ΔK_c and/or ΔN_c (see Table I); the nominal age range represented in their sample is 0.3 to 20 Myr. In Fig. 5, we plot the reddening-corrected index $(J-L)_0$ against spectral type for the stars observed by Dutkevitch et al. Also plotted in this figure are (a) the color-spectral type relationship for dwarf standard stars obtained on the same night with the same instrument; and (b) the expected values of $(J-L)$ for optically thick disks viewed at inclination angles $i = 0^\circ, 60^\circ$ and 80° . Note that 10 of the 15 stars in this sample show $(J-L)$ values consistent with their identification as candidate optically thin disks with discernible infrared excesses; 4 show colors consistent with photospheric colors, while one lies in the region occupied by candidate optically thick disks. For the number of stars in the Taurus-Auriga sample surrounded by optically thick disks (33), we expect to observe ~ 5 optically thick disks at inclination $i > 80^\circ$, and thus to show infrared excesses that fall below the critical values for this view angle, but above photospheric levels. Such stars would be expected to show the accretion and wind signatures found to characterize nearly all objects surrounded by optically thick disks (as judged from $\Delta K \geq \Delta K_c$) in the Cabrit et al. (1990) sample; indeed, 5 stars in the Dutkevitch et al. sample have $H\alpha$ luminosities which are typical of stars surrounded by optically thick disks. The remaining 5 stars with intermediate $(J-L)_0$ values may be objects surrounded by disks which are optically thin in their inner regions.

Figure 5. A plot of reddening-corrected color index, $(J-L)_0$, against spectral type for solar-type PMS stars in Taurus-Auriga selected to have $\Delta N < 1.2$ and $\Delta K < 0.2$ dex (filled circles), and dwarf standard stars (open circles) observed on the same system. The dashed line is the color-spectral type relationship which defines the photospheric colors expected for stars in this spectral-type range. The horizontal lines labeled $i = 0^\circ$, 60° and 80° represent the colors expected for a star of the indicated spectral type surrounded by a slightly flared ($h \sim r^{9/8}$) reprocessing disk. Solar-type PMS stars with colors which fall below the $i = 80^\circ$ line and above the expected photospheric colors either (1) are surrounded by optically thick disks viewed at $i > 80^\circ$, or (2) are surrounded by disks which are optically thin in the regions giving rise to the observed (small) $(J-L)$ excesses.

B. Older Solar-Type Stars

Evidence of emission arising from optically thin disks surrounding older solar-type stars comes from observation of significant infrared emission at $\lambda \geq 12 \mu\text{m}$ for nearby G and K main-sequence stars (Walker and Wolstencroft 1988; Backman and Gillett 1987). In all cases, the reported fluxes exceed expected photospheric emission, but fall below the critical values predicted for flat, optically thick disks. Because there is no evidence of emission arising from optically thick disks among main-sequence G and K stars, inclination effects cannot account for small infrared excesses; hence, if these excesses arise from disks, the disks must be optically thin. As the *minimum* ages for these stars exceed 50 Myr (the PMS evolution time for a G star), we must conclude that if this emission arises in optically thin disks, such disks must persist as observable entities for at least this long.

It would be extremely valuable to carry out high-precision, near-infrared observations of older solar-type stars both in order to diagnose the inner-disk

structure in objects which show mid- and far-infrared excesses, and perhaps more importantly, to examine a much larger sample of objects spanning a wide range of (known) ages by virtue of the higher sensitivity of current groundbased measurements to small excess emission.

C. Young Intermediate-Mass Stars

Examination of the IRAS *Point Source Catalog* (Waters 1986; Waters et al. 1987; Cote 1987) reveals significant infrared excesses among main-sequence B stars. In some cases, this excess emission can be attributed to free-free emission in gaseous envelopes surrounding rapidly rotating Be stars (not to be confused with Herbig Be stars where excess emission is believed to arise in disks; Strom et al. 1972). However, in many cases, *normal* main-sequence B stars show significant excesses, typically of a size consistent with that expected from optically thin disks. The ages represented by stars in these samples cannot exceed their main-sequence lifetimes (20 Myr at B0; 500 Myr at A0; Iben 1967), and could be as short as their PMS evolution times (0.3 Myr at B0; 3 Myr at A0)

Figure 6. A histogram depicting the frequency distribution of $12\mu\text{m}$ excesses ($\log_{10}[F(\text{observed})/F(\text{photosphere})]$) derived for main-sequence B stars in the young ($t \sim 7$ to 10 Myr) Scorpio-Centaurus Association; only objects with detections at a level 3σ or greater are included. From Table I, we note that candidate optically thick disks surrounding a B5 star would have an excess $\Delta N > 1.5$ dex.

An investigation currently underway (S. E. Strom and G. Condon) yields a preliminary estimate of the fraction of *young* B stars surrounded by optically thin disks. In Fig. 6, we present the frequency distribution of $12\mu\text{m}$ excesses for a sample of 42 stars in the Sco-Cen OB Association (age ~ 7 to 10 Myr). Values of $\Delta(12\mu\text{m})$ were estimated from $\Delta(12\mu\text{m}) =$

$[(V-12\mu\text{m})_0 - (V-12\mu\text{m})_{\text{std}}]/2.5$. Here $(V-12\mu\text{m})_0$ is the reddening-corrected $(V-12\mu\text{m})$ color index derived from the co-added IRAS survey, and from extant visible photometry and spectral types; $(V-12\mu\text{m})_{\text{std}}$ is the color index appropriate to a standard star of identical spectral type. The $\Delta(12\mu\text{m})$ value corresponding to a flat, optically thick disk surrounding a star of type B5 is 1.5 dex (if viewed at an inclination $i = 80^\circ$). The typical $12\mu\text{m}$ flux uncertainty is about 20% for the stars in their sample. We conclude from Fig. 6, that $\sim 17/39$ main-sequence B stars have $0.15 < \Delta(12\mu\text{m}) < 1.5$ dex and may thus be surrounded by optically thin disks. We caution that the IRAS beam is relatively large ($\sim 1'$ at $12\mu\text{m}$) and may include emission from either nearby red companions or infrared cirrus. Careful study of each object (ultimately involving imaging) will be necessary before unambiguous attribution of excess $12\mu\text{m}$ flux to disk emission can be made.

D. Older Intermediate-Mass Stars

One of the most dramatic revelations of the IRAS survey was the ‘‘Vega’’ phenomenon: the discovery of extended infrared emission associated with α Lyr and several other nearby A stars. Aumann et al. (1984), Gillett et al. (1984), and Aumann (1985) argue that this emission very likely arises in optically thin circumstellar disks. Persuasive evidence that this excess emission indeed arises from disks (as opposed to circumstellar shells) is provided by optical observations of light scattered by small dust grains in the nearly edge-on ($i > 76^\circ$) disk surrounding β Pictoris (Smith and Terrile 1984; Paresce and Burrows 1987; Artymowicz et al. 1989). The β Pic disk has a radius, $r \sim 1000$ AU, a mean visual optical depth $\tau \sim 3 \times 10^{-3}$ and a mass of $10^{-7} M_\odot$ in micron-size grains.

Subsequent analysis of IRAS survey data reveals that a significant number of nearby main-sequence A and F stars exhibit infrared excesses consistent with emission arising from optically thin disks (Backman and Gillett 1987; Chapter by Backman and Paresce), though none comes within an order of magnitude of the excess emission observed for β Pic. In the sample of main-sequence A and F stars studied by Aumann (1985), disk optical depths range from $-5 < \log \tau (0.55\mu\text{m}) < -2.5$, and estimated disk sizes range from 3 to 100 AU. The ages of these stars range from 100 to 1000 Myr.

From the range of excess emission observed around nearby stars, combined with the known limiting fluxes of the IRAS survey, Backman and Gillett (1987) estimate that 23% of all A stars, and $\geq 10\%$ of all F and G stars are surrounded by disks with emission optical depths $\tau > 10^{-5}$; by comparison the zodiacal cloud has an optical depth $\tau \sim 10^{-7}$. The true number of optically thin disks may be even greater. IRAS sensitivity levels are sufficient to locate disks with optical depths as small as 10^{-6} among luminous nearby A stars (though not around less luminous F and G stars). At this level, the fraction of A stars exhibiting excess emission increases from the 23% with excesses consistent with $\tau \geq 10^{-5}$, to 45% consistent with disks with $\tau \geq 10^{-6}$. This result suggests that the detected fraction of F and G stars surrounded by disks

would likely increase were higher sensitivity observations available.

E. The Origin and Implications of Optically Thin Disks

Although considerably more work is needed to establish the frequency with which optically thin disks are found around stars of differing ages, it seems clear that some main-sequence stars of all types exhibit small infrared excesses above photospheric levels, and may thus be surrounded by optically thin disks.

Accretion in Optically Thin Disks. All PMS stars which lack infrared excesses above photospheric levels (no disk, or undetectable optically thin disk), and most PMS stars (with small excesses consistent with identification as *candidate* optically thin disks, show no evidence of either (1) the strong boundary layer emission; or (2) the energetic winds which diagnose disk accretion. In contrast, nearly all PMS stars surrounded by optically thick disks extending inward to the stellar surface show (a) the excess ultraviolet and blue continuum emission produced in a boundary layer; (b) the strong, broad H α emission arising in the inner regions of energetic winds; and (c) large infrared excess luminosity, some of which must be produced by self-luminous accretion disks (Bertout 1989; Cabrit et al. 1990; Hartigan et al. 1989a, 1990a; Chapter by Edwards et al.). We thus conclude that when disks become optically thin, they can no longer sustain accretion, at least at observable rates ($\dot{M}_{\text{acc}} \geq 10^{-8} M_{\odot} \text{ yr}^{-1}$).

Replenishment of Optically Thin Disks. The observed excesses in optically thin disks are produced by small ($a \sim 1 \mu\text{m}$ diameter) radiating grains. If these grains are located in a gas-free region, then Poynting-Robertson drag will cause them to spiral into the central PMS star from distances r on time scales $t_{PR} < 400 (r/\text{AU})^2 \text{ yr}$ (Burns et al. 1979). If the grains are suspended within a residual quiescent gas layer, sedimentation and coagulation of small grains into $a > 1$ centimeter-sized objects can occur in $\sim 1000 (r/\text{AU})^{3/2} \text{ yr}$ (Weidenschilling 1980). Aerodynamic drag on these larger bodies forces them to spiral into the protostar in $< 10^4 \text{ yr}$ (Weidenschilling 1977). Hence, the detection of near-infrared emission from small grains surrounding stars with $t > 1 \text{ Myr}$ means that their inner disks must be re-supplied continuously with fresh grain material (see Gillett 1986; Backman and Gillett 1987).

Fresh grains could be introduced into the inner disk regions via Poynting-Robertson drag operating on micron-size grains located in outer disks at $r > 4 \text{ AU}$; such cold grains would be detectable only from sensitive millimeter-continuum measurements. The efficacy of this mechanism depends on the total momentum which can be transferred to the grains, and therefore on the geometry and optical depth of the outer disk. The magnitude of the observed near- and mid-infrared excesses produced by small grains introduced into the inner disk will reflect a balance between the rate of injection of fresh grains from the outer disk, and the rate of depletion by Poynting-Robertson or aerodynamic drag in the inner disk. Grains can also be produced *in situ* as a by-product of collisions which fragment pieces of larger parent bodies (e.g., large grains; planetesimals), or as a result of evaporation of cometesimals

gravitationally scattered into the inner disk by one or more massive planets. The mass in small ($a \sim 1 \mu\text{m}$) grains which must be resupplied over a Poynting-Robertson or aerodynamic drag time is $\sim 10^{-10} M_{\odot}$ for a star of luminosity $L_{*} = 1 L_{\odot}$ which exhibits $\Delta N = 0.2$ dex.

It is currently believed that Earth-mass planets were built by inelastic collisions of planetesimals over time scales $t > 100$ Myr; micron-size dust grains are by-products of such collisions. If the presence of cold, outer disk regions containing a significant store of small grains can be excluded, then measurement of infrared excesses diagnosing optically thin inner disks might establish the rate at which micron-size dust is replenished via planetesimal collisions: a decrease in the infrared excess surrounding older stars would indicate a decrease in the rate of planetesimal collisions. Determining the time scale for near-infrared excess emission to become undetectable would thus provide an important astronomical constraint on the time scale required to build terrestrial planets from planetesimals. It is thus critical (1) to determine disk optical depths around main-sequence stars having ages ranging from 10 Myr to 1000 Myr; (2) to establish from millimeter-continuum observations whether stars that show evidence of infrared emission arising from optically thin disks, are surrounded by massive outer disks comprised in part of cold micron-size dust which might "feed" small grains into the inner disk regions; and (3) to ascertain the dominant source of grain replenishment.

There is some evidence that the infrared excess (and by inference, the disk optical depth) decreases with age. The bulk of the evidence thus far comes from the work of Backman and Paresce (see their Chapter) who examine the excess infrared emission associated with main-sequence A stars in three nearby ($d \leq 150$ pc) clusters: α Per (age ~ 30 – 50 Myr); the Pleiades (age ~ 70 – 100 Myr); and the Ursa Major cluster (age ~ 200 – 300 Myr). They find that the typical excesses among the α Per and Pleiades A stars are significantly larger than those characterizing the A stars in the older Ursa Major cluster. Systematic examination of mid- and far-infrared excesses for lower-mass stars in these clusters is impossible from the IRAS survey, because these stars have photospheric (and thus optically thin disk) luminosities that are too faint to admit reliable detection at IRAS sensitivity limits.

Groundbased near- and mid-infrared ($1.2 \mu\text{m} \leq \lambda \leq 10 \mu\text{m}$) observations have the sensitivities required to establish the frequency with which optically thin disks surround main-sequence stars of all types, and to derive characteristic time scales for their evolution from observation of main-sequence stars located in clusters of differing age. Systematic studies aimed at measuring infrared excesses for large and representative samples in clusters sampling the age range 10 to 1000 Myr are currently underway (Backman, Witteborn and Stauffer, unpublished; Strom, Edwards, Skrutskie and Dutkevitch, unpublished).

Large millimeter-antennae located at good sites (IRAM, CSO, JCMT, respectively) are capable of detecting millimeter-continuum excesses arising from disks containing dust masses as small as 10^{-4} to $10^{-5} M_{\odot}$ around

main-sequence G stars in nearby clusters. Strom, Edwards and Skrutskie are currently carrying out a program on the CSO aimed at detecting or placing strong limits on millimeter-continuum excesses for stars in the α Perseii, Pleiades and Ursa Major clusters, and thus constraining the mass of cold dust grains located in outer disk regions.

VI. TRANSITION DISKS

The arguments presented in Secs. III and V establish the presence of both (1) massive, optically thick disks surrounding young stars ($t < 10$ Myr) of all masses, and (2) optically thin disks surrounding older stars of all masses. If optically thin disks represent the descendents of massive, optically thick structures, it may be possible to identify disks *in transition* between these two states, and to define a characteristic time scale for the transition phase. Currently available observational techniques force us to search for a particular type of transition structure: one in which the inner disk regions are optically thin, while the outer disk regions are optically thick. Such disks can be diagnosed from infrared spectral energy distributions in the manner described in Sec. II.

To select candidate transition cases, we make use of the infrared excesses tabulated by Strom et al. (1989a) and Skrutskie et al. (1990) for a representative sample of 83 solar-type PMS stars in Taurus-Auriga. We examine the spectral energy distributions of all stars in their sample in order to determine whether any have optically thin *inner* but optically thick *outer* disks. Three candidate cases (DI Tau, V819 Tau, SAO76411A) exhibit the small near- and mid-infrared, and large far-infrared excesses which diagnose such structures. As noted in Sec. II, current limits on the sensitivity of mid- and far-infrared measurements preclude detection of disks which might first become optically thin in their outer regions.

In Fig. 7, we plot the spectral energy distribution of V819 Tau along with that of a "typical" T Tauri star, AA Tau. Superposed in each case is a line indicating the location of the composite star plus disk spectrum (for a flat reprocessing disk viewed at $i = 60^\circ$). Note that the observed spectrum of AA Tau lies above that of the predicted composite spectrum at all infrared wavelengths $\lambda > 1.2 \mu\text{m}$, and is thus consistent with that of an optically thick disk that extends inward to within a few stellar radii of the PMS star surface. In contrast, the observed excesses for V819 Tau at $\lambda \leq 10 \mu\text{m}$ must be produced in a disk with an "inner hole" ($\tau < 1$ in regions $r < 0.2$ AU). At radii $r > 0.5$ AU, the disk appears to be optically thick, as the observed infrared fluxes at $\lambda > 25 \mu\text{m}$ fall above the flat disk spectrum. V819 Tau is also detected as a millimeter-continuum source (Beckwith et al. 1990); the amount of disk material at $r > 0.5$ AU is $\sim 0.03 M_\odot$, or comparable to that of a minimum-mass solar nebula.

The ratio of the number of transition cases (3) to the number of PMS stars surrounded by optically thick disks in the Strom et al. (1989a) and Skrutskie

Figure 7. A plot of the spectral energy distribution observed for V819 Tau (upper panel) and AA Tau (lower panel). Superposed on these plots in each case, is a solid line indicating the location of the composite star plus optically thick, flat reprocessing disk ($i = 60^\circ$); the dashed line corresponds to the emission arising from the stellar photosphere. The observed spectrum for AA Tau lies above that of the predicted thick disk + star spectrum at all wavelengths $\lambda \geq 1.2 \mu\text{m}$. The observed spectrum for V819 Tau lies *below* the thick disk + star spectrum at wavelengths $2.2 \mu\text{m} \leq \lambda \leq 25 \mu\text{m}$ and above at longer wavelengths. These data suggest that the *inner* disk of V819 Tau is optically thin, while the outer disk is optically thick. It is noteworthy that V819 Tau is readily detected at millimeter wavelengths.

et al. (1990) samples (33 as judged from ΔK), yields a *transition time* of $3/33 \times 3 \times 10^6$ yr or ~ 0.3 Myr, assuming a mean age of 3 Myr for PMS stars surrounded by optically thick disks.

A. Possible Implications of Inner Holes

The End of the Disk Accretion Phase. The development of a “transition” disk with an optically thin inner region appears to signal the cessation of disk accretion. None of the three stars (DI Tau, V819 Tau, SAO 76411A) apparently surrounded by transition disks shows evidence of either (1) the strong boundary-layer emission, or (2) the energetic winds which diagnose disk accretion. As noted in Secs. III and V, their presumed precursors, young stars surrounded by optically thick disks extending inward to the stellar surface, show evidence of (correlated) accretion and wind signatures; their presumed descendents, disks which are optically thin throughout or show no evidence of excess emission, also lack accretion signatures (see also the Chapter by Edwards et al.).

Possible Evidence for Giant Planet Formation. Creation of an optically thin region in the interior regions of circumstellar disks may reflect the shorter dynamical times and consequently shorter grain agglomeration times in such regions: the agglomeration of small grains into larger bodies will decrease the optical depth in the inner disk regions. However, the presence of an optically thin region interior to an optically thick outer disk may be indicative of more profound effects. Such structures appear to require a mechanism to keep the “inner hole” isolated from the outer regions of the disk. In the absence of an isolating mechanism, Poynting-Robertson drag will cause small grains located at the inner boundary of the outer disk to spiral in toward star on a time scale $t < 6000$ yr (see above), or much shorter than the estimated “transition time” ($t \sim 0.3$ Myr). The mass in small grains introduced into the inner disk (and thus the infrared excess produced) depends critically on the geometry and transparency of the outer disk; more physically extended, optically thinner outer disks can introduce more grains into the inner disk, and produce larger near- and mid-infrared excesses.

S. Ruden (1989, personal communication) and G. Morfill (1989, personal communication) suggest that the formation of a Jupiter mass protoplanet can isolate regions of a disk interior to its orbit from those outside its path as a result of tidal torques generated by the protoplanet. Preliminary calculations carried out by Ruden indicate that once a Jupiter-mass body forms in the disk, it creates a “gap.” Small dust particles and gas interior to the gap accrete onto the parent star on a time scale $\sim 5 \times 10^5$ yr (for a Jupiter-mass planet initially located at a distance 5 AU from a solar mass star surrounded by a minimum-mass nebula; the time scale is set by the orbital time scales and the viscous coupling efficiency in the inner disk). Material exterior to the gap can no longer enter the inner disk. The resulting structure (an optically thick outer disk with an inner hole) will produce an infrared signature in qualitative agreement with those of the transition structures discussed above, and on a time scale comparable to our estimated transition time, $t \sim 0.3$ Myr. In the context of the hypothesis that giant planets produce and sustain inner holes, the ages of our three candidate transition cases, $t \sim 0.3$ to 1 Myr (DI Tau), and

$t \sim 3$ to 10 Myr (V819 Tau and SAO 76411A), provide upper limits to the time required to agglomerate a Jupiter mass body.

By isolating the inner disk, the formation of a giant planet may permit the initial clearing of the inner disk via accretion. Although the inner disk will thus be depleted of gas and small dust grains, larger bodies (e.g., planetesimals) will remain behind, presumably to continue agglomeration into planet-sized bodies. High-precision infrared observations may permit indirect diagnosis of the presence of planetesimals or cometesimals located in or scattered into the inner regions of transition disks. Because the giant planet keeps the outer reservoir of gas and dust dammed up, and because Poynting-Robertson drag sweeps the optically thin inner disk clean on short time scales, dust responsible for excess near-infrared radiation must be continuously resupplied to the inner disk regions.

VII. SEARCHES FOR CIRCUMSTELLAR GAS

The evidence regarding the frequency of disk formation, as well as estimates of time scales for disk evolution rests entirely on observations of excess infrared and millimeter-continuum emission produced by circumstellar dust. What is the fate of the dominant constituent of circumstellar disks—the gas? Determining the survival time for the gas component is essential to understanding the evolution of nebular disks, and is particularly crucial for establishing the time available for building the giant, gas rich outer planets.

Thus far, the only direct evidence regarding the gas content of circumstellar disks derives from high angular resolution CO observations carried out with the Owens Valley Radio Observatory millimeter-wave interferometer. CO emission has been detected for HL Tau and L1551 IRS 5, two extremely young ($t < 1$ Myr) solar-type pre-main-sequence stars (see, e.g., Sargent and Beckwith 1987; Sargent et al. 1988). The gas mass in these disks is ~ 0.1 to $1.0 M_{\odot}$, while the optical depth in the ^{12}CO (1–0) transition is $\tau \sim$ several thousand. Presumably, as the disks evolve and assemble material into planets, the gas content should decrease from this initial value. Ultimately, the gas will either be accreted by rocky or icy cores, removed by winds, or stripped by encounters between solar-type stars and other molecular clouds. However, ^{12}CO will remain optically thick until the disk mass decreases to $\sim 10^{-4} M_{\odot}$ (for a disk of diameter ~ 100 AU).

In order to predict the required sensitivity for detection of remnant gaseous disks, we rely upon a purely geometrical argument, assuming the CO emission is optically thick out to an outer disk radius of 100 AU, with $T_K(\text{CO}) = 20$ K. Such a disk surrounding a star located at $d \sim 25$ pc will fill $\sim 4\%$ of the Five College Radio Astronomy Observatory (FCRAO) 14-m telescope antenna beam; with the IRAM 30-m diameter telescope, disks surrounding stars located at $d \sim 100$ pc will have similar beam-filling fractions. For a beam dilution of 4%, an assumed beam efficiency of 0.5, we predict a peak antenna

Figure 8. A plot of antenna temperature against heliocentric velocity for 8 stars in the Ursa Major Stream observed in the ^{12}CO (1–0) transition at the FCRAO 14-m telescope by Skrutskie et al. (in preparation). The arrows locate the heliocentric velocities of the stars where known. The typical 1σ detection limit is estimated as 25 mK/100 kHz channel. No star shows evidence for ^{12}CO emission.

temperature $T_A = 40$ mK for a disk viewed at an inclination $i = 60^\circ$, and 400 mK for a disk viewed pole-on.

Recently, Skrutskie et al. (1991) have carried out preliminary searches at FCRAO for ^{12}CO (1–0) emission arising from disks surrounding main-sequence F and G stars in the nearby ($d = 25$ pc) Ursa Major cluster (age ~ 200 to 300 Myr). Typical integration times were 2 to 3 hr on source, and similar times off source. The resulting position-switched difference spectra for the sources examined to date are reproduced in Fig. 8; the typical noise level achieved was 25 mK/100 kHz channel (100 kHz corresponds to 0.26 km s^{-1}).

None of these objects was detected. Hence, either (1) the disks have radii $r < 100$ AU; (2) the CO/H₂ ratio is much smaller than the ratio which obtains in molecular clouds (as might be the case if the CO in an unshielded, dust-free disk is dissociated); or (3) the ^{12}CO emission is optically thin, and the disk mass is $\leq 10^{-4} M_\odot$ (or 0.01 times the mass of the “minimum-mass” solar nebula). If the disk mass is indeed small, our observations imply that the gas survival time in disks cannot exceed $t \sim 200$ to 300 Myr. It is essential

to extend such studies to solar-type stars located in younger clusters. Because such clusters are more distant than the Ursa Major cluster, the power of larger millimeter-wave telescopes (e.g., the IRAM antenna) is required in order to detect disk gas or to place significant upper limits on the disk gas content.

VIII. SUMMARY AND FUTURE DIRECTIONS

Efforts to date allow us to draw the following conclusions regarding the frequency of disk occurrence and the time scales for disk evolution as follows:

- A. Optically thick disks ($\tau > 1$ in regions sampled by excess emission $\lambda \leq 10 \mu\text{m}$) are found around 30 to 50% of young ($t < 3$ Myr) stars of all masses $M < 3 M_{\odot}$. Optically thick disks are found around PMS stars of higher mass, but with unknown frequency. For the relatively limited sample of objects for which sub-millimeter and millimeter-continuum measurements are available, nearly all stars with $\tau > 1$ show disk masses $M_d > 0.01 M_{\odot}$ ($\equiv M_{mm}$). Disk sizes range from ~ 10 to ~ 1000 AU. Hence disks of solar system sizes, and of masses comparable to or greater than the minimum-mass solar nebula appear to form around a large fraction of stars with $M < 3 M_{\odot}$.

Three major uncertainties associated with these conclusions are:

1. The inference of disks associated with intermediate-mass stars. Current arguments rest primarily on the observation of excess infrared and millimeter-continuum emission similar to that observed for solar-type PMS stars (T Tauri stars) surrounded by optically thick disks (see Fig. 1), and economy of hypotheses. Blueshifted forbidden line emission has been observed for only a few intermediate-mass stars. Moreover, the links between infrared excess emission arising in optically thick disks, energetic winds diagnosed by Balmer line and forbidden line emission, and ultraviolet and optical excess emission arising in a boundary layer are not nearly so well established for intermediate-mass stars. Efforts to solidify the arguments supporting the existence of disks associated with these stars are badly needed.
2. The completeness of our census of newly born stars. While the proper motion studies in NGC 2264 and Orion provide comprehensive membership lists for stars $M \geq 1.5 M_{\odot}$, no comparably complete lists of young solar-type stars are available either in these clusters or in nearby star-forming complexes such as Taurus-Auriga. Present samples of solar-type stars are amalgams of samples selected on the basis of strong $H\alpha$ emission (classical T Tauri stars or CTTS) or X-ray emission (objects which include CTTS and weak emission T Tauri stars, or WTTS), and may not be representative of either the true proportion of CTTS and WTTS, or the total population of young solar-type stars.

3. The mass determinations. While sub-millimeter and millimeter-continuum excesses measure emission arising from optically thin dust and thus provide the most sensitive probe of disk masses, the emissivity of the dust is not well known. Hence, *absolute* mass estimates may be highly uncertain (perhaps by a factor of 10 or more).
- B. Nearly all optically thick disks show evidence of (1) boundary layer emission diagnosed by “spectral veiling” at optical wavelengths, and indicative of accretion of material onto the stellar surface; and (2) strong, broad H α emission and forbidden line emission arising in energetic winds whose mechanical luminosity is proportional to the disk accretion luminosity (Cabrit et al. 1990; Chapter by Edwards et al.). We conclude that optically thick disks are accretion disks with typical accretion rates $\dot{M}_{\text{acc}} > 10^{-8} M_{\odot} \text{ yr}^{-1}$.
- C. Disks survive as massive, optically thick structures extending nearly to the stellar surface for times ranging from $t < 3 \text{ Myr}$ to $t \sim 10 \text{ Myr}$ around solar-type PMS stars. No optically thick disks have been identified around solar-type stars with ages $t \geq 30 \text{ Myr}$. The survival times for disks around more massive stars are not well established, particularly for stars $M > 3 M_{\odot}$. However, the limited data available suggests that the disk survival times for such massive stars may be considerably shorter ($t < 1 \text{ Myr}$) than those for solar-type stars.
- D. The descendents of massive, optically thick disks are disks containing masses of distributed micron-size dust grains $M < 10^{-4} M_{\odot}$; such disks are optically thin, and perhaps analogous to the structures observed to surround the intermediate-mass stars Vega and $\beta \text{ Pic}$. Evidence of infrared excess emission consistent with emission arising in optically thin disks is found for stars of all masses. Stars surrounded by optically thin disks show none of the signatures associated with disk accretion (strong boundary layer emission; emission from spectral features arising in energetic winds). Hence, when disks become optically thin, disk accretion ceases.
- E. The presence of micron-size grains in optically thin circumstellar disks at distances $r < 1 \text{ AU}$ from the surface of solar-type stars, requires that such grains be continuously supplied to these disk regions; Poynting-Robertson or aerodynamic drag would otherwise deplete the grains on time scales short compared to the age of stars surrounded by optically thin disks. Small grains can be supplied either by collisions among larger grains or planetesimals; by evaporation of cometesimals gravitationally scattered into the inner disk regions; or by grains spiraling in from cold, outer disk regions ($r > 1 \text{ AU}$). Eventually, millimeter-continuum observations can place stringent limits on the amount of distributed cold dust.
- F. Older stars of intermediate mass surrounded by optically thin disks appear on average to show smaller mid- and far-infrared excesses than do

younger stars surrounded by such disks. This result, based on results from the IRAS survey for nearby clusters, motivates sensitive near- and mid-infrared measurements aimed at establishing characteristic time scales for systematic changes in disk optical depth (a measure of the mass in micron-size dust). Establishing such time scales may provide an astronomical constraint on the rate of planetesimal collisions or cometsimal evaporation as a function of time during the planet-building epoch.

- G. Disks with apparent "inner holes" ($r \gtrsim 0.2$ AU) have been discovered. These are most likely structures in transition between disks that extend inward to the stellar surface and are optically thick throughout, and those that are optically thin. The presence of an inner hole may require that the inner regions of a disk be isolated from the exterior, optically thick disk regions. If so, the formation of a giant planet provides an attractive mechanism for tidally isolating the outer and inner disk regions. In this picture, the formation of a giant planet creates a gap in the disk. Gas and small grains located inward of the gap accrete onto the parent star; small grains, and possibly gas exterior to the gap survive for times $t > 0.1$ Myr.
- H. Our discussion of disk properties rests entirely on observations of emission arising from the dust component. Interferometric observations reveal CO millimeter-line emission arising in disk gas surrounding two extremely young solar-type PMS stars (HL Tau and L1551, IRS 5). The estimated gas mass for these systems lies in the range 0.1 to 1 M_{\odot} . Systematic searches for disk gas associated with stars of differing ages and masses are critical to determining characteristic times for the evolution of the gas component. However, no such searches are yet available, primarily because the sensitivity required demands extensive time on large millimeter-wave telescopes. We report preliminary results of a search for CO emission associated with G and K main-sequence stars in the nearby Ursa Major cluster ($d = 25$ pc; $t \sim 200$ to 300 Myr). We find no evidence of CO emission associated with these stars, despite the fact that our measurements are sensitive enough to permit detection of $M \sim 10^{-4} M_{\odot}$ of gaseous material with a CO/H₂ ratio comparable to interstellar values. If CO survives in the circumstellar environment, then these observations suggest a gas survival time $t < 200$ to 300 Myr.

The presence and properties of disks associated with solar-type PMS stars have thus far been inferred from indirect observations. *Direct detection* of a low surface brightness region of dust-scattered light from a disk at an angular distance $\theta < 0''.5$ ($r < 70$ AU for PMS stars in Taurus-Auriga and other nearby star-forming complexes) from a bright central star, represents a daunting task for groundbased telescopes. Despite the application of speckle imaging and resolution enhancement techniques, the great range of light intensity over the small angular scale of the star/disk system has precluded detection of candidate PMS disks except in a few cases. Over the next few years, the Hubble Space Telescope (HST), equipped with the second generation Wide

Field Planetary Camera, should permit direct detection and imaging of such disks. HST, with a diffraction-limited beam size of $\sim 0''.05$ at 5000 \AA and a stable point spread function is uniquely capable of:

1. Placing decisive limits on the occurrence frequency of disks, by virtue of its ability to image dust-scattered light from low-mass, low optical depth, low-surface-brightness disks. With HST, a 600 second exposure with Wide Field/Planetary Camera II can image a disk with a dust mass as low as $10^{-9} M_{\odot}$ (comparable to the dust mass in the disk surrounding the nearby main sequence A star, β Pictoris) distributed uniformly within a 50-AU region surrounding a typical PMS star in Taurus-Auriga. The ability of HST to image disks around PMS stars will thus allow us to learn for the first time from direct observations whether our planetary system is likely to represent a common and expected result of star formation, or whether formation of our solar system required a fortuitous combination of circumstances reproduced only rarely in nature.
2. Establishing characteristic time scales for disk evolution by imaging disks during a wide range of evolutionary phases: from the earliest stages when the disk mass and surface brightness may be high, to the epoch of dust settling and planetesimal building when the mass of *distributed* material and the disk surface brightness is low. HST will be able to obtain images of disks to limiting surface brightnesses $V \sim 21 \text{ mag arcsec}^{-2}$ around a typical PMS star in Taurus-Auriga, and should be capable of establishing the presence of circumstellar "holes," possibly resulting from planet-building episodes in the disk interior to $\sim 10 \text{ AU}$.

Sensitive near- and mid-infrared and millimeter-continuum measurements should permit indirect detection of circumstellar material in disk regions within $r \sim 10 \text{ AU}$ of the surfaces of typical solar-type and intermediate-mass PMS stars in nearby star-forming regions ($d < 200 \text{ pc}$), and main-sequence stars in nearby clusters. By increasing the size of PMS star samples, and by studying stars with ages ranging from 10 to 1000 Myr, we should be able to place more convincing limits on characteristic disk evolutionary time scales (1) from a more complete census of optically thick disks, leading to better estimates of their frequency and survival times; (2) from identification of candidate optically thin disks surrounding stars sampling a wide range in age, providing the basis for determining the rate at which the optical depth in such disks decreases with time; and (3) from identification of additional transition cases analogous to the 3 objects discussed here. It will be of particular interest to locate stars which lack near- and mid-infrared excesses, but which show strong millimeter-continuum fluxes. The age of systems which exhibit large holes ($r > 5 \text{ AU}$), may provide an astronomical constraint on the time scale over which giant planet building takes place.

Finally, CO observations (carried out with large millimeter-wave telescopes) of large samples of stars covering a wide range of ages and masses

are required in order to measure the gas content of circumstellar disks, to determine the range in disk gas mass associated with young stars, and gas survival times.

Acknowledgments. We wish to extend our deepest thanks to K. M. Strom, D. Dutkevitch, L. Hillenbrand, G. Condon, and L. Gauvin for their many helpful contributions. EXTINCT RADIONUCLIDES AND EVOLUTIONARY TIME SCALES

TIMOTHY D. SWINDLE

University of Arizona

Extinct radionuclides, radioactive nuclides with half-lives of 10^5 to 10^8 yr, potentially provide sensitive clocks for dating events that occur within a few half-lives of their nucleosynthesis. Strong evidence for at least seven of these has been found in meteorites. In principle, these can constrain several time scales, including the length of time between the last episode of nucleosynthesis and the formation of solids in the solar system, the duration of the nebula, the length of time from the formation of solids to the formation of bodies large enough to differentiate, and the length of time from the formation of solids to the formation of terrestrial planets.

I. INTRODUCTION

The study of the primitive solar nebula is essentially a historical study. Although we can perform experiments and make observations today to provide constraints, our ultimate goal is to reconstruct events that happened long ago. As in any historical study, chronology is an important facet; to fully understand what happened, we must know the order and duration of events.

One of the most effective ways to study early solar system chronology turns out to be the study of the abundances of extinct radionuclides in meteorites. These are radioactive isotopes with half-lives long enough for them to have survived from their nucleosynthesis until incorporation into solar system solids, but not long enough to survive until the present. In practice, this translates into half-lives of roughly 10^5 to 10^8 yr. Their abundances are frequently measured with accuracies of a few percent (sometimes even greater), so each extinct radionuclide potentially provides chronological information with an accuracy of a fraction of its half-life.

A number of reviews of extinct radionuclides are available (see, e.g., Podosek 1978; Begemann 1980; Wasserburg and Papanastassiou 1982; Wasserburg 1985; Podosek and Swindle 1988). As many of these contain detailed descriptions of various searches for extinct radionuclides, the present chapter contains only a general description of such searches. Instead, it emphasizes the chronological information that extinct radionuclides can provide. The time scales addressed include: (1) the length of time from nucleosynthesis to incorporation into solar system material; (2) the duration of the solar nebula;

(3) the length of time between the formation of early solids and the formation of bodies big enough to differentiate; and (4) the length of time required to form a planet-sized body (Earth).

II. EXTINCT RADIONUCLIDES

A. Detection

Extinct radionuclides are, by definition, no longer present in meteorites. Therefore, the only way to determine that they were once present is to find indirect evidence of their existence. That evidence is usually an excess of the daughter isotope of the extinct radionuclide that correlates with the presence of another isotope of the parent element. An example is given in Fig. 1, from the work that established the presence of ^{26}Al (Lee et al. 1977). The data points represent the measured Mg isotopic composition and Al/Mg ratios for mineral separates from an inclusion in the Allende meteorite. The $^{26}\text{Mg}/^{24}\text{Mg}$ ratio varies by 10%, far more than the experimental uncertainties or the normal variations in isotopic ratios. Furthermore, the samples with the highest Al/Mg ratios have the highest $^{26}\text{Mg}/^{24}\text{Mg}$ ratios. Because ^{26}Al decays to ^{26}Mg , the simplest explanation for the correlation of excess ^{26}Mg with Al is that the inclusion formed with isotopically normal Mg but that the Al contained some ^{26}Al , which subsequently decayed. The slope of the correlation line gives the initial $^{26}\text{Al}/^{27}\text{Al}$ ratio, 5×10^{-5} in this case. Analogous plots have been used for the identification of all other extinct radionuclides presently known except for ^{244}Pu , which was detected by the presence of a xenon isotopic pattern matching the ^{244}Pu fission yield spectrum.

In order to detect a given extinct radionuclide in a sample, two conditions must be met: 1) the sample must have contained that extinct radionuclide, and 2) there must be some parts of that sample where the ratio of the parent to daughter element is high enough that the decay-produced excesses are measurable. The first condition is frequently met by using samples from Allende, a large meteorite with inclusions that formed early enough to contain several extinct radionuclides. The second condition is frequently a showstopper. The fractional excess produced by an extinct radionuclide can be written as

$$(D/S_D)_{\text{ex}} = (E/S_E) \times (S_E/S_D) \quad (1)$$

where E is the extinct radionuclide (e.g., ^{26}Al), D is the daughter isotope (^{26}Mg), and S_E and S_D are stable isotopes of the same elements as the extinct radionuclide and its daughter (^{27}Al and ^{24}Mg). Because most extinct radionuclides that have been observed are no more than 10^{-5} to 10^{-3} as abundant as stable isotopes of the same element (E/S_E), that means that elemental ratios (S_E/S_D) of 10 to 1000 are necessary to produce an excess of 1%. Thus it is not surprising that the first two extinct radionuclides confirmed (^{129}I and ^{244}Pu) were the two with noble gas daughter products, and hence large typical

Figure 1. Correlation of $^{26}\text{Mg}/^{24}\text{Mg}$ with $^{27}\text{Al}/^{24}\text{Mg}$ in Allende inclusion WA (figure from Lee et al. 1977).

elemental fractionation. Further detections occur as mass spectrometric precision and sensitivity increase, as more highly fractionated samples are found, or both.

B. The Roster

Table I lists the six extinct radionuclides whose presence has been confirmed, along with their half-lives and their daughter products. Wasserburg (1985) and Podosek and Swindle (1988) have reviewed the detection and implications of each of these, so those discussions will not be repeated here.

Databases for two of the six, ^{53}Mn and ^{146}Sm , have expanded considerably since the previous reviews. The first evidence for ^{53}Mn was a correlation of ^{53}Cr excesses (and deficits) in Allende inclusions with higher (and lower) than normal Mn/Cr ratios (Birck and Allègre 1985). Since then, evidence for extinct ^{53}Mn has been found in about a dozen other meteorites by at least four different groups (Birck and Allègre 1988; Birck et al. 1990; Davis and Olsen 1990; Hutcheon and Olsen 1991; Nyquist et al. 1991). Although some evidence for the presence of ^{146}Sm has been available for more than a decade (Lugmair and Marti 1977), early results were of marginal statistical significance, and measurements by different laboratories gave different results. Recently, three different laboratories have reported new evidence for the existence of ^{146}Sm in several different samples (Prinzhofer et al. 1989; Nyquist et al. 1990, 1991; Lugmair and Galer 1989), although it is still not

TABLE I
Extinct Radionuclides^a

Radio-nuclide	$T_{1/2}$ (Myr)	Daughter	Abundance	Comments
Confirmed				
²⁶ Al	0.7	²⁶ Mg	²⁶ Al/ ²⁷ Al = 5×10^{-5}	Shortest $T_{1/2}$; possible heat source
⁵³ Mn	3.7	⁵³ Cr	⁵³ Mn/ ⁵⁵ Mn = 4×10^{-5}	Most recent discovery
¹⁰⁷ Pd	6.5	¹⁰⁷ Ag	¹⁰⁷ Pd/ ¹⁰⁸ Pd = 2×10^{-5}	Only found in metal
¹²⁹ I	16	¹²⁹ Xe	¹²⁹ I/ ¹²⁷ I = 1×10^{-4}	First discovered; found in > 75 meteorites
¹⁴⁶ Sm	103	¹⁴² Nd	¹⁴⁶ Sm/ ¹⁴⁴ Sm = .005 – .015	Uncertain abundance
²⁴⁴ Pu	82	Fission Xe	²⁴⁴ Pu/ ²³⁸ U = .004 – .007	Also α -decays, leaving damage tracks
Strong evidence				
⁹² Nb	36	⁹² Zr	⁹² Nb/ ⁹³ Nb = $(2 \pm 1) \times 10^{-5}$	Based on single Nb-rich grain
Hints				
⁶⁰ Fe	1	⁶⁰ Ni	⁶⁰ Fe/ ⁵⁶ Fe $\leq 2 \times 10^{-6}$	Excess ⁶⁰ Ni observed; could be nucleosynthetic effect
¹³⁵ Cs	2.3	¹³⁵ Ba	¹³⁵ Cs/ ¹³³ Cs $\leq 2 \times 10^{-4}$	Deficit in ¹³⁵ Ba observed; could be nucleosynthetic
¹⁸² Hf	9	¹⁸² W	¹⁸² Hf = $1-10 \times 10^{-5}$	Deficit in ¹⁸² W observed in Hf-depleted metal
Interesting upper limits				
⁴¹ Ca	0.13	⁴¹ K	⁴¹ Ca/ ⁴⁰ Ca $< 1 \times 10^{-8}$	Must be cogenetic with ²⁴⁴ Pu
²⁴⁷ Cm	16	²³⁵ U	²⁴⁷ Cm/ ²³⁵ U $< .004$	

^a From compilation of Podosek and Swindle (1988), with additional data from Prinzhofer et al. (1989), Birck and Lugmair (1988), McCulloch and Wasserburg (1978), and Harper et al. (1991a, b).

possible to reconcile the data from all the laboratories with a single simple scenario.

In addition, Harper and colleagues have recently reported strong evidence for another extinct radionuclide, ^{92}Nb . The evidence consists of the measurement of a clear excess (13σ) of ^{92}Zr in an Nb-rutile sample from the Toluca type IAB iron meteorite (Harper et al. 1991*b*). While it seems likely that the excess ^{92}Zr was produced by ^{92}Nb decay in this grain, there is no guarantee that a single grain is representative of the bulk solar system.

The number of extinct radionuclides that were actually present in the solar nebula is probably far larger than the seven for which strong evidence exists. Wasserburg (1985) lists another two dozen isotopes that have half-lives comparable to those seven. Searches have established upper limits for many of those. Two of the more interesting upper limits, which are used later in this chapter, are given in Table I. It is likely that more extinct radionuclides will be discovered as a result of improvement in analytical techniques or simply of finding the right samples. Three candidates for which hints already exist are ^{60}Fe , ^{135}Cs and ^{182}Hf . Variations in their daughter isotopes, ^{60}Ni , ^{135}Ba and ^{182}W , have been observed (Birck and Lugmair 1988; McCulloch and Wasserburg 1978; Harper et al. 1991*a*). For the first two, it has not been possible to determine whether these variations correlate with the parent element. For ^{182}Hf , a deficit of ^{182}W occurs in the (Hf-free) metal phase of the Toluca iron meteorite. In this case, the argument would be that ^{182}Hf decay increased the bulk solar system $^{182}\text{W}/^{184}\text{W}$ ratio after the separation of the Toluca metal. Further work will be needed to confirm this story.

III. TIME SCALES

A. Duration from Stellar Nucleosynthesis to Collapse of the Solar Nebula

The first time scale that can be addressed, and the one where the results are most difficult to reconcile with theoretical models, is the length of time from nucleosynthesis to the formation of surviving solids. In principle, an upper limit can be determined from the difference between the nucleosynthetic production ratio and the observed early solar system ratio for any element pair. In practice, there are a number of stumbling blocks along the path of this simple calculation, which are addressed below.

(1) We must know the nucleosynthetic production ratio. Of course, to know that, we must know the production mechanism. Table II lists the stellar sites and/or processes that may be responsible for each of the observed extinct radionuclides. Although the mechanism and production rate seem to be well understood for some nuclides (most notably ^{244}Pu), they are not for others. The identities of the sources of ^{26}Al and ^{146}Sm are particularly controversial.

(2) Even if we can determine a time scale, if the nucleosynthesis occurred locally rather than in a stellar environment, the meaning of that time scale is quite different. At least one of the extinct radionuclides, ^{244}Pu , must have been produced in a stellar environment, as its production requires extremely

TABLE II
Nucleosynthesis of Extinct Radionuclides^a

Nuclide	Process	Site ^b
²⁶ Al	nonexplosive H-burning	MMLS
	explosive H-burning	N
	C- or Ne-burning	SN Type II
	production in	AGB
	spallation	Neb
⁵³ Mn	Si-burning or NSE	SN Type I or II
	spallation	Neb

high doses of neutrons that seem impossible to obtain in the solar system. However, many of the others might be produced with high-energy particle fluxes that could exist in the solar system. Shortly after the discovery of the first extinct radionuclide, ¹²⁹I, Fowler et al. (1961) suggested that it might have been synthesized in the solar system. Although their specific model predicts effects that are not observed (Reynolds 1967), the idea of a local irradiation is still attractive. Wasserburg (1985) has pointed out that ²⁶Al/²⁷Al, ⁵³Mn/⁵⁵Mn, ¹⁰⁷Pd/¹⁰⁸Pd and ¹²⁹I/¹²⁷I all have observed ratios of $\sim 10^{-4}$, despite half-lives that differ by a factor of 25. Synthesis of 10^{-4} of the nebular material in the nebula itself, perhaps in local irradiations, would be a tidy explanation. For example, Wasserburg and Arnould (1987) have suggested that spallation reactions caused by solar energetic particles might produce both ²⁶Al and

^{53}Mn . This model would then predict that these two extinct radionuclides would correlate with each other, a prediction that will be tested as more data is acquired for ^{53}Mn . The discovery of a γ -ray line due to ^{26}Al in the interstellar medium (Mahoney et al. 1984) suggests that there are stellar sources, but these results do not preclude the possibility of local production.

(3) The surviving grains that we see must have been produced in the solar nebula. If, for example, we are merely seeing grains that condensed around a supernova and then were transported to the solar nebula and incorporated intact into meteorites, the chronological information does not apply to the solar nebula. For most of the confirmed entries in Table I, there is at least one case where the evidence for the existence of the extinct radionuclide comes from a differentiated object with a formation age close to the age of the solar system, and because differentiation normally leads to isotopic equilibration, decay almost certainly occurred in the solar nebula. The only nuclide which has not been found in a differentiated object is ^{26}Al (but see discussion in Sec. III.C), the one with the shortest half-life.

Several models have been developed, in particular by Clayton et al., that would remove ^{26}Al decay from the solar nebula (Clayton and Leising 1987). In one model, the correlation of excess ^{26}Mg with Al would occur because Al is more refractory than Mg. If objects condensed with extremely high $^{26}\text{Al}/^{27}\text{Al}$ ratios (0.1), were transported to the solar nebula over some length of time much longer than the ^{26}Al half-life, then heated to temperatures high enough to drive off most of the Mg but little of the Al, and finally mixed with isotopically normal Mg, objects containing random amounts of presolar grains would define a mixing line that would mimic an isochron in Fig. 1. However, this model would predict Mg isotopic fractionation (produced during distillation) that is not observed. Furthermore, it is not clear whether it is physically possible to add normal Mg without equilibrating Mg isotopes, particularly as many of the objects in question have been molten at some point in their histories. Less complicated models fare less well. For example, could macroscopic samples (e.g., Ca-Al-rich inclusions) be presolar? There is no evidence for the spallogenic rare gases that would be produced by interactions with cosmic rays during the interstellar passage, nor is there any strong evidence from other isotopic systems for formation ages that vary by more than a few Myr (see, e.g., Chen and Wasserburg 1981*b*). While it might be possible to select a temperature high enough to volatilize and/or re-equilibrate noble gases without equilibrating Mg isotopes, it seems unlikely that all the chronometers based on elements other than the noble gases could be reset without affecting Mg.

(4) We must know what fraction of the material in the solar nebula arrived with the extinct radionuclide. For example, for a production ratio of 1 for $^{26}\text{Al}/^{27}\text{Al}$ the observed abundance ratio of 5×10^{-5} can occur either because 5×10^{-5} of the ^{27}Al was synthesized with the ^{26}Al and then incorporated in meteorites within a fraction of a half-life of ^{26}Al , or because all the ^{27}Al and ^{26}Al were synthesized in a single event ~ 10 Myr before incorporation into

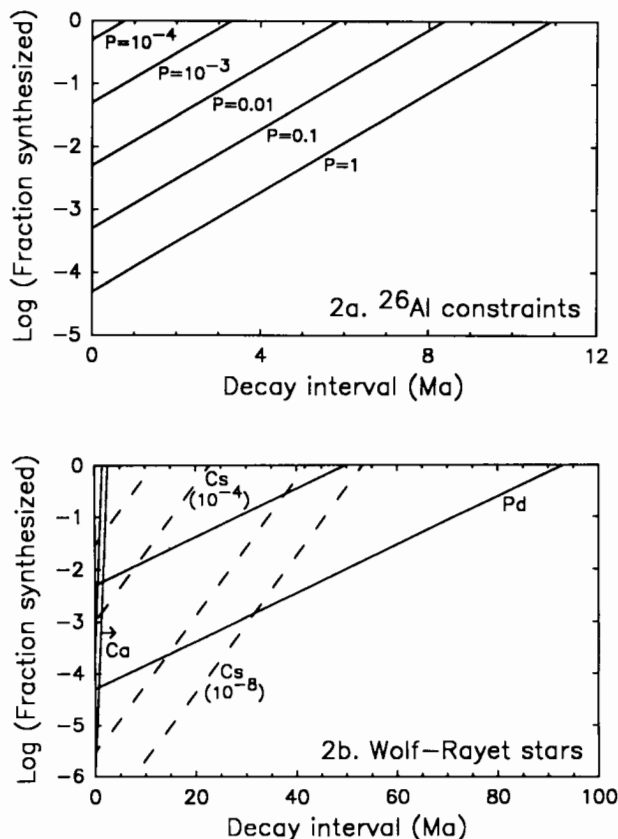

Figure 2. Combined constraint on the decay interval (the time between nucleosynthesis and incorporation into solids) and the fraction of the element synthesized in the last event. (a) ^{26}Al . The solid lines give the constraints for an early solar system $^{26}\text{Al}/^{27}\text{Al}$ ratio of 5×10^{-5} and relative $^{26}\text{Al}/^{27}\text{Al}$ production rates P as indicated. (b) Constraints based on calculations for Wolf-Rayet star nucleosynthesis of ^{41}Ca , ^{135}Cs , and ^{107}Pd (Dearborn and Blake 1988). In each case, the lower line represents the maximum production rate calculated, and the upper line represents the average production rate for a $50 M_{\odot}$ star. Early solar system ratios of $^{41}\text{Ca}/^{40}\text{Ca} = 1 \times 10^{-9}$ (the upper limit), $^{107}\text{Pd}/^{108}\text{Pd} = 2 \times 10^{-5}$, and $^{135}\text{Cs}/^{133}\text{Cs} = 1 \times 10^{-4}$ and 1×10^{-8} are plotted. Note that the fraction synthesized does not have to be the same for all three elements.

solids. The truth is likely to lie somewhere in between (Fig. 2a).

With these caveats in mind, we can evaluate the time scales provided. Because the extinct radionuclides were probably not all produced at the same time and place (Table II), the constraints provided by different extinct radionuclides probably apply to different nucleosynthetic events. Thus, as long as the list of extinct radionuclides does not contain a single pair that has to have

been produced together, it is difficult to use the time scale of one to constrain that of another. However, there are already some useful upper limits, and there are candidate extinct radionuclides that could be extremely useful.

The best constraints are on the actinide-producing *r*-process. Although ^{244}Pu is the only extinct radionuclide whose production requires such a high neutron flux, the upper limit on shorter-lived ^{247}Cm suggests a decay interval of >70 Myr between the last significant actinide production and the formation of the solar nebula (Chen and Wasserburg 1981*b*), while the abundance ratios of longer-lived ^{238}U , ^{235}U and ^{232}Th indicate that actinide production must have occurred over a period of time much longer than the half-life of ^{244}Pu (Schramm 1982).

Similarly, Dearborn and Blake (1988) calculated that nucleosynthesis in a Wolf-Rayet star, followed by 2 to 80 Myr of decay, could satisfy the constraints on both ^{107}Pd and ^{41}Ca (Fig. 2*b*). These calculations predict the presence of ^{135}Cs , but indicate that Wolf-Rayet stars could not be the source of ^{129}I . Note that there are other possible sites for production of ^{107}Pd .

The mechanism and rate of production of proton-rich nuclides are still uncertain (Rayet 1987). If the detection of ^{92}Nb can be confirmed, and the initial $^{92}\text{Nb}/^{93}\text{Nb}$ and $^{92}\text{Nb}/^{146}\text{Sm}$ ratios pinned down, this pair of proton-rich nuclides could constrain both the timing and the mechanism of the *p*- (or γ -) process (Harper et al. 1991*b*). Local production of ^{92}Nb is a possible complication, as ^{92}Nb could be produced within the solar nebula with proton fluxes that would contribute only 2% of the ^{146}Sm (Harper et al. 1991*b*). Even without considering ^{92}Nb , the early solar system abundance of ^{146}Sm has led to a reconsideration of γ -process production rate calculations (Woosley and Howard 1990).

The most interesting constraint is provided by ^{26}Al , whose presence seems to demand that some nuclides were synthesized within 10 Myr of their incorporation into the meteoritic objects in which they are now found (Fig. 2*a*). It is possible that the source of the ^{26}Al γ -ray line, which is still not known with certainty, is also the source of the meteoritic ^{26}Al , although the interstellar $^{26}\text{Al}/^{27}\text{Al}$ ratio appears to be lower than the meteoritic one (Clayton and Leising 1987). It also is possible that the time scale has nothing to do with interstellar transport, if either the nucleosynthesis was nebular or if the ^{26}Mg excesses were fossil. It is worth noting that some of the strongest suggestions that the chemistry be reinterpreted come from an astrophysical perspective (see, e.g., Clayton and Leising 1987), while some of the strongest suggestions that the astrophysics be reinterpreted come from a chemical perspective (see, e.g., Wasserburg 1985).

Models in which 10^{-3} to 10^{-4} solar masses of newly synthesized material is added to the solar system in a single event shortly before formation of meteorites can account for the common 10^{-4} ratio of radionuclides to their stable neighbors (Birck and Allègre 1988), but it does not seem astrophysically reasonable to have all extinct radionuclides synthesized by the same star. In his chapter, Cameron shows that it is possible to construct a series of individually

plausible astrophysical events that can reproduce the solar system abundances of the extinct radionuclides. Whether his specific scenario is, as a whole, plausible remains to be seen, but there is now sufficient information available that better and better models can be constructed and tested.

B. Duration of the Solar Nebula

In principle, we could set a lower limit to the duration of the solar nebula if we could determine the elapsed time between any two nebular events. Since that time is probably a few Myr or less, the most promising chronometers are extinct radionuclides, particularly ^{129}I and ^{26}Al , for which the most data exist. In practice, we cannot set any limits, both because of the difficulty of identifying isotopic systems that have been affected only by nebular events and because of uncertainties about the extent of isotopic inhomogeneity.

The condensation of CAIs and formation of chondrules are both high-temperature nebular events that could be expected to equilibrate the Xe and Mg isotopic systems (i.e., reset the clocks). For the I-Xe system, the difference in apparent age between the oldest (CAI-rich) carbonaceous chondrite, Vigarano, and the oldest chondrules from unequilibrated ordinary chondrites is ~ 5 Myr (Swindle and Podosek 1988). However, the I-Xe system is based on two volatile elements, so processes such as aqueous alteration, mild thermal metamorphism and shock all might be capable of resetting the clock. Furthermore, although there are cases where correlations with elemental and isotopic parameters that indicate the I-Xe system is varying because of decay rather than inhomogeneity, this is not one of them.

The Al-Mg system is less likely to be susceptible to such secondary processes, but is demonstrably susceptible to Al isotopic heterogeneity. This was suspected based on the existence of petrographically similar inclusions with grossly different $^{26}\text{Al}/^{27}\text{Al}$ ratios (Wasserburg and Papanastassiou 1982). The strongest confirmation of heterogeneity comes from an inclusion in the carbonaceous chondrite Efremovka that has a $^{26}\text{Al}/^{27}\text{Al}$ ratio that is an order of magnitude lower than that of the rim, which surrounds the inclusion and must post-date it (Fahey et al. 1987). Thus, although differences of three orders of magnitude in $^{26}\text{Al}/^{27}\text{Al}$ ratios (which would take several Myr of decay) are observed among nebular objects, they may not say anything about the duration of the nebula.

C. Time from First Solids to First Differentiation

A time scale that is easier to address is that from the formation of the first solids to the accretion of bodies large enough to differentiate. In this case, we can set a lower limit by comparing an age set by a nebular event with one set by a differentiation event. Comparisons based on four different radionuclide systems are summarized in Table III. The time scale seems to have been less than 10 Myr, perhaps as short as 2 Myr.

Dating techniques based on long-lived radionuclides such as U isotopes can provide some information. Tilton (1988) has reviewed the subject, con-

TABLE III
Time from Early Solids to Differentiation

Technique	Primitive Sample	Differentiated Sample	ΔT (Myr)
U-Pb ages	Allende (4559 Myr)	Angra dos Reis (4551 Myr)	8
$^{53}\text{Mn}/^{55}\text{Mn}$	Allende (4.4×10^{-5})	Springwater (1.4×10^{-5})	6
$^{129}\text{I}/^{127}\text{I}$	Vigarano (1.60×10^{-4})	Happy Canyon (1.16×10^{-4})	7
$^{26}\text{Al}/^{27}\text{Al}$	Allende (5×10^{-5})	Semarkona chondrule (8×10^{-6})	2

cluding that comparison of Pb-Pb ages of Angra dos Reis (a differentiated meteorite) with Allende (a primitive meteorite) provides the best data. The range in apparent ages for Allende (~ 15 Myr) is larger than can be explained by statistical uncertainties, and may mean that sampling is important (i.e., that Allende contains objects with a range of ages). The ages of Angra dos Reis are in better agreement. Even taking the most extreme values, the difference in age between the two meteorites is < 20 Myr. Tilton (1988) argues that 8 Myr is the best estimate.

Extinct radionuclides provide more precise apparent ages. The $^{53}\text{Mn}/^{55}\text{Mn}$ ratio in the (differentiated) pallasite Springwater (1.4×10^{-5} ; Hutcheon and Olsen 1991), when compared to the ratio in Allende (4.4×10^{-5} ; Birck and Allègre 1988), gives an apparent age difference of 6 Myr. The presence of ^{107}Pd in iron meteorites (Chen and Wasserburg 1990) also suggests a time scale of a few times 10 Myr or less. However, without knowing the $^{107}\text{Pd}/^{108}\text{Pd}$ ratio in any undifferentiated object (see Chen and Wasserburg 1991), it is impossible to be more quantitative than that.

For ^{129}I , Swindle and Podosek (1988) have suggested that the oldest well-defined apparent age comes from the meteorite Vigarano. Vigarano belongs to the same class, CV3, as the canonical "oldest" meteorite Allende (most I-Xe studies of Allende objects have produced variable younger apparent ages, probably dating secondary alteration involving halogens rather than nebular condensation). Several differentiated meteorites contain ^{129}I -derived Xe, with the highest $^{129}\text{I}/^{127}\text{I}$ ratios found in the enstatite achondrites Happy Canyon and Shallowater. These correspond to apparent ages ~ 7 Myr later than Vigarano.

The most precise apparent ages can be provided by the shortest-lived extinct radionuclide, ^{26}Al . However, there is only one case, an anorthite-bearing chondrule in the ordinary chondrite Semarkona, where the presence of ^{26}Al has been detected in what might be a differentiated object. Hutcheon and Hutchison (1989) found a ratio of ^{26}Al to ^{27}Al of $\sim 8 \times 10^{-6}$, which would correspond to an apparent age of 1.9 Myr after typical Allende inclusions (5×10^{-5}). However, this chondrule (and similar objects in Allende) could have been products of nebular processes, rather than differentiation (see, e.g., Kring and Boynton 1990), so it may not be telling us anything at all about the time scale for differentiation. Searches in unambiguously differentiated meteorites have so far failed to find any evidence for live ^{26}Al (see, e.g., Bernius et al. 1991).

The possibility of isotopic heterogeneity should not be forgotten when trying to infer ages from the presence of extinct radionuclides, and ages based on any single radionuclide are certainly suspect. However, unless natural processes have conspired to have lower intrinsic abundances of ^{26}Al , ^{53}Mn and ^{129}I in the region of formation of the carbonaceous chondrites than in the regions of formation of the ordinary chondrites, pallasites and enstatite achondrites, respectively, a 10 Myr upper limit on the time between formation of early solids and differentiation is valid.

D. Time from First Solids to Planets

There are only two planet-sized solar system bodies, the Earth and its moon, for which we have any chronologically significant isotopic data. In each case, ages of 50 to 100 Myr after the formation of primitive meteorites are suggested (Swindle et al. 1986a; Carlson and Lugmair 1988).

Two different approaches have been applied to the problem of the age of the Earth. The first approach, pioneered by Patterson (1956), involves identifying times of early U-Pb differentiation. Such calculations give ages ranging from contemporaneous with meteorites to ~ 100 Myr later. However, this first differentiation could be within the planetesimals from which the Earth formed, rather than the time of formation of the Earth as a planet. The second makes use of the apparent presence of ^{129}I -derived Xe (and, in some models, ^{244}Pu -derived Xe) in the Earth's atmosphere, and dates the time of the last loss of Xe from the Earth's atmosphere or the material that was destined to become the source of the atmosphere. Determination of the abundance of the decay products in the atmosphere is dependent on models of primordial Xe isotopic composition, and the age calculations are extremely sensitive to the poorly constrained I and actinide abundances of the atmospheric source. As in the case of the U-Pb system, ages of ~ 100 Myr after meteorite formation are typical, but contemporaneous ages cannot be excluded (Wetherill 1975b).

For the Moon, the U-Pb and I-Pu-Xe systems can be used in slightly different fashions, and there are some rocks that may be close to the age of the Moon itself. Analyses of the U-Pb system suggest differentiation events at 4420 Myr and perhaps 4590 Myr (Wasserburg et al. 1977; Tera and Wasserburg 1976). The I-Pu-Xe chronometer can, in principle, be applied to rocks which have ^{129}I - and ^{244}Pu -derived Xe, unaccompanied by the ^{129}I or actinides that would be expected for *in situ* decay. This Xe, which is found only near the surfaces of grains, has apparently been produced by decay within the Moon and then transported to the lunar surface where it was somehow implanted into the rocks where it is now found. Swindle et al. (1986a) have suggested that the ratio of ^{129}I - to ^{244}Pu -derived Xe in some samples suggests that the decay occurred in the Moon no more than 50 to 100 Myr after the time of formation of meteorites. Finally, there are some very old lunar rocks. In particular, there are two rocks (76535 and 60025), both of types expected to be created in the earliest lunar crust, for which two different dating methods give an age of 50 to 120 Myr after the time of formation of meteorites (Table IV). However, in each case, the ages derived by different methods differ by more than the statistical errors, leaving the results open to interpretation (Carlson and Lugmair 1988).

Thus for both the Earth and Moon, formation intervals of ~ 50 to 100 Myr after the formation of primitive meteorites are suggested, in agreement with accretion calculations (Wetherill 1980a). However, there are large enough uncertainties in the calculation of these formation intervals that the agreement

TABLE IV
Ages of the Oldest Lunar Rocks

Sample	Age (Myr)	Technique	Reference
76535	4340 \pm 80	K-Ar	Bogard et al. 1975
	4080 – 4230	K-Ar	Huneke and Wasserburg 1975
	4260 \pm 20	K-Ar	Husain and Schaeffer 1975
	4260 \pm 60	Sm-Nd	Lugmair et al. 1976
	4530 \pm 70	Rb-Sr	Papanastassiou and Wasserburg 1976
	4510 \pm 80	Pu-REE-Xe	Caffee et al. 1981

	4440 \pm 20	Sm-Nd	Carlson and Lugmair 1988

with calculated time scales should not be taken as proof that the calculated time scales are correct.

IV. SUMMARY

From the study of extinct radionuclides, we calculate the following time scales:

1. The time between nucleosynthesis and formation of surviving meteoritic grains was <10 Myr for at least 10^{-4} of the Al in some meteorites. Unless virtually all the Al was synthesized in a single late event, the time was probably no more than a few Myr. Although suggestions of local nucleosynthesis and of incorporation of non solar system grains have been made, it seems likely that these time scales apply to the transport of freshly synthesized material from another star to the solar nebula. Other extinct radionuclides set different, less stringent, limits, but as production probably occurred in different settings, these need not be dating the same event.
2. We cannot set any firm constraints on the duration of the nebula. Major confounding factors are the possibility of isotopic inhomogeneities in the solar nebula (particularly for ^{26}Al) and a lack of understanding of what nonnebular events could reset isotopic clocks (particularly for ^{129}I).
3. The time from the formation of surviving solids to the formation of bodies large enough to undergo differentiation is almost certainly <10 Myr, and may be as short as 2 Myr.
4. The time from the formation of solids to the formation of the Earth and Moon seems to be 50 to 100 Myr. Most of these calculations are quite uncertain, but the results are comfortably close to theoretical predictions.

Future work that is likely to occur includes:

(a) Identification of the mechanisms and sites of production of extinct radionuclides. It is particularly important to understand whether some of these could have been synthesized within the solar nebula. If not, then the challenge is to understand how ^{26}Al was transported into the solar nebula so quickly (see Cameron's Chapter).

(b) Determination of the distribution of extinct radionuclides within the solar nebula. Demonstrations of isotopic homogeneity, if possible to achieve, might make it possible to address some of the early time scales with more confidence, while demonstrations of inhomogeneity could be used to constrain the amount of mixing within the nebula. The distribution of ^{26}Al is particularly important, not just because of its chronological significance, but because it is a potential heat source in early solar system bodies. The search for clear evidence of ^{26}Al in clearly differentiated objects is certain to continue.

(c) Identification of more extinct radionuclides. This is more than just an exercise in expanding Table I. A single extinct radionuclide, even if its production rate is well known, can only constrain the combination of (1) time since nucleosynthesis, and (2) fraction of material synthesized. Adding a second radionuclide that was produced at the same time and place can resolve that ambiguity. The current list does not contain a single pair of extinct radionuclides that *must* have been synthesized together, although there are several pairs that *may* have been synthesized together. Although there are some upper limits for the abundance of some potential extinct radionuclides that can be paired with confirmed extinct radionuclides to provide limits on transport times (Fig. 2), actual values will be even more useful.

PHYSICAL AND ISOTOPIC PROPERTIES OF SURVIVING INTERSTELLAR CARBON PHASES

U. OTT

Max-Planck-Institut für Chemie

Primitive meteorites contain grains that clearly represent surviving interstellar material. These grains are carbonaceous in the three cases that are well documented and are discussed here: tiny (size $\sim 0.003 \mu\text{m}$) diamonds, graphitic carbon and silicon carbide. Unambiguous proof for the interstellar origin of these grains is their isotopic composition, which not only for the trace elements they carry (notably the noble gases) is unusual, but also for the structural elements (C, N, Si) is both unusual and (at least in the case of the graphite and SiC grains) variable on a grain-to-grain basis, pointing to an origin from specific nuclear sources. The survival of these grains as well as their ability to retain the volatile noble gases that we find in them puts constraints on the temperature and/or the chemical environment to which they have been exposed. It remains to be shown, however, that they were part of the solar system during its formative stage if, from their survival, one wants to draw conclusions regarding conditions during solar system formation.

I. INTRODUCTION

It has become clear during the past 2 decades, through the study of the isotopic composition of meteorites, that the matter from which the solar system formed cannot have been totally homogenized at any one stage. Rather, isotopic heterogeneity on a small scale (refractory Ca-Al rich inclusions in carbonaceous meteorites; see, e.g., Papanastassiou and Brigham 1989; Ireland 1990) and on a large scale (variations in the oxygen isotopic composition among different meteorite parent bodies; Clayton et al. 1976) appears to have been the rule despite evidence that, in establishing the *elemental* composition of these objects, high-temperature events before or during their formation must have played a crucial role (cf. Ireland 1990; Chapter by Palme and Boynton).

In addition, work performed during the past 3 yr (i.e., after *Protostars and Planets II*) has identified refractory carbon phases as the carriers of isotopically anomalous noble gases which testifies to the almost intact survival of whole grains of interstellar material. The properties of such refractory carbon phases will be described in this review. Unless specified otherwise, properties of the phases of interest such as their abundances etc. refer to the observations on the C2M meteorites Murray and Murchison, where their study has been most complete. For another recent survey see Anders (1988).

II. CONDITIONS FOR SURVIVAL OF INTERSTELLAR MATTER AND ITS IDENTIFICATION

Before a detailed discussion of specific phases of surviving interstellar matter, we shall address the question of what one might expect to find, that is, the likelihood of interstellar matter surviving and being identified as such.

A. Identification

The only generally accepted way to prove an interstellar origin of matter that we find in meteorites today (and, hopefully, in the future on other primitive bodies such as comets) is by means of its isotopic composition. Only if it differs from the common, solar-system composition in a way not explicable by prosaic processes such as mass fractionation, radioactive decay or cosmic ray interaction, can we be reasonably sure about its interstellar origin. Because in the region of space where the solar system formed the average composition of interstellar matter 4.6 Gyr ago must have been (for the nuclides not affected by these prosaic processes) just that of the solar system now, our ability for identifying interstellar matter as such is surely restricted. In addition, we have to distinguish between matter formed *in* the solar system from insufficiently mixed presolar material and truly surviving presolar matter. To identify the latter without any doubt may be possible only in the case of direct stellar condensates, which still carry the isotopic signature of a single nucleosynthetic source.

B. Survival

Two properties appear useful. First, the matter of interest should be refractory (i.e., temperature-resistant). And second, it should be chemically resistant (inert) under the conditions prevailing in the interstellar medium, during formation of the solar system and during evolution of the meteorite parent body, which has been the host until its delivery to Earth via a meteorite. (Chemical resistivity in the laboratory, i.e., resistance to acids, has also been essential in the isolation of the presolar carbon phases discussed here.) Based on these requirements, one can expect basically two forms of matter to have survived and to be identifiable as interstellar: refractory oxides and refractory carbon compounds, which are the chemically stable forms for different C/O ratios. For a solar system-like C/O ratio (0.42; Anders and Grevesse 1989) the oxides, not the carbon compounds, are the stable phases. However, it is for the carbon phases, not the oxides, that the case for survival of presolar matter is strongest. Isotopic anomalies in refractory oxides have been found in the high-temperature Ca-Al-rich inclusions (CAI's) in carbonaceous meteorites (see, e.g., Papanastassiou and Brigham 1989; Ireland 1988, 1990); but, although the isotopic anomalies there appear not to have been fully wiped out, the CAI's and their constituents do *not* represent unaltered, presolar material, and may constitute a case of formation *in* the solar system from insufficiently mixed presolar material (MacPherson et al. 1988; Ireland 1990). In this review, therefore, we concentrate on the C phases.

In addition to the other isotopic properties that will be discussed below in detail, one of the strongest arguments that sets aside the refractory carbon phases as almost certainly presolar against these oxides is the level in which extinct radioactive ^{26}Al ($T_{1/2} = 7 \times 10^5$ yr; now showing up as an excess of stable ^{26}Mg) occurs in them (Zinner et al. 1991). Ratios $^{26}\text{Al}/^{27}\text{Al}$ at the time of formation of these phases (or introduction of Al into them) of up to 0.2 have been inferred from the measurements on graphite and silicon carbide; this is close to the expected production ratio and requires almost immediate formation of these phases (or introduction of the Al) after the nucleosynthetic event that produced this Al. In contrast, the corresponding value of typically 5×10^{-5} for the oxides in the refractory inclusions is 4000 times lower, leaving some extra 10 Myr time between formation and fixation of the observed ratio.

Besides the refractory carbon phases which are likely to be of circumstellar origin (Anders 1988), there is evidence for the presence of (also carbon-bearing, but more volatile) material for which an origin in interstellar *clouds* is indicated (Zinner 1988), notably because of its high D/H ratio. In addition, there are at least two cases of clearly strongly processed material possibly carrying extreme isotopic anomalies: Ag in iron meteorites (Kaiser and Wasserburg 1983) and nitrogen in the stony-iron meteorites Bencubbin and Weatherford (Prombo and Clayton 1985; Franchi et al. 1986). However, a prosaic origin, as defined above, of the large deviations from the isotopic normals has not yet been ruled out in these cases.

III. NOBLE GAS COMPONENTS AND THEIR ISOLATION

The identification of carbonaceous interstellar matter has been largely the result of the quest for the host phases of isotopically anomalous trapped (i.e., not *in situ* produced) noble gases. Noble gases are easier to separate, study and characterize than other elements (Anders 1988), and, especially important, are "diluted" to a much smaller extent by "normal" matter because even the most primitive bulk meteorites contain only a small fraction ($\sim 10^{-4}$ for Xe to $\sim 10^{-9}$ for He) of their solar abundances. For that very reason, at least in bulk matter isotopic variations in noble gases are quite often orders of magnitudes larger than the isotopic variations in the rock-forming elements (Clayton et al. 1988; Lee 1988) which are usually measured in per-mill (10^{-3}) or ϵ -units (10^{-4}) deviations from the normal. As discussed below in more detail, the anomalous noble gases reside in a small amount of very resistant carbonaceous carrier material. As such they have served as the guide in the isolation of these phases, in which isotopic anomalies found in other elements are actually of the *same* order of magnitude as those of the noble gases. Along the way, more phases with distinct C isotopic compositions have been found, but no connection to other elements has been established yet (see Ash et al. 1990). As only the noble-gas-carrying phases have been identified so far, we restrict the discussion to these. Contributions from other local sources (^4He and ^{40}Ar of radiogenic origin, ^3He and Ne of cosmogenic origin in the case of

the noble gases) are usually only a minor complication in the isotopic study of these phases.

Figure 1. Composition of important Ne components in the solar system in a 3-isotope $^{20}\text{Ne}/^{22}\text{Ne}$ vs $^{21}\text{Ne}/^{22}\text{Ne}$ diagram. The presolar phases discussed here carry the Ne components marked by filled circles: Ne-A2 (carried by diamonds) and Ne-E (carried by graphite and SiC). Compositions as summarized in Swindle (1988) except for Q-Ne (Wieler et al. 1989) and Ne-A1 (Tang and Anders 1988c). See also Table I.

Most prominent are the isotopic variations in Ne and Xe. Although, formally, for an element with 3 isotopes, any isotopic composition can be described by a mixture of 3 extreme components, there is compelling evidence for the existence of more than 3 distinct components of trapped Ne the relation between which is not well understood (see, e.g., Swindle 1988). Figure 1 shows the position of major components found in solar system materials in a 3-isotope diagram of $^{20}\text{Ne}/^{22}\text{Ne}$ vs $^{21}\text{Ne}/^{22}\text{Ne}$. Note that in this representation with a common denominator mixtures of 2 components lie along a straight line connecting the end-member compositions. Most spectacular is Ne-E, which is almost pure ^{22}Ne (Table I). Based on their occurrence in different host phases (see below) two varieties, Ne-E(L) and Ne-E(H) have been distinguished; there appears to be also a slight difference in isotopic composition, with Ne-E(H) containing finite amounts of ^{21}Ne (Lewis et al. 1990).

The case of Xe with its large number of isotopes (9) is most complex; for a detailed discussion see the review by Swindle (1988). Figure 2 shows the composition of the 2 isotopically anomalous Xe components which are most interesting in the context of this chapter. Plotted is also AVCC-Xe, which is not a pure component but the composition measured for total Xe in carbonaceous meteorites of type 1 and 2. Shown are the deviations in ‰ of the ratios $^i\text{Xe}/^{130}\text{Xe}$ from the same ratios in solar wind xenon as identified in lunar soil. ^{129}Xe has been omitted because of possible radiogenic contribu-

Figure 2. Exotic Xe components Xe-HL (carrier: diamond) and *s*-process Xe (carrier: SiC) compared with solar Xe as inferred from measurements of solar wind Xe implanted in lunar soil (Swindle 1988). Shown are the deviations in ‰ in the ¹³⁰Xe-normalized isotopic ratios from the solar composition. Note that not pure inferred endmember compositions are shown but highly extreme *measured* compositions that are still diluted to some extent with "normal" Xe: Xe in A-II-D/HClO₄ (Ott et al. 1981) for Xe-HL and Murchison CFOc/1080°C (Ott et al. 1988b) for Xe-S. Also shown for comparison is the composition of AVCC-Xe, not a pure component, but what is measured in bulk analyses of C1 and C2 carbonaceous chondrites.

tions from now-extinct ¹²⁹I with a 16 Myr half-life. Note that what is plotted for the exotic components Xe-HL and Xe-S are the *measured* ratios for samples extremely enriched in these components; the inferred compositions of the pure components would be even more extreme. Xe-HL is characterized, relative to ¹³⁰Xe and the solar wind composition, by an overabundance of the light and heavy Xe isotopes by up to a factor >2. Xe-S shows approximately,

though not in detail, opposite deviations from solar Xe. Relative to ^{128}Xe and ^{130}Xe , which are produced in the *s*-process only (with minor *p*-process contributions), all other isotopes are strongly depleted. The pattern is consistent with the addition to isotopically normal xenon of Xe as it is produced in the slow neutron capture process (*s*-process) of nucleosynthesis.

A major breakthrough in the search for the host phases of both exotic and isotopically ordinary noble gases occurred when their resistance to acids was noted by the Chicago group of Anders and coworkers (Lewis et al. 1975) in their work on the carbonaceous chondrite (C3V) Allende. [A similar, earlier, result for the carrier phase of the trapped noble gases in the ureilite Haverö has been obtained by Weber et al. (1971), but ureilite meteorites do not contain isotopically anomalous noble gases.] Later work (Alaerts et al. 1980; Lewis et al. 1987; Tang and Anders 1988a) showed that almost all the phases of interest were resistant to extremely harsh chemical treatments (with the notable exception of the host phase of Ne-E(L); see Tables I and II).

The procedures leading to their isolation can be summarized as consisting of 3 basic steps:

1. Dissolution of ~99% of meteoritic material (the exact amount depending on meteorite type) in HF/HCl;
2. Use of oxidizing agents that remove (the carriers of) the normal type trapped noble gases (Q; Table I);
3. Separation of the exotic components from each other according to physical properties such as grain size and density.

Most of the work described here has been done by the Chicago group of Anders and coworkers (isolation of carrier phases, noble gas work) in collaboration with the group of Pillinger at Milton Keynes, U. K. (formerly Cambridge, U. K.; C and N isotopes) and E. Zinner and coworkers at St. Louis (ion probe analyses of C, N, Si, Mg isotopes). The author's own group has been involved in the isotopic characterization of the heavy noble gases Kr and Xe and other so-called heavy elements.

In some way, results of the work since 1975 are reminiscent of nested Russian dolls, with the noble gas of interest always contained in another subfraction of the isolated material. Table II gives a summary of our current understanding of the compositions of the Ne and Xe components and the host phases assigned. Their physical properties are summarized in Table II. Below, each is discussed in detail. Of these phases, diamond (C δ) and SiC (C β , C ϵ) appear to be fairly well characterized by now (Anders 1988; Lewis et al. 1989; Tang et al. 1989), with progress being currently made in the case of C α (Amari et al. 1990a). But even within each of these phases there still exist isotopic variations, as has been shown by ion probe work (Zinner et al. 1989, 1990), which may not be surprising given the fact that there may be a number of sources (stars) for these phases (see below). In addition, as pointed out above, more phases distinct in the isotopic composition of C, but

^b Release- T refers to the temperature where major release of noble gases occurs during laboratory analyses (heating in vacuum). Ion probe measurements have shown the C isotopic composition of SiC and C α graphite to vary from grain to grain. No comparable information is available for the C δ diamonds because of their small size.

with unknown relation to other elements, have been identified by stepwise combustion experiments (see summary by Ash et al. 1990).

IV. DIAMOND (C δ)

Identification of the C δ phase (Swart et al. 1983) that carries Xe-HL and Ne-A2 as being a form of diamond had to wait until 1987 (Lewis et al. 1987), 12 yr after the discovery of its acid resistance (Lewis et al. 1975). The principal reason for the surprisingly long time span was probably its extremely small grain size of only ~ 2.6 nm on the average (Lewis et al. 1989). The log-normal size distribution contrasts with the inferred power-law distribution for interstellar dust (Mathis et al. 1977).

Diamond is by far the most abundant of the anomalous gas-carrying phases. In carbonaceous meteorites of type C2, it amounts to something like $400 \mu\text{g g}^{-1}$ of bulk meteorite. It has also been observed in the less primitive type 3 meteorites (carbonaceous as well as ordinary and enstatite types), although in lower abundance (Schelhaas 1987; Huss 1990; Schelhaas et al. 1990). Under laboratory conditions, noble gas release occurs at around 1000°C ; in an oxygen atmosphere it combusts at around 500°C . The somewhat lower combustion temperature as compared to terrestrial diamond is probably caused by its small grain size (Ash et al. 1987), but possibly also its H-rich composition (Bernatowicz et al. 1990) plays a role. In the case of the other 2 carrier phases discussed below, graphite and SiC, grain-to-grain variations in the isotopic composition of the major elements (C, N, Si) have been found. Similar information on the diamonds cannot be obtained with currently available techniques because of their small grain size. Their inferred carbon isotopic composition, which therefore could be only a mean value, is within the range observed in terrestrial materials and (by itself) does not provide a basis for identification as interstellar material. $\delta^{13}\text{C}_{\text{PDB}}$ is -32‰ (Ash et al. 1990), i.e., $^{13}\text{C}/^{12}\text{C}$ is 32‰ lower than in the terrestrial PDB standard or $^{12}\text{C}/^{13}\text{C} = 92$. Nitrogen carried by the diamonds, however, is clearly isotopically unusual. The deviation of $^{15}\text{N}/^{14}\text{N}$ from the AIR value, i.e., $\delta^{15}\text{N}$, is -330‰ (Lewis et al. 1983a; Anders 1988), which corresponds to $^{14}\text{N}/^{15}\text{N} = 406$ rather than the normal 272.

A. Compositional Properties

The compositional properties of the meteoritic microdiamonds have been extensively described in a review by Lewis et al. (1989). In aqueous solution, the diamonds behave like a weak acid, forming colloids at high pH values and coagulating at lower pH. The presence at the surface of weakly acidic groups such as $-\text{COOH}$ has been suggested as an explanation. The presence of $-\text{COOH}$ may also be responsible (in part) for the O-H peak at 3402 cm^{-1} and the C=O feature at 1777 cm^{-1} in the infrared spectrum (Lewis et al. 1989). There are also other infrared features that can be attributed to C-H and nitrogen (or C-O).

Other spectral data indicate an amorphous character of (part of) the diamonds (Blake et al. 1988; Bernatowicz et al. 1990). Electron energy loss spectra (EELS), in particular, suggest that the diamond residues actually consist of a mixture of diamond proper and some form of amorphous carbon, probably "diamond-like hydrocarbon," in roughly equal proportions (Bernatowicz et al. 1989, 1990).

B. Formation of Diamond, C δ

In principle, 2 mechanisms appear possible: formation from graphitic precursor material under high pressure (static or shock) or direct condensation from the vapor phase (chemical vapor deposition; CVD). Static high pressure can be safely ruled out. Formation by interstellar shock has been suggested by Tielens et al. (1987), and comparison was made by Greiner et al. (1988) to diamonds produced as solid detonation products. Formation by CVD as suggested by the discoverers (Lewis et al. 1987) appears more likely, however. The available evidence is discussed by Anders (1988) and Lewis et al. (1989). Their conclusions are supported by the result of recent calculations by Badziag et al. (1990) which indicates that CVD diamond may be not the metastable condensation product as previously thought but rather the thermodynamically stable product. According to these authors, for grain sizes ≤ 3 nm, the formation of diamonds is energetically favored over that of polycyclic aromatics (thought to be graphite precursors). Such a formation process may also imply a closer connection between the isotopic compositions of the trapped noble gases and that of their host phase.

C. Origin of Xe-HL

First suggestions for the origin of Xe-HL (formerly also called CCF-Xe, CCFX, Xe-X and DME-Xe) were based on the observed enrichments in the heavy Xe isotopes and called for a fission origin of these. Because the fission spectrum did not match any of the known fission spectra, *in-situ* fission of a superheavy element was suggested (Srinivasan et al. 1969; Anders and Heymann 1969; Dakowski 1969; Anders et al. 1975; Anders 1981). This interpretation, however, has been discarded meanwhile. Following Manuel et al. (1972), who pointed out the need to account for the excesses not only of the heavy, but also of the light (not fission-produced) Xe isotopes, a nucleosynthetic origin is generally accepted since at least 1983. Crucial observations in that year were (a) the detection of a nitrogen isotopic anomaly in the Xe-HL carrier phase (Lewis et al. 1983a) and (b) the negative result of Lewis et al. (1983b) in their search for CCF-Ba associated with CCF-Xe (i.e., Xe-HL). Such a result could not be explained by the *in situ* fission model, where comparable amounts of fission-Ba and fission-Xe were expected to be present. Lewis et al. obtained an upper limit of 0.03 for the ratio HL-¹³⁵Ba/HL-¹³⁶Xe, but in retrospect it appears that in their work (which was performed *before* the identification of C δ as diamond) the diamonds proper could not have been analyzed for their Ba. New data on diamonds from the Allende meteorite

give only an upper limit of ~ 1 (U. Ott, unpublished), but it seems likely that a limit lower than this can be set after more complete separation of extraneous Ba from the diamonds.

Formation of Xe-HL during nucleosynthesis appears to require the action of a supernova. The most extensive studies have been performed by Heymann and Dziczkaniec (1979, 1980). Other, later work (see, e.g., Clayton 1989) has mostly focused on the H part (heavy isotopes) of Xe-HL only. Heymann and Dziczkaniec have investigated explosive nucleosynthesis in a massive star of $25 M_{\odot}$. According to their results, Xe-H can be produced in the C shell by neutron capture reactions, a "mini-*r*-process" intermediate between the slow *s* and rapid *r* neutron capture processes of nucleosynthesis that phenomenologically describe the synthesis of the bulk of the heavy nuclides in their solar system abundances. Xe-L could have been produced in the same star in deeper zones (O-shell) at higher temperatures (2.7×10^9 K) by photodisintegration of a Xe/Ba seed.

D. Trapping Process

Lewis and Anders (1981) have pointed out that there is no evidence for a significant ^{129}Xe enrichment in Xe-HL. Such an enrichment would be expected if present-day HL- ^{129}Xe had been largely trapped in the form of its progenitor ^{129}I , and if the trapping process were condensation or adsorption as these processes would favor chemically active elements over the noble gases (Anders 1988). This reasoning is also supported by the lack of enrichment of Ba-HL relative to Xe-HL. Anders (1988) suggests trapping by ion implantation in a scenario proposed by Clayton (1981), where the hot plasma of a supernova, containing Xe-HL, overtakes a dust shell previously expelled during the star's red giant or planetary nebula stage. However, according to Jørgensen (1988) Xe-HL and the C δ diamonds that carry it cannot have been produced by the same star. He suggests that both were produced in the two stars of a close binary system, the diamonds in the smaller of the two companions near the end of its evolution, Xe-HL in the compact remnant (white dwarf) of the bigger star, after it accreted enough mass from its companion to explode as a type I supernova. However, clearly more work on the nucleosynthetic processes and possible sites needs to be done. Only then will we be able, by building on the observed properties of the surviving interstellar diamonds in meteorites, to identify also the trapping process.

V. GRAPHITIC CARBON (C α)

Being less resistant to chemical attack than diamond or silicon carbide and, at the same time, being much rarer ($< 1 \mu\text{g g}^{-1}$ bulk C2 meteorite), C α , the host phase of Ne-E(L) has proved to be the most difficult one to characterize, but progress is currently being made. First results indicated C α to be a graphitic phase, being destroyed by HClO_4 treatment at 200°C . In the laboratory, a

combustion temperature for $C\alpha$ of $\sim 650^\circ\text{C}$ (Ash et al. 1990) and a Ne-E(L) release temperature, upon heating in vacuum, of $\sim 700^\circ\text{C}$ were inferred (Anders 1988). Stepwise combustion analyses indicated both carbon and nitrogen to be isotopically unusual. The inferred compositions (Table II) are $\delta^{13}\text{C}_{\text{PDB}} \sim +340\text{‰}$ and $\delta^{15}\text{N}_{\text{AIR}} > +250\text{‰}$, corresponding to $^{12}\text{C}/^{13}\text{C} \sim 66$ and $^{14}\text{N}/^{15}\text{N} < 220$ (Tang et al. 1988).

Figure 3. Carbon and nitrogen isotopic compositions measured in single grains of separate Murchison LFC1 (Zinner et al. 1990) which is enriched in the carrier phase of Ne-E(L) ($C\alpha$). Note the logarithmic scales on both axes. The "normal" solar compositions are indicated by the dashed lines. Especially large are the variations in $^{12}\text{C}/^{13}\text{C}$. The composition of C δ diamond is also shown for comparison (figure provided by E. Zinner).

However, the latest ion probe and noble gas work (Amari et al. 1990a, b, c) shows growing complexity. Ion probe analyses reveal that the C and N isotopic compositions for individual grains are variable (Fig. 3; note the logarithmic scales) so that the $\delta^{13}\text{C}$ of $+340\text{‰}$ must be a mean value for the earlier prepared $C\alpha$ -rich samples. They do not support a link with heavy nitrogen (Amari et al. 1990b; E. Zinner, personal communication). According to this latest work, round grains with 1 to $6\text{ }\mu\text{m}$ diameter appear to be those that carry Ne-E(L). The composition of the individual $C\alpha$ grains correlates with morphology, with $^{12}\text{C}/^{13}\text{C}$ for the round grains ranging from 0.05 to 50 times the solar value, but C in the other forms close to normal (Amari et al. 1990b, c).

Noble gas work on a new set of Ne-E rich samples (Amari et al. 1990a) indicates the existence of two Ne-E(L) carrier phases, C α 1 and C α 2, both of grain size $>1\ \mu\text{m}$, but differing in release temperature of the anomalous Ne ($\sim 700^\circ\text{C}$ vs $\sim 900^\circ\text{C}$) and density. The apparent host phase of the low-temperature Ne-E(L), C α 1, consists of heavier carbon of lower density with generally higher contents of other elements, whereas C α 2 is isotopically light and consists of well-crystallized graphite with low impurity content.

A. Nuclear Source of Ne-E

There appears to be a variety of possible sources that can produce Ne-E. In thermonuclear reactions under nonexplosive conditions neon with $^{20}\text{Ne}/^{22}\text{Ne} < 0.01$ can be produced at low density and high temperatures ($< 10\ \text{g cm}^{-3}$, $4 \times 10^8\ \text{K}$). This neon, however, would be accompanied by large amounts of ^4He (Arnould and Nørgaard 1978) from which it has to be separated. The extreme isotopic purity of Ne-E(L) favors production via the precursor ^{22}Na ($T_{1/2} = 2.6\ \text{Gyr}$), which would allow easy separation from the noble gases. Partly based on the apparent enrichment of ^{15}N , novae have been favored as a source of Ne-E (Clayton and Hoyle 1976; Arnould and Nørgaard 1981), but this will have to be re-assessed with the new ion probe N isotope data for C α (Amari et al. 1990b). On the other hand, the composition of Ne-E(H), which is isotopically less pure ^{22}Ne (Table I) and is carried by silicon carbide (see below) is consistent with an origin from a low-mass AGB (asymptotic giant branch) star, as are the other anomalies detected in SiC.

VI. SILICON CARBIDE

Silicon carbide (Fig. 4) occurs in C2 meteorites in abundances of a few ppm (Tang et al. 1989; Zinner et al. 1989). According to these authors (and references cited therein) SiC occurs in two varieties, C β and C ϵ , that differ in grain size and associated noble gas components. C β with a grain size between 0.03 and $0.2\ \mu\text{m}$ and, like the C δ diamonds, a log-normal size distribution (Tang and Anders 1988a), is defined as the carrier of *s*-process Xe, while C ϵ (grain size $> 0.1\ \mu\text{m}$) is thought to carry Ne-E(H). There is some doubt, however, about this division into two types of SiC. For one thing, the latest noble gas data for SiC by Lewis et al. (1990) indicate nearly uniform concentrations of $^{82}\text{Kr-S}$ in various size ranges, with Xe-S declining and Ne-E(H) increasing in abundance with grain size. [Note that this behavior is different from the trend in Table I of Zinner et al. (1989), because these authors assumed constant Ne-E(H) content of SiC in order to estimate the SiC content of their samples.] In addition, as already pointed out by Ott et al. (1988a) and confirmed by these newer data, changes in the Ne-E(H)/Xe-S (as well as Kr-S/Xe-S) ratio are accompanied by changes in the isotopic composition of *s*-process Kr, with higher Ne-E/Xe-S ratios accompanying krypton that has been produced under more neutron-rich conditions. Such a correlation is not a natural consequence of mixing two SiC carrier types, one carrying

Figure 4. SEM photograph of one of the largest SiC crystals (figure courtesy of E. Zinner). Scale bar is 10 μm .

N-E(H), the other carrying *s*-process material. Independent of whether a two-component mixture or a continuous spectrum is a better description of reality, it appears that the *s*-process Kr and Xe found in meteoritic SiC may be naturally accompanied by Ne-E(H) as both can be produced in low-mass thermally pulsing asymptotic giant branch (TP-AGB) stars (Gallino et al. 1990). To complicate matters further, there are more recent noble gas results of Amari et al. (1990a) obtained in conjunction with their work on graphite that suggest the existence of a "super-carrier" of the *s*-process gases (an even smaller Russian doll), that possibly makes up only a small subfraction of the SiC; but even the identification of SiC as the (sole) carrier of the *s*-process anomalies may have to be questioned based on their results.

Variations in the isotopic composition of the structural elements of SiC are extreme (Table III). $^{12}\text{C}/^{13}\text{C}$ varies by a factor >350 , $^{30}\text{Si}/^{28}\text{Si}$ by a factor of almost 3, and, of course, the variations in nitrogen ($^{14}\text{N}/^{15}\text{N}$ varies by >300 times) and the noble gases that appear associated with SiC are huge as well. As an example, ion probe data for Si obtained by Zinner and coworkers for individual grains (Wopenka et al. 1989) are shown in Fig. 5 (see also the results obtained for a morphological subclass of SiC grains by Stone et al. [1990]). From the fact that (in a previous set of samples) single grains occupied isotopically distinct places, Zinner et al. (1989) have inferred the existence of at least 6 isotopically independent Si components. Since the

C and N data (see below) indicated the action of processes that could have altered the Si isotopic composition in only 2 of these cases (but cf. Gallino et al. 1990), they have argued that they were dealing with SiC contributions from at least 4 individual stars.

TABLE III
Isotopic Ratios in Meteoritic SiC^a

Ratio	Solar System	Silicon Carbide	
		Absolute	Normalized
$^{12}\text{C}/^{13}\text{C}$	89.0	3.0 – 1135	0.03 – 13
$^{14}\text{N}/^{15}\text{N}$	272.2	18 – 6200	0.07 – 23
$^{29}\text{Si}/^{28}\text{Si}$	0.0506	0.031 – 0.064	0.62 – 1.26
$^{30}\text{Si}/^{28}\text{Si}$	0.0336	0.014 – 0.038	0.41 – 1.14
$^{20}\text{Ne}/^{22}\text{Ne}$	13.7	0.23	0.017
$^{130}\text{Xe}/^{132}\text{Xe}$	0.55	1.38	2.51

^a Source: Zinner et al. (1989) and Zinner (1990, personal communication). See also Fig. 6. The last row shows the measured ratios normalized to the solar system values. C α (graphite) has a range in the C isotope ratio that extends to even higher values (Fig. 3).

Carbon and nitrogen isotopic data for the same samples as in Fig. 5 are shown in Fig. 6, where the composition of “normal” carbon and nitrogen is indicated by the horizontal and vertical lines. (Note the logarithmic scale for both axes.) Most of the data points plot in the upper left, indicating dominant contributions from H burning via the CNO-cycle, although only in one case is the CNO-cycle equilibrium value (cross in Fig. 6) approached. A rightward shift (higher $^{12}\text{C}/^{13}\text{C}$) may be due to contributions from He-burning or ^{12}C dredged up during the AGB phase. Contributions from these processes are consistent with a red giant origin for the SiC which had been proposed early on after the discovery of *s*-process Xe (Srinivasan and Anders 1978) as red giants are considered as the place where the *s*-process occurs.

A downward shift (to lower $^{15}\text{N}/^{14}\text{N}$), on the other hand, could possibly result from He or explosive H-burning. There is no obvious regular relationship between the Si and C, N isotopic compositions in Figs. 5 and 6. Again, this is not unexpected for a red giant origin, because, due to dredge up, red giant atmospheres keep changing in C and N composition probably without much affecting Si.

A. Implications for the *s*-Process

Enhanced contributions from the process of slow neutron capture (*s*-process) in trace elements other than the noble gases have recently been reported for Ba and Sr in acid-resistant residues from Murchison by Ott and Begemann (1990*a, b*). While they have not actually demonstrated the presence of SiC in their samples, it seems likely, after the chemical treatments to which their samples were subjected, that SiC is the carrier phase of Ba-S and Sr-S in their

Figure 5. Si isotopic variations in single SiC grains of Murchison LS and LU (ion probe data by Wopenka et al. 1989; figure courtesy of E. Zinner). The straight line is the terrestrial mass fractionation line. Several independent components are necessary in order to describe the isotopic variations.

samples as well. Combined with the noble gas data, these results can be used to constrain the conditions prevailing during the *s*-process. Of course, this can be done with a much higher degree of confidence from such data than from average solar system abundances because more or less pure *s*-process matter reveals its isotopic signature much clearer than does average solar system matter where the contributions from all relevant nucleosynthetic processes are always inseparably intermingled.

In Ba, an enrichment of *s*-only ^{134}Ba and ^{136}Ba relative to the *p*-only isotopes ^{130}Ba and ^{132}Ba of $\sim 50\%$ has been found (Ott and Begemann 1990a; Fig. 7). The inferred $^{138}\text{Ba}/^{136}\text{Ba}$ ratio of the *s*-process component indicates that the conditions for the production of this *s*-process component were dif-

Figure 6. Isotopic variations of carbon and nitrogen in single SiC grains from Murchison LS and LU. Ion probe data by Wopenka et al. (1989) provided by E. Zinner. The solar system ratios are indicated by the lines. Note logarithmic scales on both axes. For comparison also the composition of the C δ diamonds is shown. See text for discussion.

ferent (lower neutron dose) from those for the solar system “main” s -process component that phenomenologically describes the solar system abundances in the Ba region of the nuclides of s -process origin (Käppeler et al. 1989). Data for krypton first reported by Ott et al. (1988b) indicate that $(^{80}\text{Kr}/^{82}\text{Kr})_s$ is lower and $(^{86}\text{Kr}/^{82}\text{Kr})_s$ higher for Murchison SiC than for the average s -process contribution to the solar system, implying higher neutron density and lower temperature (Fig. 8). Beer and Macklin (1989) have shown that such krypton can be produced in intermediate mass AGB stars with the $^{22}\text{Ne}(\alpha, n)^{25}\text{Mg}$ reaction acting as the neutron source but that the same models cannot reproduce the composition of the average solar-system s -process contribution. In addition, the data of Ott et al. (1988b) showed variations of $(^{86}\text{Kr}/^{82}\text{Kr})_s$ and $(^{80}\text{Kr}/^{82}\text{Kr})_s$ with combustion temperature. From the most recent data by Lewis et al. (1990), it appears that these variations were caused by SiC of different grain sizes combusting at different temperatures. Their new, high-precision, data extend the observed range of variations (as a function of SiC grain size). Calculations reported in a companion paper by Gallino et al. (1990) show that the data for Kr as well as those for the other noble gases can be described by mixing s -process material produced

Figure 7. Composition of Ba in Murchison RICPD and RICPF (Ott and Begemann 1990a). Relative to the *p*-process-only isotopes ^{130}Ba and ^{132}Ba the *s*-only isotopes ^{134}Ba and ^{136}Ba are enriched by $\sim 50\%$ when compared to the “normal” composition.

during thermal pulses in low mass TP-AGB stars with envelope matter from the same star. At present, it is an open question, however, how important or how typical the kind of nuclear contributions we see in the silicon carbide grains from meteorites are with regard to the solar system as a whole.

B. Trapping Process

In contrast to the case of the diamonds that carry Xe-HL, trapping by SiC of the *s*-process nuclides seems to have occurred under conditions that resulted in elemental fractionation. Ott and Begemann (1990a) report a fractionation factor between *s*-process Ba and *s*-process Xe of ~ 1800 favoring Ba. As an explanation they suggest that trapping occurred by implantation of ions with the fractionation factor reflecting the different degrees of ionization of the elements involved, i.e., ambipolar diffusion as has already been suggested for trapping of noble gases in other cases (Jokipii 1964; Göbel et al. 1978). From the Ba/Xe fractionation, a relevant temperature around 10,000 K has been implied (Ott and Begemann 1990a), quite similar to the temperatures implied from the elemental abundance pattern of the isotopically normal ureilite noble gases. Interestingly, there have been recent identifications of former red giants, post-AGB stars, having high effective temperatures in that range, strong, rapid winds, and many circumstellar grains (Buss et al.

Figure 8. Composition of *s*-process Kr released in different analysis steps from Murchison CFOc (Ott et al. 1988b). The data show variations in the composition of *s*-process Kr; the individual compositions cannot be produced under the conditions of temperature and neutron density as commonly assumed in the phenomenological description of the *s*-process contributions to the solar abundances. See also Beer and Macklin (1989) and the new, more precise data by Lewis et al. (1990) and calculations by Gallino et al. (1990).

1989). Noting the strong fractionation between Ba and Xe on the one hand, but comparably little fractionation between the noble gas elements, when compared to the TP-AGB calculations, on the other hand, Lewis et al. (1990) have suggested that SiC grains were impregnated with *s*-process material by *two* types of stellar wind: a high-temperature, highly ionized one, that accounts for the noble gases and the small fractionation among them and a cool wind that shows strong elemental fractionation and which could account for the high abundance of Ba relative to Xe. Still, these ideas must be regarded as speculative at this time. The high abundance of Al relative to Mg (Zinner et al. 1991) as well as the relative lack of Rb-S relative to Sr-S (U. Ott, unpublished) certainly indicate that volatility must have played a role in establishing the elemental abundance pattern.

VII. SUMMARY AND IMPLICATIONS

The survival of interstellar materials such as diamond, graphite and silicon carbide puts significant constraints on the thermal and environmental history of the medium/media they have been stored in from their birth until their

arrival at Earth. As discussed in Sec. II, these phases belong to those that can (under nonoxidizing conditions) be expected to be among the most resistant. Nevertheless, we know that under laboratory conditions (oxygen pressure ~ 10 mbar, time scale ~ 1 hr) diamond/graphite and SiC combust at $\sim 600^\circ\text{C}$ and 1000°C , respectively, and it is clear that the surviving material cannot have experienced high-temperature episodes under oxidizing conditions, for any extended period of time. And even for the case of nonoxidizing conditions, there are severe limits to the temperature they can have experienced which are given by the temperature at which the associated noble gases would be lost (Table II). Provided diamond, $\text{C}\alpha$ graphite and SiC have been part of the solar nebula during solar system formation, it follows that there must have existed niches where the corresponding limits of temperature and/or oxygen fugacity have not been exceeded. The question then is how large a fraction of interstellar material did survive in those niches.

The case of SiC has been discussed by Zinner et al. (1989). In their view there must have been a tremendous loss/destruction of the SiC phase (of at least some 99.9%). Their conclusion rests on the differences in the fraction of Si that occurs in the form of SiC between what is thought to be produced at the source and what is observed in the meteorites. On the one hand, there are the carbon stars, which are thought to contribute to the interstellar medium $\sim 1/3$ of the total matter ejected by stars, and which appear to eject at least 20% (and possibly 100%) of their Si in the form of SiC; on the other hand, even in the most primitive C2 meteorites, only 4×10^{-5} of Si is present in that form. Zinner et al. (1989) favor that most of the destruction did not occur in the solar nebula, but earlier, perhaps by supernova shocks or some other selective interstellar process(es). According to their estimates, the survival rate of that fraction of SiC that entered the solar system must have been on the order of 50%. However, with $\text{C}\delta$ diamond both much more abundant and (under laboratory conditions as they are employed for isotopic analysis by conventional mass spectrometry of C, N, and the noble gases) more susceptible to oxidation and noble gas loss, the survival of this phase and its noble gases may put more severe limitations on early solar system history. From these laboratory experiences it seems that 700°C , the temperature at which noticeable noble gas loss starts, cannot have been exceeded for any extended period of time. As in these experiments oxygen fugacity is not well controlled, dedicated investigations that try to reproduce relevant conditions in the solar nebula are desirable.

In discussions of these observations, it has been generally assumed that the presolar phases took part in the processes during formation of the solar system (see, e.g., Huss and Lewis 1990; Huss 1990). In fact, this is something that remains to be shown and to do so is not a trivial task. At present, we cannot exclude that the interstellar material we are detecting today entered the solar system *after* some of the critical steps in its formation. We do not even know whether these phases predate formation of the solar system. Carrying none of the elements that can be used for age dating via their radioactive

decay (K, Rb, U, etc.) to any significant degree and, in addition, coming from exotic nucleosynthetic sources for which we do not know with certainty the underlying composition of the elements that would be changed by the decay process, there is no way to obtain a definite absolute age for them. The only thing safe to say is that their introduction into the solar system must have happened before compaction of the meteorites because of their fine dissemination throughout the meteorite matrices; SiC at least appears to exist as single grains there with little, if any, connection to other minerals (Alexander et al. 1990). Even their presolar age based on early cosmic ray interaction with the grains before incorporation into the meteorite parent bodies (Tang and Anders 1988*b*; Zinner et al. 1989) is hard to obtain in the case of SiC because of the uncertainty of the amount of recoil losses in such small particles, possibility of other losses (Lewis et al. 1990) and the possibility (Amari et al. 1990*a*) that only part of the SiC is the phase of interest; it is all but impossible in the case of diamonds with a size of only ~ 30 Å.

In addition, as pointed out in Sec. VI, the *s*-process trace elements carried by the SiC do not have the isotopic composition of the typical *s*-process contribution to the solar nebula. And, similarly in the case of the diamonds, Xe-HL is quite different from the typical *r*-process contribution to the solar abundance of that element. In other words, the fractions of those phases that survived may have been quite atypical of the matter that formed the solar system and may be even unlike the bulk of C and SiC that was present in the early solar nebula.

In conclusion, the analyses of surviving interstellar materials allow us to have a glimpse of various nuclear sources of solar system materials, and *provided* they were part of the solar system during its formative stage, their existence implies that there must have been niches that allowed survival of some, possibly tiny, fraction of such material. Conditions in the niches must have been characterized by comparatively low temperature and/or oxygen fugacity. What remains to be shown is that these materials were really part of the solar system during its formation.

Acknowledgments. I thank E. Zinner for both generously providing Figs. 3–6 including some unpublished data and a constructive review, and F. Begemann for discussions and a critical reading of this manuscript that contributed to its improvement.

ENERGETIC PARTICLE ENVIRONMENT IN THE EARLY SOLAR SYSTEM: EXTREMELY LONG PRE-COMPACTION METEORITIC AGES OR AN ENHANCED EARLY PARTICLE FLUX

DOROTHY S. WOOLUM

and

CHARLES HOHENBERG

Washington University, St. Louis

Individual mineral grains from meteorites have been exposed to energetic particles prior to inclusion in the host meteorite matrix, an event which occurred quite early in solar system history. Spallation-produced noble gases in such grains are observed to be orders of magnitude greater in abundance than could be produced after meteorite formation and thus provide a record of pre-compaction irradiation by energetic particles. If attributed to the contemporary particle environment (current galactic and solar cosmic rays) a minimum exposure time for these grains in the CM parent-body regolith of 150 Myr is obtained, with more realistic models suggesting an active parent body regolith for 300 Myr. Constraints on when meteorite compaction occurred and current models for meteorite evolution suggest that this is unreasonably long, that the time available for exposure to energetic particles on the surface of the parent-body regolith is much less than this. Pre-compaction exposure, compressed into a shorter span of time by constraints on the compaction times of carbonaceous meteorites, would require energetic particle fluxes in excess of those in the contemporary solar system and point toward an active early (T Tauri) Sun as its source.

I. INTRODUCTION

We are fortunate to have pristine samples from our own early solar system. These can provide a measure of “ground truth” by which we are able to assess our understanding of conditions and processes important in the formation and subsequent evolution of nebulae, protostars and planetary bodies. When compared to all known natural solar-system materials, a class of meteorites called chondrites, is known to: (1) have the oldest formation ages (Patterson 1956; Tilton 1988, and references therein); (2) have a bulk chemical composition closest to that of the Sun, which represents 99.9% of the present solar system’s mass, presumably reflecting the average composition of the original solar nebula (Suess and Urey 1956; Anders and Grevesse 1989); and (3)

contain the products of short-lived radionuclides that are long since extinct but that appear to have been "alive" at the time they were incorporated in their present host materials (see, e.g., Podosek and Swindle 1988; Chapter by Swindle). Recent detailed assessment of nuclide abundance smoothness for certain (type CI) carbonaceous chondritic meteorites strengthens the case for associating the composition of these particular chondrites with average solar-system abundances (see, e.g., Woolum 1988; Burnett et al. 1989, 1990). Furthermore, convincing cases have been made for the preservation of pristine materials of solar nebula origin, as well as those of presolar origin (see, e.g., Kerridge and Matthews, eds. 1988; Chapter by Ott).

Studies of chondritic meteorites have provided insight and constraints for models of the formation and early evolution of our solar system and of the nucleosynthesis of the elements, and the status of these efforts as of 1987 is well summarized in Kerridge and Matthews (1988). Timely updates in select areas appear in this book, provided by Swindle, by Morfill et al., by Palme and Boynton, and by Prinn.

In this chapter, we focus on the meteorite record regarding the energetic particle environment in the early solar system. We review the evidence for the exposure of individual meteoritic grains to energetic particles prior to their ultimate incorporation in the host meteorite, and we discuss the interpretations of these data, concluding that the observed pre-compaction exposures can only be explained by either extremely long pre-compaction meteorite time intervals or by exposure to a primitive Sun much more active than the present Sun. We include a discussion of the astrophysical implications of both of these alternatives, and compare these with information available from astronomical observations. We conclude with a look toward the future and the need for additional studies.

II. PRE-COMPACTION EXPOSURES OF INDIVIDUAL METEORITE GRAINS TO ENERGETIC PARTICLES

Goswami et al. (1984), Caffee et al. (1988), Wieler et al. (1989) and Hohenberg et al. (1990) give recent overviews of the diverse irradiation records recorded in meteorites. Of interest here are the records produced by solar-flare and galactic cosmic-ray (GCR) particles. Both sources contain protons and heavy ions with broad energy spectra, but solar-flare particles have energies peaking between 1 and 100 MeV/nucleon, and they penetrate in geologic materials to depths of hundreds of microns and the order of 1 cm for heavy ions and protons, respectively. GCR particles have a broader energy spectrum and energies are typically well in excess of 100 MeV/nucleon (more like a few GeV/nucleon), and they penetrate centimeters and meters for heavy ions and protons, respectively.

Energetic heavy ions (in the solar [SCR] or galactic [GCR] cosmic rays) near the end of their range can produce permanent radiation damage in the lattice which can be revealed with an appropriate chemical etchant. The

etchant preferentially removes the damaged material and produces a conical hole that can be viewed in an optical or an electron microscope. These radiation-damage scars in the lattice are called nuclear particle tracks, or, more simply, tracks.

Energetic particles in the SCR and GCR are capable of inducing nuclear reactions in geologic materials, producing stable and radioactive nuclides relatively close in mass to the target nuclei; these are called spallation reactions. The depth dependence of these effects are strongly dependent on the range (and hence the energy and charge) of the specific cosmic ray particle involved. Secondary neutrons and primary protons and alpha particles, being much more prevalent and having a lower Coulomb barrier to surmount, are most efficient in inducing nuclear reactions in planetary materials. The most important reaction for this work is nuclear spallation in which a small fragment is ejected, leaving a large residual nucleus.

^{21}Ne is one of the more important cosmogenic nuclides produced in nuclear reactions. It is very low in natural abundance so ^{21}Ne is very prominent as a nuclear reaction product. Furthermore, it is produced in copious amount by energetic protons and secondary neutrons in spallation reactions on common rock-forming elements like Mg, Al, Si and Fe. Thus spallogenic ^{21}Ne is both abundant and easy to resolve from other sources of neon. Because ^{21}Ne is stable, the measured accumulation of spallogenic ^{21}Ne provides a measure of the total integrated exposure to energetic particles. This includes both the recent, well-studied, cosmic-ray exposure just before terrestrial impact when the meteorite was a small object, penetrable by energetic particles. It also can include any exposure that may have occurred before the meteoritic material was consolidated into a large solid object.

It is important here to point out how these two exposures can be distinguished. Adjacent mineral grains within a meteorite must have received comparable exposure during the recent cosmic-ray exposure because the object is a rigid solid. However, as we shall show, some grains have received energetic particle doses far in excess of that received by a similar grain residing nearby. The difference in exposure must, therefore, have occurred before the meteorite was consolidated, when different grains could have had different energetic particle exposures. Differential exposure simply could not have happened after the grains were fixed by the rigid geometry of the host meteorite.

The vast majority of meteoritic grains were exposed only during the recent cosmic-ray exposure age, indicating that during the pre-compaction era only a small fraction of the grains could have spent significant time near the surface of the parent body. Consequently, the spallogenic ^{21}Ne measured in bulk meteoritic material provides only a record of the time during which the meteorite existed as a meter-sized object in its transit to the Earth (referred to as the pre-atmospheric meteorite body). Until grain-by-grain studies were done in the manner presented here, little was known about the energetic particle environment of the pre-compaction era although the conventional cosmic ray

exposure ages were well documented.

In 1983, Caffee et al. reported cosmogenic ^{21}Ne results for sets of individually selected large grains from the Murchison carbonaceous chondrite, (analyzed in groups of ~ 10 grains each). They discovered that some of the sets of grains contained amounts of cosmogenic ^{21}Ne exceeding (by more than an order of magnitude) that ^{21}Ne which accumulated during the conventional cosmic ray exposure age of the meteorite, i.e., the time the meteorite existed in space as an object small enough to be exposed to energetic particles from galactic cosmic rays. As all grains reside, embedded side by side, in a fine-grained matrix in the meteorite, Caffee et al. concluded that the excess cosmogenic ^{21}Ne must have been produced prior to the time that the individual grains were finally incorporated in the meteorite. Further, they found that the excess ^{21}Ne was correlated with the occurrence of solar-flare particle tracks at the grain surfaces, and in no case was excess ^{21}Ne found in the sets of grains selected by the absence of solar-flare tracks. Thus, the excess ^{21}Ne was correlated with an effect that indicated an exposure to solar radiation, either in free space, or at the very surface of the meteorite parent body. Additionally, the pre-compaction spallation effects observed by Caffee et al. were not only large, but there was a significant variation among the different sets of solar-flare irradiated grains analyzed. They therefore expected that if they were capable of analyzing individual grains, they would find even greater excesses than were evident as the ensemble averages observed for the sets of grains.

Since then, Hohenberg et al. (1990) have succeeded in analyzing individual grains ranging in mass from a few tens of μg down to somewhat less than one μg . Briefly, the meteorite samples are disaggregated and the grains are extracted, mounted in epoxy, polished and etched to determine whether they have solar-flare particle tracks; this is an important selection criterion, because in carbonaceous chondrites only about 2% of the extracted grains are solar flare irradiated. The elemental compositions of the irradiated grains and a representative subset of unirradiated grains are determined using energy dispersive X-ray analysis on a scanning electron microscope. The grains are then extracted from the epoxy mount, individually weighed, and transferred to individual wells in a target holder which is connected to the mass spectrometer. With the aid of optical microscopic viewing, the grains are then individually volatilized using a 70-watt CW Nd-Yag laser (a 20-watt CW argon-ion laser has been used also) and, in sequence, the extracted noble gases for each grain are purified, separated and isotopically analyzed.

Large olivines were analyzed from Murchison, Murray and Cold Bokkveveld, all CM carbonaceous chondrites. In all cases, cosmogenic ^{21}Ne dominated the signal at mass 21 and corrections made for solar neon and molecular interferences were not significant. Based on the determined grain chemistry and calculated production rates (Reedy et al. 1979; Hohenberg et al. 1978), it is possible to calculate apparent exposure ages from the excess spallogenic neon assuming it was produced by GCR.

Figure 1 shows the exposure ages determined for the track-free grains,

which show no evidence of direct exposure to solar radiation. The exposure ages in this case are calculated assuming that only the minimally required (4π geometry) exposure of the meter-sized meteorite to GCR in transit to Earth is relevant. The peaks in the histograms of data from individual grains (at 1.93 Myr for Murchison, 6.08 Myr for Murray, and 340×10^3 yr for Cold Bokkeveld) occur at ages that agree well with the known conventional cosmic-ray exposure ages of these meteorites (Goswami et al. 1984), particularly considering uncertainties in the pre-atmospheric meteorite size and uncertainties in the depth of the grain in the pre-atmospheric meteorite object.

Figure 1. A histogram of 4π exposure ages calculated from excess ^{21}Ne contents of unirradiated Murchison and Murray olivines and unetched Cold Bokkeveld olivines. The peaks correspond well with the known conventional cosmic-ray exposure ages of these meteorites. Deviation of grains to the right of the prominent peaks possibly indicate some pre-compaction irradiation.

The data for the track-rich grains show large excesses of spallation-produced ^{21}Ne , much more than could have been produced during the cosmic-ray exposure age. Figure 2 shows the measured quantity of excess ^{21}Ne in

the track-rich grains, converted to apparent exposure ages, this time assuming that the grains were irradiated by GCR in a parent-body regolith, therefore with 2π exposure geometry.

Figure 2. A histogram of model 2π exposure ages for irradiated Murchison and Murray olivines and irradiated (closed boxes) and unetched (open boxes) Cold Bokkeveld olivines. Maximum ^{21}Ne production rates are assumed, so these are minimum GCR exposure ages.

GCR are responsible for essentially all spallation effects currently observable in meteorites. The production rates are depth dependent, and the production rate assumed in the calculation of these exposure ages is the *maximum* modern-day production rate, as if all of the exposure occurred at the optimum depth. Thus, these apparent exposure ages, which for Murchison and Murray are about 150 Myr, represent the *minimum* regolith exposure time for these grains. This is a strict lower limit, because it requires that the grains spend their entire regolith history at the depth of maximum spallation production; we are confident that cannot be true because we know that, because the grains contains solar-flare tracks, they had to have spent some time at the surface as well, where the GCR production rate is lower. Similar

minimum pre-compaction regolith exposure times are obtained if maximum SCR (energetic solar flares) production rates at 3 AU (i.e., at the asteroid belt, the presumed source of these meteorites) are assumed, although it requires a contrived regolith history to achieve a dominance of SCR production over GCR production with current fluxes (Caffee et al. 1983; Hohenberg et al. 1990).

Figure 3. A histogram of 4π exposure ages of unirradiated (closed boxes) and irradiated (open boxes) Murchison olivines having <10 Myr 2π exposure ages. There is little overlap between the irradiated and unirradiated sets.

Figure 3 shows a superposition of solar-flare irradiated and unirradiated grains from Murchison, which demonstrates the strong correlation between the presence of solar flare tracks and pre-compaction spallation effects. This is rather surprising, given the difference in the range of GCR and solar-flare ions. If due to GCR irradiation, such a correlation appears to require a two component regolith: one very mature with virtually all grains exposed to GCR in the upper few meters cycled to the surface to register the solar-flare tracks, as well; and one very immature, having neither tracks nor pre-compaction spallation effects.

The correlation could be more easily understood without this requirement if spallation effects were due to solar-flare protons. However, at the current level of solar activity GCR spallation effects dominate over SCR effects in most materials. Only fluxes of solar-flare protons orders of magnitude greater than present fluxes could readily reconcile the spallation neon-solar heavy

ion effects with a simple exposure history. Figure 4 demonstrates the fact that while there is a good correlation between the presence of solar-flare tracks and pre-compaction spallation neon, there is no quantitative correlation between solar-flare track density and spallation neon. Such a separation of the two effects is not unreasonable given the range difference between solar-flare heavy ions and SCR or GCR protons.

Figure 4. Track density is plotted versus minimum exposure age for Murchison and Murray grains. Although there is no quantitative correlation between the track density and the quantity of pre-compaction spallogenic ^{21}Ne , a good correlation exists between the presence of the two effects.

III. IMPLICATIONS OF THE PRE-COMPACTION EXPOSURES

It is possible to assess the ^{21}Ne results and attempt to model a more realistic exposure history by comparison with lunar results. The Moon is, albeit, a larger body, but it is atmosphereless; its regolith histories are relatively well constrained, providing us with some basis for interpreting the meteoritic record in terms of regolith processing. Data from the Heidelberg group (Kirsten et al. 1972), discussed by Langevin and Maurette (1976), provide ^{21}Ne age data from lunar regolith grains extracted from regoliths of known age. Comparison of the age distributions for the meteoritic and lunar cases yields a "model" meteorite regolith age of about twice the minimum age inferred from the most heavily irradiated meteorite grains. If the pre-compaction exposure effects in the CM meteorites are due to the contemporary particle environment, the regolith exposure ages required are certainly greater than

the 150 Myr minimum inferred from the most heavily irradiated grains; the "model" regolith age for the CM parent body is about twice that, or 300 Myr.

Regolith exposure ages of hundreds of Myr appear very long when compared to current models for present-day asteroidal regoliths (Housen and Wilkening 1982, and references therein), where exposure ages range largely between 1 and 10 Myr. If the regolith exposures relevant to the meteoritic data are ancient, such long exposures may not be unreasonable. It is difficult to assess the relevant parameters needed in the models. However, based on the lunar comparison, where exposures on the order of a few 100 Myr are obtained, meteorites appear to represent far less mature regoliths. Table I compares regolith maturity factors like volume-percent impact glass and abundances of track-rich grains, glassy spherules and micrometeorite craters for lunar soils and meteorites. In the lunar case, maturity indicators are much more prevalent, which, taken at face value, would indicate much shorter regolith exposures for the meteorites. However, more complex two-component models, with 1 to 10% admixtures of mature, lunar-type regolith with 90 to 99% immature regolith are also consistent with the data.

TABLE I^a
Abundance of Maturity Features

Feature	Gas Rich Meteorites	Lunar Soils and Breccias
Impact Glass	rarely > 1 vol%	up to 50%
Glassy Spherules	rare	up to ~ 10%
Micrometeorite Craters	rare	pervasive
⁴ He (cm ³ STP/g)	10 ⁴ –10 ⁵	> 10 ⁷
Track-Rich Grains	1–10%	20–100%

^a Table adapted from Housen et al. (1979) and Crozaz (1980).

Based on our present understanding of regolith histories and modeling and the short evolutionary histories inferred for carbonaceous meteorites, the long regolith exposures implied by conventional interpretation of the ²¹Ne data do seem unlikely. A more plausible alternative explanation for the data may be offered by the possibility for exposure of the grains to an enhanced particle flux. It is unlikely that such an enhanced flux would be due to an increased GCR activity as the Galaxy 4.6 Gyr ago was probably much as it is today. The Sun, however, was contracting toward the main sequence and the existence of an early active Sun is astrophysically reasonable. It is widely agreed among stellar evolution theorists that the Sun and stars similar to the Sun evolve through especially active phases (so-called T Tauri phases) just prior to settling down to the main sequence. As is clear from a number of chapters in this book, astrophysical observations of T Tauri stars in the last decade have placed important empirical constraints on the nature and evolution of these young stars. An active Sun could easily have flare activity

three (or more) orders of magnitude greater than the contemporary Sun.

Despite the fact that it is reasonable to presume that all solar-type stars go through a T Tauri phase, there is no well-documented unambiguous evidence of this portion of solar-system history in the record provided by previous studies of solar-system materials; now the ^{21}Ne data provided by the St. Louis group presents the first serious suggestion of this possibility. It may be that the T Tauri phase was too violent an epoch for most solids to survive. It may be that most of the matter in the solar accretion disk was well shielded from the stellar particles, and irradiation of solids was possible only after removal of most of the nebula gas (during the so-called naked T Tauri phase), after accretion, in which case only a small fraction (the skins) of solid bodies would have been exposed. Because grains of interstellar origin have been identified in primitive meteorites, there is encouragement that there may be preserved grains which were exposed to the early active Sun, too. Perhaps we have not looked in the right place(s), or in the right way(s) yet.

If, in fact, exposure to a T Tauri Sun is the explanation for the pre-compaction ^{21}Ne spallation excesses, one thing is certain: the compaction of the CM meteorites is required to be very early. Time scales estimated for the T Tauri phases are on the order of from 10^5 to somewhat more than 10^7 yr.

IV. COMPACTION AGES OF THE CARBONACEOUS METEORITES

In attempting to resolve the question as to whether very long regolith exposures or exposure to an early active Sun was responsible for producing the pre-compaction ^{21}Ne excesses, an attempt to date the time at which these meteorites were compacted could prove critical. An unambiguous compaction age would place a lower limit on the time, relative to the present, at which the pre-compaction exposure could have occurred. If these irradiations occurred very close to 4.55 to 4.6 Gyr ago, the age inferred for the major solar-system differentiation events, and are constrained to a short duration by the compaction ages, then the pre-compaction record provided would have to be most reasonably attributed to a very active early Sun, as this would indicate that there were high fluxes and insufficient time to allow for very lengthy regolith residences.

In 1976, Macdougall and Kothari reported compaction ages for five meteorites, two of which are represented in the Hohenberg group data. The ages were based on the nuclear particle track densities on large euhedral olivine crystal surfaces in contact with the matrix of these meteorites. These are model ages for the times at which the matrix (containing all the elements in roughly cosmic proportions) and the large olivines (serving as essentially actinide free detectors) became associated. The model is illustrated in Fig. 5. Briefly, the normal sources of the nuclear particle track densities at the olivine surfaces would be expected to be GCR and SCR and the energetic charged products of the fissioning of uranium (both in the olivine and in the matrix).

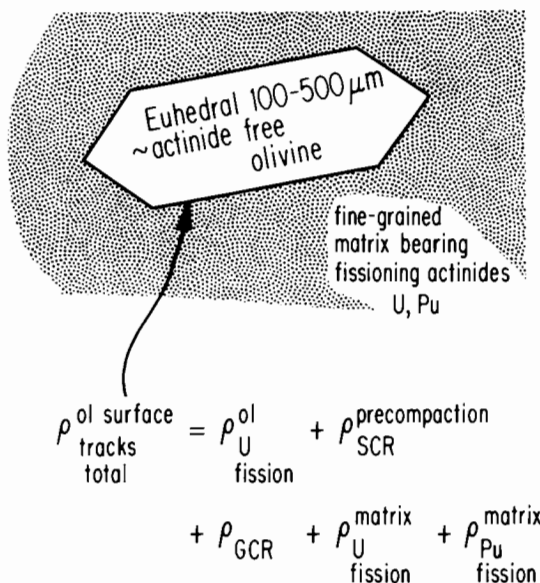

Figure 5. A cartoon showing the sources of possible contributions to the surface track density of the isolated olivine grains. Olivine is actinide poor, and pre-compaction SCR exposure is readily recognizable. Further, the GCR contribution is generally small. Thus, grains selected for study have surface track densities dominated by actinide fission contributions from the matrix. Correction for the determined U contribution, allows for the calculation of the Pu fission surface track density, which can be related to a contact age, assuming an initial Pu/U (or Pu/LREE) ratio at 4.56 Gyr.

If the olivine came into contact with the matrix early enough, an additional contribution due to the fissioning of extinct ^{244}Pu (72 Myr half-life) could be expected. Of these contributions to the total olivine surface track density the olivine U fission contribution was negligible, based on the measured U content for the olivines. The SCR contribution could be identified by the steep depth dependence of the tracks in the grains and, thus, eliminated. The GCR track density would be essentially uniform throughout the grain and was found to be negligible, or at most require a small correction to the total track density. Contributions from matrix U fission were significant based on the measured matrix U content, but the dominant contribution was actually from matrix Pu fission. This already implies that the matrix and olivine were in contact very early, at least 4.2 Gyr ago, or before, as the ^{244}Pu half-life is so very short. The excess track density associated with the fission of Pu in the matrix was determined for each grain, and contact ages of ~ 4.4 Gyr were calculated for those meteorites identified as having received a heavy pre-compaction exposure. This was done assuming an initial (4.56 Gyr ago) $^{244}\text{Pu}/^{238}\text{U}$ ratio

in the matrix materials of 0.0154, the chondritic ratio from Podosek (1970). Currently, the accepted value of the same initial Pu/U isotopic ratio is 0.007 (Hudson et al. 1989), and so the revised model compaction ages now range from 4.48 to 4.52 Gyr for these meteorites (Fig. 6). Compaction this early would appear to preclude the extremely long regolith exposures necessary to explain the excess spallation ^{21}Ne in terms of GCR. However, nothing is quite so straight forward, and there are problems with accepting these compaction ages at face value.

Figure 6. The relative surface track densities expected for the isolated olivine grains versus contact age, the time before present at which the grain came into contact with the actinide-rich matrix. The dotted line shows the theoretical expectation, assuming the initial (at 4.56 Gyr) Pu/U ratio of 0.0154, the previously accepted value (Podosek 1970). The current value of this ratio is 0.007 (Hudson et al. 1988), and this yields higher compaction ages based on the relative track densities determined in the meteorite (shown by the labelled horizontal line in the figure). For example, Murray and Murchison model compaction ages are about 4.53 and 4.48, respectively. This figure is adapted from Macdougall and Kothari (1976).

The primary problem is that the ages are calculated using the average olivine crystal surface track density calculated for each meteorite, but the track densities for individual grains vary significantly, by factors ranging from about 50 to more than 2 orders of magnitude in the meteorites studies, excluding the grains with obvious solar-flare track gradients. This variation is well

beyond uncertainties due to counting statistics. Because the measured matrix U distribution in all the meteorites appeared homogeneous on a $100\text{ }\mu\text{m}$ scale (the typical grain surface dimensions), the variations could imply a varying Pu (and thus Pu/U ratio) in the matrices of the meteorites. The simplest interpretation of the Macdougall-Kothari (1976) work is that Pu (and Pu/U) is variable, but that the mean value is interpretable in terms of a compaction age. On the other hand, it may also be that the dispersion is telling us that the story is more complicated, involving multiple compactations, with different grains registering different contact ages. These may not provide the most satisfactory estimates of compaction ages for CM meteorites, but they are all we have at present.

There are more confident constraints on CI carbonaceous chondrite compaction ages, and CI meteorites are thought to represent our best samples of unfractionated solar-system materials (Anders and Grevesse 1989; Burnett and Woolum 1989). In CI meteorites, there are veins of calcium carbonates and sulfates due to aqueous activity on the parent body (DuFresne and Anders 1962; Richardson 1978; Kerridge and Bunch 1979). Simple physical examination of these meteorites shows that the emplacement of these veins into the host matrix surely cannot predate the compaction of the meteorite. Thus, if such veins could be dated they would provide confident lower limits to the compaction ages. Richardson (1978) recognized three generations of mineralization: first the carbonates, dolomite $\text{CaMg}(\text{CO}_3)_2$ and breunnerite $\text{Fe, Mg}(\text{Mn})\text{CO}_3$ —these occur as single crystals and sometimes aggregates which are thought to be residual vein fragments; second, Ca-sulphates; and third, Mg-sulphates. Because these phases are expected on geochemical grounds to contain Sr ($a + 2$ anion, as are Ca and Mg) but virtually no Rb ($a + 1$ anion) and because the CI meteorites have high bulk Rb/Sr ratios, these phases should be sensitive indicators of the time of their formation. This reasoning was used by Macdougall et al. (1984) and Macdougall and Lugmair (1989) to obtain a compaction age for the CI meteorite Orgueil illustrated in Fig. 7.

Starting with a primitive $^{87}\text{Sr}/^{86}\text{Sr}$ ratio of 0.699 4.55 Gyr ago, indicated by a star in the figure, the bulk meteorite would evolve with time along the line labeled bulk Orgueil as ^{87}Rb beta decayed to ^{87}Sr . If at some time later, Δt , aqueous activity resulted in the production of Rb-poor phases from the bulk material, the Sr evolution would be halted, locking in the 87/86 Sr ratio at the time of the vein emplacement. Isotopic ratios can be very accurately determined making the time resolution achieved very accurate.

Macdougall et al. (1984) and Macdougall and Lugmair (1989) prepared mineral separates of vein materials. Their separates were not pure, but samples with no detectable Rb gave initial Sr ratios which must be upper limits to the true carbonate formation age values, considering the possibility of contamination with the high Rb ground mass. These initial Sr values are equivalent to the lowest yet observed in solar-system materials (Allende CAI inclusions; Gray et al. 1973; Minster et al. 1982) and imply that carbonate deposition occurred *contemporaneously with parent body formation*, or shortly

Figure 7. An illustration of the Sr evolution method for determining the time of formation of Rb-poor phase in the CI meteorite Orgueil. The curve labeled bulk Orgueil shows the expected evolution of the Rb $87/86$ isotopic ratio of the meteorite with time, as the beta decay of 87Rb to 87Sr alters the Sr $87/86$ ratio. The arrow on the line indicates the evolution, starting from the most primitive initial Sr $87/86$ ratio preserved, represented by the Moore County plagioclase value. Two carbonates (Rb-poor mineral) from Orgueil yielded Sr isotopic ratios indicating that they were formed and isolated from the bulk meteorite (thus, preserving a very primitive, nonradiogenic Sr $87/86$ ratio) at formation intervals (Δt) that were short: from 0 to 50 Myr. This figure was adapted from Macdougall et al. (1984) and used data from Macdougall and Lugmair (1989).

afterwards—certainly within 50 Myr, but probably even less. If the CI meteorite studied were the CM meteorite Murchison or Murray, this study would effectively preclude a 150 to 300 Myr pre-compaction regolith residence time for that meteorite and would thus compel us to conclude that the ^{21}Ne data reflected the exposure to an active early Sun.

In summary, then, while constraints on compaction ages do exist for the relevant meteorites (CM), the compaction ages are model dependent and rest on assumptions that have not been adequately tested. More rigorous constraints exist for related meteorites (CI), but the applicability of these compaction ages for the case of the CM meteorites is not clear. Future work is necessary to address this issue.

V. ASTROPHYSICAL IMPLICATIONS OF THE EARLY SOLAR EXPOSURE MODEL

If additional studies support the idea that the ^{21}Ne data reflect a pre-compaction exposure to an active early Sun, this would have important consequences for

nebular modeling. Because the source region of the CM meteorites is thought to be the asteroid belt, this would imply that the irradiation occurred at a time when the nebula was already well cleared, assuming that the irradiation occurred near the plane of the ecliptic. T Tauri protons might be expected only to penetrate a few 10 g cm^{-2} of matter, which would imply average nebula densities of only about $10^{-12} \text{ g cm}^{-3}$ within the inner 3 AU radius of the solar nebula. This might mean that the exposure occurred not during the initial T Tauri phase but later, in the weak-line T Tauri phase (the so-called naked T Tauri phase, which can last hundreds of Myr [Micela et al. 1985; Feigelson and Kriss 1989]), when the circumstellar disk is believed to be substantially cleared or in the process of clearing. However, the solar-flare track densities observed in the track-rich grains are rather low in comparison with solar-flare track densities in lunar grains (Goswami et al. 1976), and lower than might otherwise be expected from the amount of spallation-produced ^{21}Ne observed in the grains. If we accept that enhanced solar-flare activity is responsible for both effects some residual shielding by nebular matter may be implied, suggesting, perhaps, irradiation during the transition. Our quantitative understanding of the detailed astrophysical conditions is somewhat fuzzy, but based on estimates of enhancements of 3 orders of magnitude in particle fluxes in the weak-line T Tauri phase (Feigelson, personal communication) and considering that the activity during this phase declines relatively slowly, it appears that a reasonable number of solar protons are available to explain the neon data.

VI. FUTURE WORK

Looking to the future, one obvious study would be to extend the ^{21}Ne studies to CI meteorites, where compaction ages are more confidently accepted. The problem in this is that the isolated olivines in these meteorites are very small and very scarce, making not only the track work, but also the ^{21}Ne determinations, very difficult.

It also is important to attempt to re-evaluate the CM compaction ages. Detailed elemental mappings of U and the light rare earth elements (LREE) should be made at the matrix-olivine grain contacts on fine spatial scale (order of $10 \mu\text{m}$) in order to assess the homogeneity of these elements specifically in the matrix areas relevant to the olivine surface track data (fission fragments have only about $15 \mu\text{m}$ ranges in the matrix). Under varied REDOX conditions Pu could be expected to behave cosmochemically in different ways (see, e.g., Burnett et al. 1982). Under reducing conditions Pu can be trivalent and would have an ionic radius between that of Ce and Pr, and so in terms of crystal chemistry, it would be expected to behave like a LREE. On the other hand, in more oxidizing conditions, it could be expected to act like U, which is tetravalent (Boynton 1978a; Benjamin et al. 1978). Homogeneity of the LREE and U, if documented, would lend support to the assumption that Pu homogeneity could be expected at the same level; there is no direct way to

check for this homogeneity, as Pu is extinct. Further, it would be important to check that LREE/U is chondritic ("cosmic"); then it is reasonable to assume the chondritic $^{244}\text{Pu}/^{238}\text{U}$ ratio (Hudson et al. 1989) or the chondritic Pu/Nd ratio for the matrix material in calculating an olivine-matrix contact compaction age. Finally, it would be very important to determine contact ages for individual olivine grains if at all possible. Fortuitous associations of the olivine grains and actinide-rich phases in the matrix might make this feasible.

Figure 8. Cerium counts versus neodymium counts for matrix abutting isolated olivine grains in Murchison. These preliminary data have not been corrected for relative efficiencies, but the differences are expected to be small compared to the observed variations. Cd/Nd values are well correlated and the elemental ratio agrees well with the chondritic (solar) ratio. Variations up to about a factor of 2 are observed, but this is small compared to the 1 to 2 orders of magnitude observed in the olivine surface track densities attributable to ^{244}Pu . Additional determinations are necessary, but if Pu behaves cosmochemically like the LREE, as is observed in some meteorites, this may imply a complex, multi-compaction history for this meteorite. Alternatively, the track data may be indicating that Pu was heterogeneously distributed in the meteorite matrix.

We (Woolum et al., unpublished data) have recently made preliminary determinations of Nd and Ce variations in the Murchison matrix adjacent to large euhedral olivine grains. The matrix was analyzed adjacent to 5 isolated

olivine grains using an ion probe with a $\sim 30\ \mu\text{m}$ beam spot size. The total variation in both the Nd and Ce abundances was a factor of ± 2 . Further, Ce and Nd abundance variations were correlated. These results are illustrated in Fig. 8, where Ce vs Nd results are plotted. The data are uncorrected for relative counting efficiencies, but we estimate that the Ce and Nd counting efficiencies might vary only by up to 20 to 30% for Murchison matrix. The line in the figure corresponds to the average Ce/Nd value of $1.22 (\pm 0.15, \text{one sigma})$, which is in good agreement with the CI Ce/Nd ratio of 1.39, given the present uncertainties.

Assuming that the Macdougall-Kothari (1976) U results are applicable for our Murchison sample, these limited data imply that for Murchison one could expect to have obtained a Pu/U ratio that varied in the matrix associated with large euhedral olivines by a factor of ~ 2 . This does not explain the 1 to 2 orders of magnitude variations in the track densities observed by Macdougall and Kothari (1976) and calls into question the validity of basing compaction ages on the average olivine track densities. These preliminary results may imply that the variable track densities reflect (at least to some extent) actual time differences and, thus, multiple compaction events. However, this is only one possible explanation, and considerably more work is necessary before any confident interpretation is possible. Extending the neon studies to other CM meteorites might shed light on the irradiation features ascribable to a common parent-body history. And the discovery of even more heavily irradiated grains could reduce further the plausibility of the long pre-compaction regolith residence scenario.

Carnegie Institution of Washington

In this review we discuss theoretical models of the collapse of a dense molecular cloud core to form the protosolar nebula that produced the Sun and planets. The theoretical models use the equations of hydrodynamics, gravitation and radiative transfer to follow the time evolution of a cloud collapsing under its own self-gravity; magnetic fields are not thought to be important during the collapse phase. Both semi-analytical and fully numerical solutions (in two and three spatial dimensions) have been calculated by several workers. Single protostars appear to result from the collapse of clouds that are initially very slowly rotating, close to thermal equilibrium, or strongly centrally condensed. Given one set of these initial conditions, the challenge is to calculate the collapse as far as possible, ideally far enough to make contact with theoretical models of planetary formation. This goal has not yet been fully achieved, largely because of numerical difficulties and because the resulting protosolar nebula must undergo significant dynamical evolution in order to transfer mass inward to form the Sun, and to transfer angular momentum outward. The agent of this large-scale, angular momentum-mass differentiation is problematical, though several promising candidates have been identified: turbulent viscosity, gravitational torques and magnetic fields. Detailed results are given for a two-dimensional model with turbulent viscosity for redistributing angular momentum, and for three-dimensional models investigating the strength of gravitational torques associated with nonaxisymmetry produced during the collapse phase. These models imply that the early protosolar nebula may have been fairly hot (~ 1500 K) in the inner few AU. As the numerical models are further refined in the future, we shall be able to improve our predictions of crucial quantities such as surface densities and midplane temperatures in the solar nebula, at a time when the Sun has largely formed and the process of planetesimal accumulation is well underway.

I. INTRODUCTION

This chapter is devoted to the formation of the protosolar nebula through the collapse of a dense molecular cloud core. The protosolar nebula is the rotationally flattened cloud of gas and dust from which the Sun and the planets are thought to have formed, as was first hypothesized in the eighteenth century by Kant and Laplace. In the intervening two hundred years, most of the work on protosolar nebula formation has necessarily been theoretical

in nature (recently reviewed by Cameron [1988], Cassen and Boss [1988], Boss et al. [1989] and Larson [1989]), because of the severe difficulties associated with observations of collapsing protostellar clouds. While direct observational evidence for collapse in low-mass protostellar clouds is still lacking, millimeter-wave interferometers are now beginning to provide measurements of physical conditions in low-mass protostellar disks that might well be analogs of the protosolar nebula (see the Chapter by Beckwith and Sargent), and optical and infrared observations are yielding constraints on the amount of gas and dust in the circumstellar environments of young stellar objects and T Tauri stars (see the Chapters by Basri and Bertout and by Strom et al.). Our review will summarize progress made in theoretical modeling of the formation of the protosolar nebula, with the emphasis being on studies finished after *Protostars and Planets II* (Black and Matthews, eds. 1985).

Protosolar nebula formation models can be conveniently divided into two categories, depending on the symmetry assumed in the model. Axisymmetric models assume symmetry about the rotation axis of the nebula; examples are the hydrodynamical models of rotating cloud collapse of Terebey et al. (1984), assuming isothermal collapse, and of Tscharnuter (1978) and Boss (1984a), both of which allowed compressional heating to occur. All three of these studies assumed initially slowly rotating clouds, but with the Terebey et al. model starting from a centrally condensed configuration with $\rho_i \propto r^{-2}$ (Shu 1977), and with the latter two starting from uniform density initial conditions. Cassen and Moosman (1981), Cassen and Summers (1983) and Ruzmaikina and Maeva (1986) constructed axisymmetric models of viscous disks formed by accretion of envelope gas, and followed the evolution as the disks grew through addition of mass and through the effects of viscous torques. The other category is nonaxisymmetric models, which allow for arbitrary deformation of the cloud about the rotational axis. Boss (1982) considered the possibility of protosolar nebula formation as a member of a three-body system, while Boss (1985) studied the formation of bar-like nebulae from the collapse of slowly rotating clouds.

Although approximate analytical investigations are very useful for getting deeper insight into collapse dynamics, they cannot compete with detailed numerical studies. Analytical results (if available at all) are always based on very stringent assumptions, e.g., on the existence of asymptotic solutions for (isothermal) collapse flows, or on expansions which make use of the fact that there are only small deviations from spherical symmetry (cf. Terebey et al. 1984). Analytical results pertaining to the early, isothermal phases have been found to be in reasonable agreement with the numerical models with respect to the spatial dependencies of the state variables. As a matter of fact, asymptotic solutions became attractive (Shu 1977) only after detailed collapse calculations had been carried out (Larson 1969). The formation of protostellar cores, the details of the ensuing accumulation process resulting from effective redistribution of angular momentum, and the radiative energy transport necessary for realistic models of nonisothermal protostellar nebulae

are well beyond the scope of any serious analytical treatment.

We restrict ourselves here to consideration of models of nonmagnetic collapse, in large part because much of the progress on protosolar nebula formation has been made with this simplification (however, see the Chapter by McKee et al., and the reviews by Mouschovias [1987*a*] and Nakano and Umebayashi [1988]). More importantly, magnetic fields decrease in dynamical importance during contraction as a result of ambipolar diffusion (Mouschovias 1987*a*) or ohmic dissipation (Nakano and Umebayashi 1988). Lizano and Shu (1989) and Tomisaka et al. (1990) have shown that even in an initially magnetically supported, quasi-equilibrium cloud (a subcritical cloud; Shu et al. 1987*a*), ambipolar diffusion coupled with cloud contraction eventually leads to a situation where dynamical collapse ensues, and while the magnetic field is carried along and amplified by this collapse, the magnetic field should not dominate the collapse dynamics. Nonmagnetic calculations thus should be appropriate for this phase of subcritical cloud evolution, as well as for clouds that are not initially supported primarily by magnetic fields (supercritical clouds). In the case of the latter type of cloud, collapse may be externally initiated by compression, such as that due to passage of a shock wave derived from a nearby massive star (see, e.g., Herbst and Rajan 1980); the presence of short-lived radioactivities in meteoritical inclusions (see the Chapter by Swindle) limits the amount of time that the protosolar cloud could have spent in any quasi-equilibrium phase to ~ 1 Myr.

In this brief review we do not have space to describe the observational implications of protostellar collapse models. Suffice it to say that the collapse models are generally consistent with observations of embedded protostellar objects (see Shu et al. [1987*a*], Boss and Yorke [1990] and Bodenheimer et al. [1990] for more details and references).

II. BOUNDARY AND INITIAL CONDITIONS

In mathematical terms, protostellar collapse models are solutions of a complex initial-boundary value problem for a nonlinear system of partial differential equations. The equations express the basic conservation laws of physics, i.e., conservation of mass, momentum and energy, and relate the gravitational potential to the density distribution. In addition, there are important transport phenomena, such as redistribution of energy and momentum by radiation and viscosity, respectively, and mixing processes associated with turbulence. The structure equations also contain functions that define the physical properties of the material. These “constitutive” relations include the equations of state for the pressure and internal energy, and relations for the opacity, viscosity coefficient(s), and thermal and electrical conductivities.

Gravitational collapse of a single cloud fragment, which takes place in the cores of dense molecular clouds and leads eventually to a star surrounded by a dusty, gaseous, disk-like nebula (i.e., to structures like the solar nebula that formed some 4.5 Gyr ago), can be treated as a localized phenomenon,

restricted to a finite domain of the interstellar space. Hence the set of structure equations and constitutive relations has to be completed by certain boundary conditions which connect the interior solution (to be determined) with the “known” exterior. For example, one can prescribe the radiation field impinging on the collapsing protostellar fragment from the outside, say, by choosing an “equivalent” (radiation) temperature T_{ex} as the simplest approximation—this determines the net energy flow across the boundary—and fix the external pressure P_{ex} , or keep the volume within which the collapse takes place unchanged with time; the gravitational field and, if taken into consideration, the magnetic field are determined by matching the interior solution and (given) exterior configuration at the outer boundary in a consistent way. One can also simulate the loss and gain of mass (cf. Wuchterl 1990*b*, *c*) and/or the transfer rate of angular momentum across the boundary of the fragment. Thus, boundary conditions serve as the necessary completion of the physical assumptions and approximations made for the modeling, and coupled with a particular set of initial data, these choices determine the resulting evolutionary sequence. The boundary conditions and initial conditions should be suggested either by a more general theory or by observations.

It is an attractive feature of protostellar collapse models that the general features and results do not depend critically on the boundary conditions, unless very peculiar and rather artificial constraints are adopted. The opposite is true for the initial configuration from which the collapse starts out. This is easily seen by looking at the characteristic time scale t_{ff} of gravitational collapse (free-fall time) which is inversely proportional to the square-root of the mean density $\bar{\rho}$ of the collapsing fragment, independent of the total mass. For a pressureless spherical collapse $t_{ff} = \sqrt{3\pi/32G\bar{\rho}}$ (G is the gravitational constant), which is also the typical time scale for the realistic case. According to Jeans’ criterion for the onset of collapse, $\bar{\rho}$ has to be greater than a critical density ρ_{crit} for a given temperature (typically 10 K for dense cores of molecular clouds), if a thermally supported cloud fragment of $1 M_{\odot}$ (say) is to become gravitationally unstable. Then $\rho_{crit} \approx 10^{-19} \text{ g cm}^{-3}$ and the corresponding collapse time scale $t_{ff} \approx 2 \times 10^5 \text{ yr}$. But the critical Jeans density ρ_{crit} is just a lower limit, because self-gravitation has to overcome not only the gas pressure but also the magnetic and the turbulent pressure. Therefore, the actual mean density $\bar{\rho}_i$ at which dynamical collapse is able to start could in principle be orders of magnitude higher than ρ_{crit} , which would correspond to a much smaller evolutionary time scale t_{ff} .

If we assume that magnetic fields dominate the structure of some cloud cores during their slow quasi-magnetohydrostatic pre-collapse evolution, e.g., in the subcritical regime (cf. Lizano and Shu 1989), then the density at which collapse actually commences is related to the leakage of magnetic flux due to ambipolar diffusion. Thereafter the neutrals can slip across the field lines, while the field strength remains almost unchanged. The transition from the quiescent, flux-conserving regime to the collapse phase should in principle be observable by measuring the magnetic field strengths in cloud cores at still

higher number densities ($> 10^5 \text{ cm}^{-3}$, Fiebig 1990, personal communication) and much better angular resolution (by 1 to 2 orders of magnitude at least) than is feasible today. It is expected that above some characteristic density ρ_m , the exponent κ in the (theoretical) relation between density ρ and the field strength $B \propto \rho^\kappa$, $1/3 \leq \kappa \leq 1/2$ (cf. Mouschovias 1978) will tend to vanish, unless there is some (not yet understood) coherent physical link to the very strong magnetic fields measured in OH and H₂O masers at 10^8 and 10^{10} cm^{-3} , for which $\kappa = 0.5 \pm 0.1$ has been derived (Fiebig and Güsten 1989). Mouschovias (1987a) estimates that ambipolar diffusion should lead to magnetic field decoupling above densities on the order of 10^4 to 10^6 cm^{-3} , while Umebayashi and Nakano (1990) maintain that ambipolar diffusion is ineffective and that ohmic diffusion leads to field decoupling only above $\sim 10^{11} \text{ cm}^{-3}$. For supercritical fragments there are no such theoretical constraints on the initial density distribution.

To summarize, we can state that, on the basis of the observational findings, a wide range of densities between 10^{-19} and $10^{-14} \text{ g cm}^{-3}$ and a variety of different density distributions are admitted as possible initial values for modeling protostellar collapse, depending on the history of magnetic field support and the mechanism that induces collapse. Accordingly, the time scales for collapse can vary from a few 10^5 yr down to somewhat less than 10^3 yr ; most workers expect that the former time scale is likely to be applicable.

III. NUMERICAL METHODS

The structure equations and constitutive relations mentioned in the preceding section form a set of nonlinear partial differential and algebraic equations. There is no hope of finding a purely analytical solution of the complete collapse problem. It is even hard to invent an algorithm which is robust enough to yield reliable numerical model sequences pertaining to protostellar collapse and stellar formation for the simplest case of spherical symmetry. For the present state of art in spherical symmetry and more details, see Balluch (1991b, c). Needless to say, the computational difficulties increase with two dimensional (axisymmetric) and three dimensional models.

Basically, there are two quite distinct methods for representing continuous, nonstationary, hydrodynamical flows on a discrete numerical grid: (i) "explicit" schemes (forward time differences); and (ii) "implicit" schemes (backward time differences). Both methods have their advantages and shortcomings. For example, it is relatively easy and straightforward to write an explicit hydrodynamics code, but the disadvantage is the fact that the time step and the spacing of the numerical grid, i.e., the spatial resolution, are coupled through the famous Courant-Friedrich-Lewy (CFL) condition for numerical stability. To be more specific, a numerical scheme of type (i), with which the physical quantities at time level n are essentially determined from the (known) quantities at level $n - 1$ by simple forward extrapolation, is CFL-stable, only

if the time step fulfills the inequality

$$\Delta t < \min_{grid} \left\{ \frac{\Delta x}{|\mathbf{u}| + c} \right\} \quad (1)$$

where Δx indicates the grid spacing and $|\mathbf{u}|$ and c denote the absolute value of the flow velocity (with respect to the grid) and the (local) speed of sound, respectively. Implicit schemes based on methods of type (ii) are always CFL-stable. In this case, the only restriction on the time step is that it must be small enough to resolve any important dynamical changes that might occur in the flow. However, for each time step a huge system of nonlinear algebraic equations has to be solved iteratively in some way or another. Particularly for the axisymmetric collapse, this very often raises the tedious question of numerical convergence, and requires almost unlimited availability of a supercomputer.

A quick inspection of a typical protostellar collapse and accretion flow gives a rough estimate of the variation of the physical variables in space and with time. The compression of the cloud to the final star spans almost 20 orders of magnitude in density, while the temperature variation is ~ 5 to 6 orders of magnitude. As a consequence, the CFL-time step drops to extremely low values as compared to the time needed for accumulation of the protostellar envelope which is at least of the order of the initial free-fall time t_{ff} . Typically more than 10^9 time steps would then be required in order to cover the main accretion phase. These simple estimates lead to the conclusion that complete and consistent models of star formation, e.g., the accumulation of the Sun together with the evolution of the protosolar nebula, are not likely to be obtained with explicit methods.

The numerical difficulties of explicit methods are considerably lessened if the protostellar accumulation process is simulated in a more qualitative way (by introducing an artificial inner boundary) so that only the global bookkeeping for the net amount of mass and angular momentum flowing toward this central "hole" is considered, but not the detailed structure of the stellar core (Boss and Black 1982). This procedure may seem to be an oversimplification of the problem, but it has the advantage that the evolution of the disk can be followed up to a much more advanced state. This was done by Morfill et al. (1985) who showed that the collapse of a rotating turbulent cloud leads to the formation of a central star surrounded by an accretion disk that is continuously fed by material still infalling from the much larger envelope. Similar techniques are used by Bodenheimer et al. (1990) for axisymmetric models of the solar nebula and by Boss (1989b) for nonaxisymmetric models (see Sec. V).

The partial derivatives appearing in the structure equations are replaced by finite differences in such a way that the global conservation of mass and (angular) momentum is numerically guaranteed. The conservation form is also adopted for the balance equation of the internal energy (first law

of thermodynamics), but a similar equation for the total energy generally does not exist and so total energy conservation cannot be guaranteed. It appears that there might be an accuracy problem for the overall energy balance of newly formed stellar embryos, which could trigger oscillations of very large amplitudes (Tscharnutter 1989). According to spherically symmetric calculations recently made by Balluch (1991c) to investigate this particular point, the number of gridpoints has to be drastically increased (at least by a factor of 10, from about a few 10^2 to a few 10^3) in order to arrive at an accuracy level that is high enough to guarantee total energy conservation to $<1\%$ (measured relative to the gravitational energy). Such high accuracy is necessary to remain on the safe side energetically, particularly during the second ("stellar") collapse triggered by the onset of H_2 -dissociation in the first, optically thick, core. During this period the density increases by ~ 6 orders of magnitude, which corresponds to ~ 2 orders of magnitude decrease in the radius of a sphere containing a fixed amount of mass (typically a few $10^{-2} M_\odot$). Hence, both the gravitational energy W and the sum of the internal and kinetic energy E rise by a factor of $\sim 10^2$ (while $E + W \approx \text{const}$), because the second collapse is adiabatic to a high degree of approximation. Thus, if one does not solve the total energy equation, we have a numerical problem. But in trying to enforce total energy conservation, one could run into trouble again, for instance, within free-falling regions of the protostellar envelope, where the kinetic and potential energies almost cancel so that the internal energy and hence the temperature is not well defined numerically. It seems as if the detailed energy balance of stellar core formation is one of the major bottle-necks in the numerical modeling of interstellar cloud collapse, even in the simplest case of spherical symmetry. This is also the reason why the complete axisymmetric model sequences, including both the formation of the disk and the detailed structure of the central star, cannot yet be conducted much beyond the end of the second collapse phase (see Sec. IV below).

IV. AXISYMMETRIC MODELS

A first step toward a realistic numerical approach to a theory of protosolar nebula formation is to study the collapse of a rotating cloud with axial symmetry. As mentioned in Sec. III, the calculations require extremely large amounts of computer time, and the complexity of the numerical methods and solutions often obscures any deeper insight into the physical connections and interrelations we want to understand first and foremost. To this end, Lin and Pringle (1990) have developed a semi-analytical approach to protosolar nebula formation, utilizing the ballistic collapse approximation of Cassen and Moosman (1981) to model the collapse, and using a simplified physical model to model the effects of turbulent viscosity and gravitational torques on the growing nebula. Lin and Pringle (1990) find that, using typical values for observed rapidly rotating molecular clouds, the resulting nebulae should be

Figure 1. Axisymmetric protostellar core evolution: log central density vs log central temperature. Labels A-I indicate salient evolutionary stages. A-B is the initial cooling phase (< 100 yr). B-C (≈ 500 yr) is the first collapse and C-D (≈ 10 yr) is the second collapse, triggered by dissociation of H_2 . During D-E (≈ 15 yr) there is a substantial loss of angular momentum from the core region caused by turbulent viscosity stresses. At epoch E the core starts to oscillate quasi-adiabatically. E-F-G and G-H-I are the first two cycles with periods of ~ 3.5 and 2 yr, respectively.

relatively large (~ 1000 AU), massive (disk mass comparable to stellar mass), and long-lived (several to ~ 10 free-fall times).

In a recent numerical study, Bodenheimer et al. (1990) calculated the formation of a protostellar disk starting from a centrally condensed sphere of radius 5×10^{15} cm, a mean density of 4×10^{-15} g cm $^{-3}$, a total mass of $1 M_\odot$ and a total angular momentum of 10^{53} g cm 2 s $^{-1}$. Because of the aforementioned numerical difficulties with resolving stellar cores (see Sec. III), only the region between 1 and 60 AU is resolved. At the end of the calculation a relatively thick, warm (several 10^2 to 10^3 K) disk formed, close to hydrostatic equilibrium. At the same time the (nonresolved) central region contained a rapidly rotating stellar core of $0.6 M_\odot$ which could be unstable to nonaxisymmetric perturbations. In order to get an idea of what such an object would look like for an external observer, frequency-dependent radiative transfer calculations have been performed as well. Even if the precise initial conditions should turn out to be inappropriate, such calculations provide a rigorous analysis of the thermodynamics associated with disk formation and at least include the phases of collapse where by far the bulk of the potential energy is released.

Tscharnuter (1987a) investigated the problem of the joint disk-core for-

Figure 2. Axisymmetric model of Fig. 1. Panels (a) and (c) illustrate the spin down of the core region, while (b) and (d) show the distribution of the radial gridpoints at the epochs D and E, respectively. Evidently, the stellar core is well resolved by automatically adjusting the numerical grid. The dependency on the polar angle is expressed by a Legendre expansion up to order 14. In panels (a,c), contours of constant density (full lines), temperature (dash-dotted lines) and angular velocity (dotted lines) are plotted in a meridional cross section. The projected velocity field is indicated by arrows; the length of the single arrow on the right side gives the scale of typical velocities. Numbers in the first, second and fourth quadrant are logarithms of the density, temperature and angular velocity, respectively. The core contains $\sim 0.06 M_{\odot}$.

mation in a rotating turbulent protostellar cloud fragment. Turbulence is taken into account by introducing an α -type “turbulent” viscosity with $\alpha = 0.1$. The initial conditions are very similar to those given above by Bodenheimer et al. (1990), but the total angular momentum is three times larger. Redistribution of angular momentum due to the amount of viscosity chosen is so efficient that the collapse shows qualitatively the same features that have long been known for the spherical case. This is best illustrated by the central density, the central temperature diagram (Fig. 1). The cloud starts with a cooling phase (A-B), since the Kelvin-Helmholtz time t_{KH} of the fragment is shorter than the free-fall time $t_{ff} \approx 720$ yr. After the core has become optically thick (den-

sities greater than $\sim 10^{-13} \text{ g cm}^{-3}$), the collapse proceeds quasi-adiabatically (B-C). Angular momentum is continuously removed from the central regions to such an extent that the core is able to contract quickly further down to a rather flattened object at point D (see Fig. 2a). Between D and E a substantial loss of the excess angular momentum ensues and the core becomes closer and closer to a spherical shape.

The evolution of the collapse and the formation of the first, optically thick core and of the outer disk are displayed in Fig. 3a-c and Fig. 3d-f on length scales of $6 \times 10^{14} \text{ cm}$ (about the diameter of the solar system), and $2 \times 10^{14} \text{ cm}$, respectively, for epochs C, D and E. Notice the anisotropic nature of the second collapse (Fig. 3f), which proceeds parallel to the axis of rotation and gives rise to the formation of an inner disk around the stellar core. Fig. 4a-d shows two disk regions of $\sim 10^{15} \text{ cm}$ and 10^{13} cm linear scale, respectively, at epoch E. The (inner) accretion shock has the shape of two "polar caps," but at lower latitudes the flow is subsonic and fairly smooth. After most of the material of the outer disk will have fallen onto the inner disk, there will emerge a single flattened structure that is on the way to becoming an ordinary α -accretion disk, which could then be justly referred to as the protoplanetary nebula.

Although an implicit numerical Newton-Raphson-Henry technique was adopted for these axisymmetric models, for which no CFL-limitations of the time step have to be observed, the onset of core oscillations (see Fig. 1, labels E through I) on a short time scale has impeded further progress, as a prohibitively large amount of computer time would be required to follow the oscillations. According to the results obtained by Tscharnuter (1987b) and Balluch (1991b, c) for spherical protostellar collapse and by Wuchterl (1990a) for giant gaseous planet formation, quasi-stationary accretion flows are basically unstable, and could conceivably account for the observational inability to detect accretion in protostars. The quasi-hydrostatic parts of such flows are found to be vibrationally and also dynamically (e.g., the second collapse) unstable; the amplitudes of the oscillations may become quite large because the (mass-weighted) adiabatic exponent Γ_1 is always around the critical value $4/3$, due to the fact that ionization of H and/or dissociation of H_2 is not yet complete in newly formed (dense and relatively cool) regions of the protostar.

V. NONAXISYMMETRIC MODELS

In a nonaxisymmetric model of protosolar nebula formation, the possibility exists that the cloud could break up during the collapse phase. If the cloud fragments into two or more nearly equal mass objects, the end result is likely to be a binary or multiple protostellar system, rather than the single star and protoplanetary nebula desired in this chapter. There appear to be three criteria (see the Chapter by Bodenheimer et al.) for enhancing the probability of single solar-type star formation: (a) slowly rotating clouds with specific

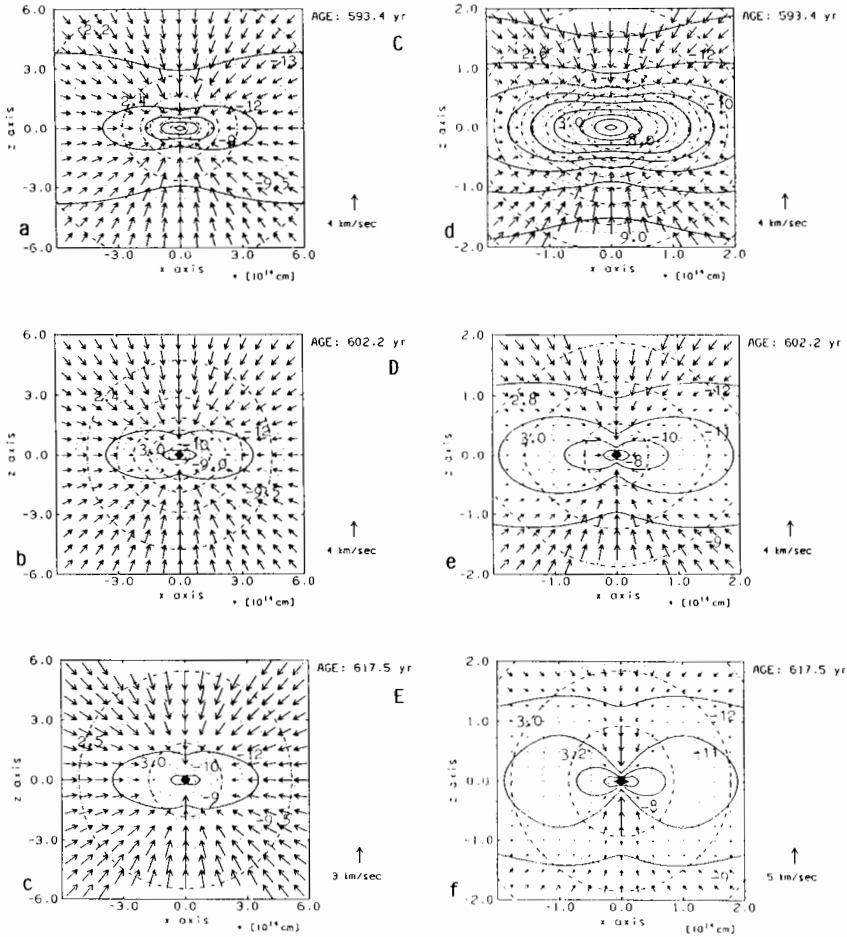

Figure 3. Axisymmetric model of Fig. 1. Meridional cross sections at two different length scales show the formation of the outer disk (a–c), the onset of the second collapse and the appearance of an inner disk (d–f) during the period C–E. Contour lines and numbers have the same meaning as in Fig. 2.

angular momentum $J/M < 10^{20} \text{ cm}^2 \text{ s}^{-1}$ (Safronov and Ruzmaikina 1978; Boss 1985); (b) centrally condensed clouds with power-law initial density profiles ($\rho_i \propto r^{-n}$), shown to be stable against fragmentation numerically for $n = 1$ by Boss (1987) and analytically for $n = 2$ (the singular isothermal sphere of Shu [1977]) by Tsai and Bertschinger (1989); and possibly (c) initially uniform density clouds that begin their isothermal collapse very close to Jeans stability (Miyama et al. 1984), though the evolution of such clouds in the nonisothermal regime is largely unknown.

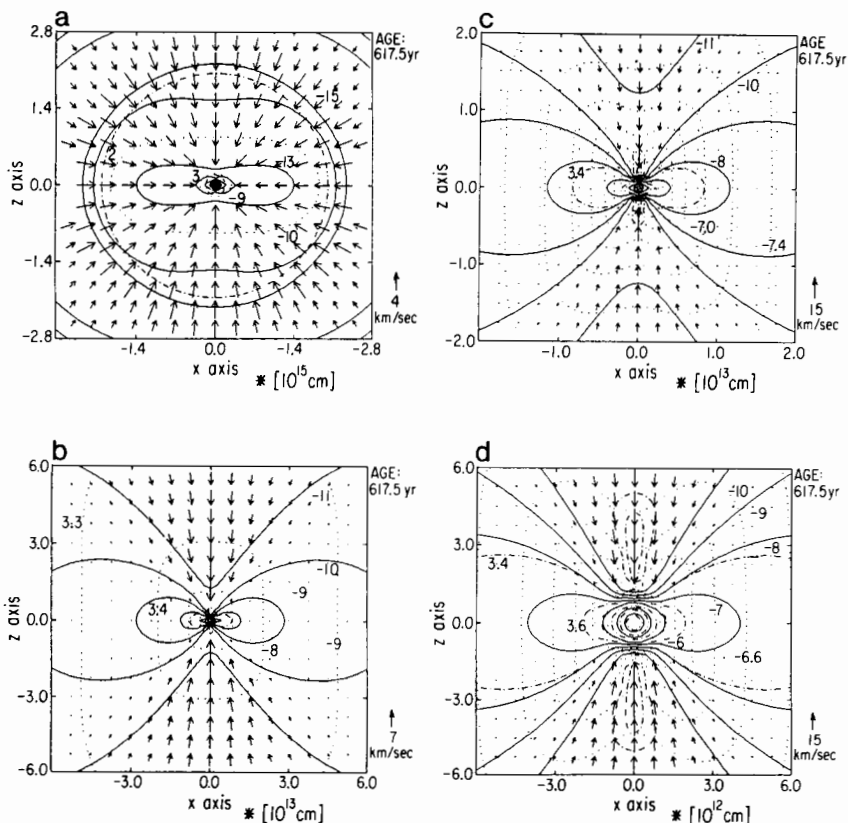

Figure 4. Axisymmetric models of Fig. 1. Panels (a–d) display meridional cross sections at various length scales at epoch E (maximum central density). Contour lines and numbers have the same meaning as in Fig. 2.

Starting from initial conditions obeying at least one of these three criteria, the challenge is straightforward: calculate the nonaxisymmetric collapse of a dense molecular cloud. However, given the formidable difficulties encountered in calculating even axisymmetric models of protosolar nebula formation (see previous sections), it is premature for definitive models of fully three-dimensional, nonaxisymmetric collapse to have emerged. Nevertheless, considering the apparent (though limited) success of nonaxisymmetric models of binary star formation through fragmentation (see the Chapter by Bodenheimer et al.), preliminary nonaxisymmetric models of protosolar nebula formation can be generated and are discussed in this section. A new three-dimensional

code is being developed to study this general problem (Myhill and Kaula 1990), but at present only one three-dimensional code exists that is capable of studying the coupled dynamical and thermodynamical evolution of protostellar nebulae (Boss 1989*a, b*).

A. Angular Momentum Transport

As advanced by Larson (1984), the protosolar nebula can be expected to become nonaxisymmetric to some extent, and hence the possibility arises of performing at least some of the large-scale angular momentum transport necessary for nebula evolution through gravitational torques (see the Chapter by Adams and Lin). Cassen et al. (1981) studied the growth of nonaxisymmetry in pre-existing, isothermal, thin disks of particles simulating a fluid, and found that marginally unstable disks produced strong trailing spiral arms (see, e.g., Cassen et al. 1981, their Fig. 5); they noted in passing that such models would lead to gravitational torques, and that the nebula might evolve along a marginally unstable path. Boss (1984*b*) used a simple analytical model to estimate the efficiency of angular momentum transport by gravitational torques, and found that $d(J/M)/dt \sim G\rho R^2$, where G is the gravitational constant and R is a characteristic length. Coupled with typical nebula densities and sizes, this yields a time scale for angular momentum transport $\tau_J = (J/M)/[d(J/M)/dt] \sim 10$ Myr. Cassen and Tomley (1988), improving on the calculations of Cassen et al. (1981) by including radiative cooling, found $\tau_J \sim 100$ yr for the evolution through spiral density waves of the very innermost (<0.1 AU) regions of their nebula model. Miyama (1989) also found that gravitational torques are likely to be effective during the nebula formation phase. Anthony and Carlberg (1988) estimated the viscosity associated with spiral waves excited in self-gravitating accretion disks by carrying out extensive numerical n -body experiments.

The main motivation for the Boss (1989*b*) study was to try to improve upon previous estimates of the efficiency of angular momentum transport by gravitational torques. Boss (1989*a, b*) calculated a suite of low-mass protostellar disk models with wide variations in the initial parameters, such as the initial mass of the cloud (0.1 to $1.0 M_\odot$), the initial mass of the central protostar (0.0 to $1.0 M_\odot$, the detailed structure of which was not considered), and the initial specific angular momentum ($J/M = 2 \times 10^{18}$ to 6.9×10^{19} cm²s⁻¹). The initial density profile was varied from uniform to strongly centrally condensed ($\rho_i \propto r^{-1}$); the initial angular velocity profiles were also varied from solid body rotation to $\Omega_i \propto R$, where R is cylindrical radius. In this section, we give detailed results (Fig. 5) for a model starting from $\rho_i \propto r^{-1}$, roughly consistent with the possibility that the solar system was derived from a subcritical, magnetically supported dense cloud core, and with the tendency of such clouds to evolve toward a power-law density profile prior to the onset of dynamic collapse (Tomisaka et al. 1989; Lizano and Shu 1989). While such subcritical cores are thought to be common in the Taurus molecular cloud, the situation may be different in other star-forming

regions, such as Ophiuchus and Orion, and we cannot be sure in which type of environment the solar system formed. As it turns out, the results of the model shown in Fig. 5 are largely independent of the initial density profile; similar results obtain even for uniform initial densities (Boss 1989*b*).

Because of the time-step limitation on explicit hydrodynamics codes (see Sec. III), the three-dimensional models were started from abnormally high initial densities, typically $\rho_i \sim 10^{-13}$ to 10^{-12} g cm $^{-3}$, leading to very high effective mass accretion rates $\dot{M} \sim 10^{-3}$ to 10^{-2} M_\odot yr $^{-1}$, compared to the usually assumed values of 10^{-6} to 10^{-4} M_\odot yr $^{-1}$. In the absence of refined calculations, the effect of this assumption on the models is uncertain. However, densities this high are consistent with models of magnetic fields that do not become dynamically insignificant until similar densities are reached (Nakano and Umebayashi 1988; see Sec. II), and they also sidestep the problem of protostellar core instabilities (Sec. IV). Most importantly, compared to pre-existing nebula models that effectively are created instantaneously (yielding $\dot{M} = \infty$), a large but finite value of \dot{M} does allow the effect of collapse on nebula dynamics to be addressed in at least a preliminary fashion.

Figure 5(a) shows that an initially nearly axisymmetric cloud will become significantly nonaxisymmetric during its formation (note that numerical dissipation should tend to damp nonaxisymmetry, so the models probably underestimate the amplitude of the density asymmetries). This nonaxisymmetry results from a combination of nonlinear coupling to the large supersonic infall velocities (Boss 1989*b*) and rotational instability of the nebula ($T/|W| = \beta = E_{\text{rot}}/|E_{\text{grav}}| > 0.274$). The model is stable to axisymmetric perturbations, according to Toomre's (1964) Q stability criterion (cf. the unstable models of Cassen et al. [1981], which were Q unstable).

While the density contours in Fig. 5(c) do not reveal a trailing spiral arm pattern, this pattern is evident in the innermost nebula in the phase pattern of Fig. 5(b). The trailing spiral arm region (out to ~ 14 AU) is largely losing angular momentum, at a peak rate of dJ/dt of $\sim 10^{39}$ to 10^{40} g cm 2 s $^{-2}$, while the outer regions are gaining angular momentum. If this rate of transfer of angular momentum could be sustained (the calculations generally are limited to fractions of a rotation period), the time scale for angular momentum evolution by gravitational torques in this model would be $\tau_J \sim 10^5$ to 10^6 yr. Smaller time scales can result in models that come closer to undergoing fragmentation during their formation (Boss 1989*b*). However, the former time scales are already comparable to those (10^5 to 10^7 yr) inferred for the bulk of nebula dissipation from observations of weak-lined T Tauri stars (see Chapter by Strom et al.) and naked T Tauri stars (Walter et al. 1988).

For computational economy, the Boss (1989*b*) models were limited to even- m modes; recent linearized models of gravitational instability in pre-existing, thin disks by Adams et al. (1989) and Shu et al. (1990) have shown that the $m = 1$ mode might be more important than the even- m modes, because the $m = 1$ mode, corresponding to eccentric particle orbits, may be the most unstable mode of all. The eccentric mode can grow even in a nebula that is

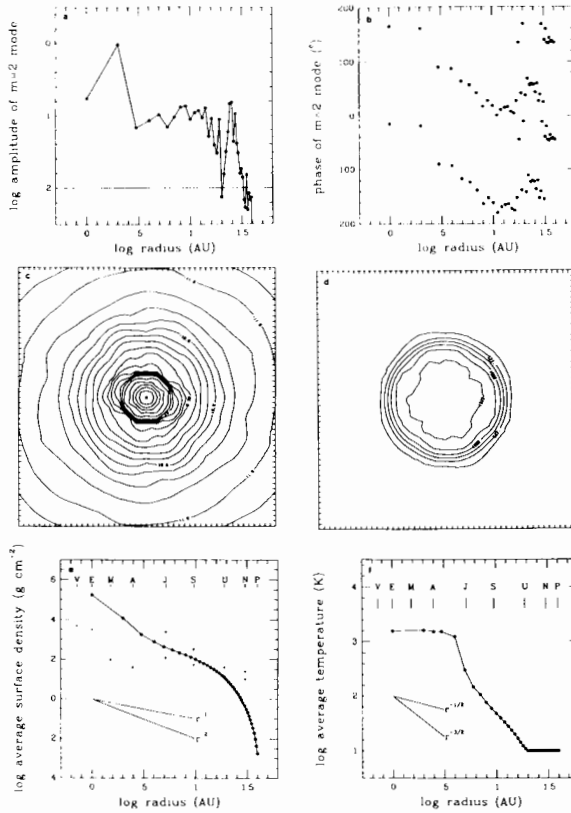

Figure 5. Three-dimensional model of a protostellar nebula at a time when the disk mass is $0.191 M_{\odot}$ and the central protostellar mass is $0.837 M_{\odot}$ (Boss 1989a). The precollapse configuration consisted of a $0.010 M_{\odot}$ protostar surrounded by a $1.018 M_{\odot}$ spherical cloud, with a power-law density profile ($\rho_i \propto r^{-1}$), and with a uniform angular velocity such that the specific angular momentum $J/M = 1.86 \times 10^{19} \text{ cm}^2 \text{ s}^{-1}$. (a) Amplitude of the $m = 2$ mode of the density as a function of radius in the equatorial plane of the disk. Horizontal line denotes the initial density perturbation, which is approximately equal to the level of nonaxisymmetric noise generated by the code. Significant growth of the $m = 2$ mode is evident. (b) Phase of the $m = 2$ mode of the density as a function of radius in the equatorial plane of the disk. Two phases are plotted for each radius, one for each end of the bar mode. A trailing spiral pattern occurs in the inner 10 AU, and a leading spiral pattern outside 10 AU. (c) Equatorial density contours for a region 10 AU in radius. Each contour represents a factor of 2 change in density; the innermost 0.5 AU is not resolved in this calculation. Contours are labeled by densities in g cm^{-3} . (d) Equatorial temperature contours for a region 10 AU in radius. Each contour represents a change of 250 K in temperature. Contours are labeled by temperatures in K. (e) Azimuthally averaged surface density as a function of radius in the disk. Locations of planets are noted. Plus signs refer to reconstituted solar nebula of Weidenschilling (1977b). (f) Azimuthally averaged midplane temperature as a function of radius in the disk. The temperature levels off at $\sim 1500 \text{ K}$ in the inner nebula because of the thermostatic effect of the evaporation of iron grains (the dominant source of opacity) around that temperature.

stable with respect to axisymmetric disturbances (Toomre 1964). However, the nonlinear behavior of this mode is uncertain, and even in the linear regime, growth of the eccentric mode requires the presence of a "sharp" outer edge to the disk; note that the relatively sharp outer edge evident in Fig. 5(e) is an artifact of the boundary conditions, not a real effect. The degree to which sharp edges exist in realistic disks is also uncertain. Regardless of the nonlinear behavior of the eccentric mode in a realistic nebula, the inclusion of odd modes should lead to decreased estimates of τ_J .

B. Surface Density and Temperature Profiles

The three-dimensional models also produced surface density and temperature profiles that are important links between nebula models and planetary formation models. The models showed no strong tendency even for massive nebulae to break up directly into giant gaseous protoplanets. Surface densities in the inner nebula were always adequate to account for the formation of the terrestrial planets (Fig. 5e), even in a minimum-mass ($\sim 0.05 M_\odot$) nebula. However, surface densities in the outer nebula always appear to be inadequate to account for rapid formation of the $\sim 10 M_\oplus$ cores needed for giant planet formation (see the Chapters by Lissauer and Stewart and by Podolak et al.), unless the nebula is substantially more massive than the minimum-mass nebula (Boss 1989a, b). This result is consistent with two-dimensional models that map clouds into thin, equilibrium disks (Stemwedel et al. 1990); the implication is that if enhanced surface densities are to occur in the outer regions of a minimum-mass nebula, the enhancement must be achieved through nebula evolution.

Midplane temperatures typically reach 1500 K in the inner nebula, but remain at 150 K or lower in the outer nebula (Fig. 5f). This implies melting of many solids in the innermost regions of the early nebula, subsequently leading to condensation (Grossman 1972) as the nebula cooled. Because the time scale for this global cooling is $\sim 10^5$ to 10^6 yr (based on a crude optical depth argument), globally high temperatures cannot account for the formation of meteoritical chondrules, whose textures require very rapid cooling (Hewins 1988). However, a hot inner nebula seems necessary in order to account for the volatile metal depletions seen in the terrestrial planets (see the Chapter by Palme and Boynton). Figure 5(f) shows that it is possible to have a hot inner nebula, while still having a nebula cool enough at 5 AU for ice condensation and cool enough at 20 AU and beyond for comet formation (see the Chapter by Mumma et al.). In addition, some nebula models are strongly nonaxisymmetric (Boss 1989b), opening up the possibility of having both high- and low-temperature regions at the same radius, possibly allowing for the survival of relict grains that remain closely coupled to their gas parcel until accumulation.

Because the three-dimensional calculations start from initial densities that are $\sim 10^6$ times those of dense cloud cores, the collapse times are 1000 times shorter than usual (~ 100 yr), possibly leading to higher temperatures than

would be the case for collapse starting from lower densities. However, if the cooling time for a dust-enshrouded nebula is $\sim 10^5$ to 10^6 yr (as estimated by Boss 1989*b*), then the amount of nebula cooling during collapse may not be significant. Counterbalancing this effect is the fact that the three-dimensional calculations of Boss (1989*b*) ignore the heating caused by the central proto-star; two-dimensional calculations by Tscharnuter (1987*a*) and Bodenheimer et al. (1990), which include protostar heating and start from lower initial densities, produce comparable or even higher midplane temperatures in the inner nebula (see Sec. IV). Refined models will be needed to improve upon these preliminary estimates of nebula thermal structure.

IV. CONCLUSIONS

It is quite obvious that, in spite of the progress made in the past five years, the calculation of completely rigorous model sequences pertaining to the formation of the solar nebula is far beyond the reach of our present computational power. Because there is a stringent limitation on the time step given by the CFL-condition 1 (Sec. III) for explicit schemes, we are able to study only the formation of the disk in some detail, whereas the accumulation of the central proto-Sun cannot be adequately treated in three dimensional models. The most important result of nonaxisymmetric model sequences carried out so far is that angular momentum can be effectively redistributed by means of gravitational torques exerted by nonaxisymmetric (bar-like or spiral-like) structures in the disk.

Major progress in multidimensional models may not be possible until still more powerful implicit methods (which are insensitive to the CFL-condition) are available. To date, variants of the classical Newton-Raphson-Henyey technique, which implies the repeated inversion of large matrices (typically $10^4 \times 10^4$ -matrices of a 10×10^2 block-diagonal structure for the axisymmetric problem), have been used very successfully. However, it turned out that the condition of these huge matrices becomes worse if the number of the numerical zones is increased. This unpleasant situation is further amplified if a self-adaptive grid is used, with the possibility of a strong local refinement in the radial direction. Current investigations are attempting to overcome this technical difficulty.

It would also be desirable to develop a technique for handling fully adaptive (both spatial directions) two-dimensional grids, but such an enterprise does not seem feasible in the near future. Likewise, there is also not much hope to attack the three-dimensional collapse problem by means of an implicit method, because an unrealistically large amount of computer time would be needed to arrive at a sufficiently accurate and reliable numerical solution. Interim progress on the multidimensional collapse problem may have to continue to rely on numerical tricks such as the use of "sink cells" (Boss and Black 1982; Boss 1989*b*) and "multiple collapses" (Bodenheimer et al. 1990).

In axisymmetric models turbulent friction is an efficient mechanism of angular momentum transport. Unfortunately, no generally accepted, consistent theory is available for the onset, maintenance and decay of turbulence, nor is it possible to determine the viscosity coefficient from first principles with complete generality (for some promising steps in this direction, however, see Cabot et al. [1987*b*] and Canuto [1989]). Hence, the α -viscosity, widely used in accretion disk theory, must still be viewed as somewhat of a free parameter that can be adjusted both to astrophysical observations and cosmochemical findings.

The role of magnetic fields during protostellar collapse and disk formation is not quite clear. Although the dynamics of the collapse are most probably not affected by magnetic forces—that is exactly why collapse is able to commence—there might be an influence on the long-term evolution of the disk; magnetic flux may be regenerated when the temperatures have become high enough and dynamo processes in the disk and/or in the central star may become active. Magnetic forces should therefore be taken into account in the next phase of modeling protostellar collapse through detailed numerical experiments. With the caveats above pertaining to the prospects of the availability of more powerful numerical tools in mind, this step could, in principle, be made immediately with axisymmetric field geometries (axis of rotation parallel to the magnetic axis), but it is our opinion that the solution of the nonmagnetic collapse and accretion problem should have a firm basis consisting of reliable and sufficiently accurate numerical results, before still more complexity is introduced in the models.

Stars and planetary systems are thought to develop more or less contemporaneously from extended disk-shaped nebulae. Because the dynamical states of such disks are far from their final equilibrium configurations, the nebulae can dissipate large amounts of energy, as matter accumulates in the center and angular momentum moves to the peripheries. Experience with cosmical systems that are far from equilibrium indicates that such rapid dissipative evolution frequently occurs through a variety of collective behaviors, sometimes producing phenomena of surprising violence. This chapter reviews the range of types of collective processes that may occur in protostellar disks and play significant roles in speeding the evolution of the disks, as well as affecting the physical state of the disk and altering the state of protoplanetary matter. The processes considered here include collective angular momentum transport processes, electrostatic lightning and magnetic flares.

I. INTRODUCTION

During approximately the past decade a great deal of attention has been given to developing a physically realistic picture of planet-forming regions around protostars and young pre-main-sequence (PMS) stars. This recent work complements the detailed chemical, isotopic and mineralogical analyses of primitive meteorites, which have been carried out during the past several decades, and which have allowed important inferences to be made about the conditions that attended the birth of our own planetary system. Among the principal theoretical developments have been numerical collapse calculations (see, e.g., Shu 1977; Morfill 1985; Morfill et al. 1985; Cassen and Boss 1988; Boss 1981; Tscharnuter 1987) and accretion disk models (see, e.g., Lin 1981; Cabot et al. 1987*a, b*; Ruden and Lin 1986; Wood and Morfill 1988; Sec. III).

The starting point of the collapse calculations can be identified with observations of dense cores in interstellar clouds. The starting point for accretion disk models is a PMS star, surrounded by remnants of the cloud from which it formed, orbiting in an equatorially flattened, disk configuration. Although collapse calculations suggest evolution toward a PMS star accretion disk system, the assumption nevertheless was that star formation occurs sufficiently rapidly, and disk dispersal sufficiently slowly, that this scenario was viable. Until recently, no observational evidence existed to support this assumption.

During these stages of development of our theoretical understanding it was natural to treat quiescent accretion disks first, to establish the basic mathematical framework, to determine the relative importance of physical processes and assess them quantitatively (e.g., the nature of the disk viscosity, density waves, opacity due to dust, coagulation and transport, etc.) and to relate these models to observable properties of our solar system. (For references see, e.g., Larson 1984; Bodenheimer et al. 1980; Pollack 1985; Levy et al. 1991; Morfill and Völk 1984; Morfill 1983,1988.) Although many of the questions which arose have not been answered yet, it has become increasingly clear that a number of the observed phenomena will not find their explanation in quiescent accretion disk models. Prominent examples are the formation of chondrules, the CAIs and possibly the isotopic anomalies.

This chapter describes active, dynamic, even violent, accretion disk processes and relates them to measurements where possible. We shall start with a brief review of the recently obtained observational evidence of accretion disks around PMS stars in order to provide a quantitative background. After that, we discuss angular momentum transport, which, together with radiation transfer, is the most important globally occurring process in accretion disks. We then turn our attention to more localized processes that might occur, and whose signatures may have been observed in our solar system: electrostatic discharges (lightning) and magnetic field flares.

II. ACCRETION DISKS AROUND PMS-STARS

The photometric identification of stars (or protostars) with protoplanetary disks is very difficult because of the small size of these objects, typically 100 AU, and the need to observe them at infrared, sub-mm and radio wavelengths. The best established example is HL Tau, which has a massive disk extending to about 1000 AU and has been resolved in radio-line emission from CO molecules (Fig. 1). Of course, observation of one (still) poorly resolved object is not sufficient to establish the character of the PMS-star/disk relationship, let alone provide quantitative disk properties. Fortunately, spectroscopic measurements have yielded a wealth of additional information so that a number of features have become clearly established during the past few years. These are the existence of disks (or disk-like objects) surrounding the central stars, the occurrence of molecular outflows and winds, the emission from the disk-star boundary layer, disk gaps, etc. The most recent compre-

hensive survey of a large number of PMS stars and associated circumstellar matter is due to Beckwith et al. (1990).

Figure 1. Flattened disk of dust and gas orbiting the PMS star HL Tauri (located at the white cross). The figure shows the radio line emission from CO molecules. Figure taken from a review by Black (1991).

Of a sample of 86 PMS stars, evidence for circumstellar disks was found in 37, or some 43%. If planets are formed in all such circumstellar disks, planetary systems would appear to be quite common around solar-type stars. Recent studies have attempted to ascertain the systematic character of this class of objects, from which the following conclusions seem to emerge (Beckwith et al. 1990):

1. Disk masses typically fall in the range: 2×10^{-3} to $10^{-1} M_{\odot}$.
2. There is no systematic correlation of disk mass with stellar age between 10^5 and 10^7 yr.
3. No disks have been detected for stars older than about 10^7 yr.
4. Disk temperatures, at 1 AU, fall in the range from 50 K to 300 K.
5. Disk temperatures vary as $T \propto r^{-q}$, temperature index $0.5 \leq q \leq 0.75$.
6. The hotter disks have $q \approx 0.5$.
7. There is a tendency for hotter disks to be found around younger PMSs.

8. Some disks have holes or gaps in their centers, ranging from 0.1 to 0.3 AU in radius.
9. Disks typically extend to about 100 AU.

Figure 2. Spectral energy distribution of the emission from HL Tauri. The dotted line is the Planck function at the stellar effective temperatures fitted to the short wavelength data; the solid line is a theoretical fit to the disk emission.

In Fig. 2 we show the measured spectrum for HL Tau, the star which has a photometrically resolved disk (see Fig. 1), as an example of the kind of signature that can be obtained and analyzed. In Fig. 3, we show a histogram of the computed temperature power-law index, q , (from $T \propto r^{-q}$) for the Beckwith et al. sample.

Theoretically, the surface temperature of a simple, self-luminous disk (i.e., one which is not seen in reflected light from the central star) should follow the relationship

$$T \propto r^{-3/4} \quad (1)$$

that is, with a temperature index $q = 0.75$. The measurements show that disks typically have lower temperature indices, with 0.75 being the upper limit. This discrepancy may not seem startling at first glance, until it is remembered how the theoretical result is derived.

The release of gravitational energy, as matter evolves inwards under the influence of viscous interactions, is (per unit mass of disk material):

$$\dot{\epsilon} = v_r \frac{\partial}{\partial r} \left(\frac{GM_c}{r} \right) \quad (2)$$

where M_c is the central mass (the PMS star or the protostar, whichever the case may be), G is the gravitational constant, v_r the radial flow velocity and

Figure 3. Distribution of temperature power-law indices g derived from a sample of 37 PMS stars with spectroscopic signatures of accretion disks.

r the distance from the center. The radial flow velocity arises from viscous interactions and need not be specified. Utilizing the continuity condition for the mass flow,

$$\dot{M} = 2\pi r \Sigma v_r \quad (3)$$

with Σ the disk surface density, we obtain the energy production in the disk in a radius interval dr , from

$$\dot{E} = 2\pi r \Sigma \dot{\epsilon} dr. \quad (4)$$

The heat generated in this way is radiated into space from the disk surface. Radiative losses from the same radius interval are

$$L = 4\pi r \sigma T_s^4 dr \quad (5)$$

where blackbody radiation has been assumed at a characteristic surface temperature, T_s . Stefans constant is denoted by σ . In equilibrium, putting $L \equiv \dot{E}$, we get

$$T_s^4 = \frac{3GM_c \dot{M}}{8\pi \sigma r^3}. \quad (6)$$

This result is quite general for self-luminous steady disks. The magnitude of the temperature at a given radial distance depends only on the central mass, M_c , and the rate of mass flow through the disk, i.e., the accretion rate \dot{M} .

Departures from expression (6) imply departures from the assumptions that went into deriving this result. One of these assumptions was axial symmetry. It is conceivable that, e.g., density waves, macroscopic instabilities or spiral shocks may modify Eq. (6). The reason is that small localized variations in the surface temperature are enhanced by the T^4 dependence and may simulate overall a different radial gradient. In Figs. 4a and 4b, we

demonstrate this effect. In Fig. 4a, we have plotted two examples of the radial temperature variation, two power laws with index $q = 0.5$ (short dashed) and 0.75 (long dashed). Figure 4b shows the computed spectrum from such a disk. The spectrum corresponding to the temperature index of 0.5 is flat over a large frequency range, the one due to $q = 0.75$ increases with frequency. In fact, theory gives $L_\nu \propto \nu^{4-2/q}$. Departures from this power law are due to the inner and outer disk edges, the spectra can therefore give information on the size of these objects. The curves also demonstrate that measurement uncertainties in the observed spectra should not be responsible for the discrepancy with the theoretical result derived in Eq. (6).

In Fig. 4a, we also show a radial temperature profile of a perturbed disk (solid line). The perturbation has a radially growing wavelength simulating a macroscopically unstable structure or a density wave type fluctuation (although our synthetic model is axially symmetric). The spectrum obtained from this perturbed disk is also shown in Fig. 4b. As can be seen, the spectrum is relatively flat and would be interpreted as having a temperature index $q \approx 0.5$.

Of course, this interpretation does not cover all of the possibilities. It is interesting to see how such perturbations may simulate flatter temperature gradients, because disk instabilities, nonaxisymmetric structures, etc. have received increasing attention in the past few years. Alternative processes which may also yield flatter spectra will have to be explored. Among other possible spectrum-flattening processes are:

1. Effects of "viewing geometry," taking account of radial thickness variations of the disk. Spectral changes are due to different weighting of high (inner) and low (outer) temperature regimes.
2. Radiation transfer, taking account of the fact that the penetration depths of different wavelengths are not the same.
3. Dust properties, taking account of the possibly fractal geometry of aggregates and the resulting modification of absorption and emission characteristics.
4. Dust size distribution, taking account of the possible dynamical and radial evolution of dust coagulation and the associated size spectra, effects of major condensation/sublimation zones (e.g., ice) on the size distribution.
5. Dust sedimentation, leading to a height-dependent size distribution.
6. Reflection of light emitted from the central star, if the disk geometry is flared.
7. Disk perturbations, e.g., macroscopic instabilities, density waves, spiral shocks, pile-up due to viscosity variations as function of radius.
8. Time dependence in the disk evolution.

Summarizing this section, it is widely accepted now that protoplanetary disks are a common feature amongst PMS stars. These disks appear to have lifetimes of about 10^7 yr, which constrains the planet formation rates. The

Figure 4. (a) Three theoretical disk surface temperature profiles plotted as a function of disk radius. (b) Corresponding spectral energy distribution. Note that the perturbed disk has a relatively flat spectrum. Figure taken from Morfill and Sterzik (1990).

disks are cool, with temperatures not higher than a few hundred degrees at 1 AU, and evidence is mounting that they are not quiescent objects, with instabilities and nonaxisymmetric perturbations playing important roles. We want to emphasize the important advance which these disk observations and the determination of their properties, have brought to theoretical modeling

of both star and planet formation. Before these disks were observed and measured, the prime observational information came from protostellar clouds, believed to be the dense cores found in the more diffuse interstellar clouds. Measured properties of such cores, including mass, size, density and angular momentum, provided the starting point for theoretical collapse calculations and the studies of star formation (see, e.g., Boss et al. 1989). Two-dimensional hydrodynamic calculations by, e.g., Tscharnuter (1987) yielded disks with quite interesting properties, surrounding and feeding the central protostar.

From the point of view of planet formation these early disks, surrounding the growing protostar, are not especially relevant. Most of the mass in these disks will end up in the star and hence the conditions in and properties of such disks cannot be directly related to the protoplanetary disks from which the planets ultimately derive. Disk modeling, for the purposes of studying the protoplanetary environment, had to assume that the early disks computed in the context of collapse calculations had properties similar to the later disks in which planets may form (without ending up inside the star). For a detailed description see Morfill (1985).

With the disk properties around young PMS stars now a subject of observational study, modeling of planet formation has been provided with an informative new starting point, a basis from which to proceed with much greater confidence than was possible before. Already there are some puzzles—observation that some disks apparently have central holes, and the temperature gradient, which we discussed above, being just two of these. The solutions of such puzzles will help us to understand the environment in which the planets of our solar system were born and to learn how the solar system was formed, provided it was not created under very special circumstances—differing greatly from the PMS disks which we can study now.

III. ANGULAR MOMENTUM TRANSPORT PROCESSES

We briefly review here several specific angular momentum transport processes. Other processes and further details are given elsewhere in this book.

A. Shear Turbulence

Historically, one of the first processes proposed to allow mass in a disk to lose angular momentum and thereby accrete onto the central object is *shear turbulence* (see, e.g., Zeldovich 1981; see also von Weizsäcker 1948). The shear in the fluid flow between neighboring orbits is similar to that in a rotating Couette flow experiment (apart from the compressibility in the astrophysical case, the equations are nearly identical). For experimental parameters (rotation rates of the inner and outer cylinders) that correspond closest to the astrophysical case, turbulence has not been observed in the laboratory, as was pointed out by Kippenhahn and Thomas (1981). Because shear flows in the laboratory always seem to lead to turbulence at sufficiently high Reynolds numbers, it is often considered obvious (see, e.g., Di Prima and

Swinney 1981) that this will also happen in the rotating Couette experiment, for all parameter values. In the astrophysical community, the question is usually considered unresolved; the effect of rotation (not present in most laboratory shear flows) is often believed to be stabilizing (Paczynski 1978*b*; cf. Pringle 1981). Numerical simulations of (parts of) thin accretion disks (Siregar and Léorat 1989; Kaisig 1989*a, b* and in preparation) have not found the expected turbulence, though instabilities operating on a dynamical time scale have been found in thick disks (Drury 1979; Papaloizou and Pringle 1985; Zurek and Benz 1986), in thin tori (Goodman et al. 1987; Hawley 1989), and at the edges of disks (Blaes and Hawley 1988). If thin disks are in fact unstable to shear turbulence, it will probably be found only in three-dimensional calculations as it is known (see, e.g., Orszag and Kells 1980; Bayly et al. 1988) that the third dimension is often essential for the instability mechanism.

Because the instability would be a dynamical one, the resulting viscosity would be high (with α —the ratio of the “turbulent” gas speed to the sound speed—of the order unity), and it would operate in the same way in *all* disks, at least those where a fluid approximation is justified. It seems that observations may well be able to shed light on the question. For example, very low values of α in some disks, or strong variations in α between objects would be hard to understand in the shear turbulence picture. Do protostellar disks give us any clues? If taken at face value, the observed typical sizes (100 AU), temperatures ($T = 300r^{-1/2}$ K; Hayashi et al. 1985), and time scales (10^6 yr or longer) imply α 's less than 10^{-2} . Even a modest improvement in the reliability of these numbers would be enough to justify doubt about viscosities due to shear turbulence.

Inasmuch as the observations of protostellar disks do not require very high α 's (compared with the case of cataclysmic variables [Pringle et al. 1986]), several proposed mechanisms are viable, especially for the inner parts of the disks. We discuss here two of these, namely angular momentum loss due to a wind from the disk, and spiral waves generated by self-gravitating processes or planets embedded in the disk. Convective instabilities, another possible turbulence-generating mechanism, has been reviewed elsewhere (see, e.g., Lin 1981; Cabot et al. 1987*a, b*) and will not be discussed here.

B. Angular Momentum Loss Due to a Magnetic Wind

The idea that a magnetized disk could lose angular momentum and thereby allow accretion to take place via a wind was proposed by Bisnovatyi and Ruzmaikin (1976), Blandford (1976) and Lovelace (1976). The idea relies on the existence of a fairly organized vertical (perpendicular to the disk) magnetic field component of uniform sign. Such a field would evolve naturally in the inner parts of an extended disk from a random field captured by accretion in the outer parts. Any nonaxisymmetric component of this field would quickly be sheared to small length scales and dissipate away (Zeldovich et al. 1983) leaving an axisymmetric part that is concentrated inward by the accretion

flow. [In addition to this field, there could be an internal field, possibly stronger, generated by dynamo action (Levy 1978). To the extent that this would fluctuate in sign on a small scale, its contribution to the acceleration of a wind would be minor (cf. Blandford and Payne 1982).] In the protostellar case, it is not even necessary to start from a random field at the disk edge, because the observations indicate that the disks are usually perpendicular to the (strong and fairly orderly) ambient cloud field (presumably because of the very strong influence of the magnetic field on the collapse of the cloud; see Chapter by McKee et al. The resulting poloidal field, kept in place by the high gas density in the disk, can accelerate a cool wind in the same way as in magnetic stellar winds (see Sakurai 1985, and references therein). Full solutions of such winds have been obtained (Blandford and Payne 1982; Sakurai 1987). In these calculations, the mass loss from the disk surface is specified as a function of radius. If no dissipative processes (such as Ohmic diffusion, ambipolar diffusion or viscosity) are present in the disk, the disk can accrete with *all* the angular momentum being carried away by the wind. In practice, angular momentum transport by the wind may be competing with, say, a viscous process in the disk. In this case, the magnetic wind will dominate only if the magnetic field accelerating the wind, and the mass-loss rate are sufficiently high. The terminal speed of the wind can (if the mass-loss rate is sufficiently low) be much higher than the escape speed from the point on the disk at which the wind started. This makes the process attractive for explaining jets, especially in cases (active galactic nuclei, SS433) in which high speeds are seen. In protostellar disks, ambipolar diffusion is likely to be effective in the outer parts of the disk. Königl (1989), and Wardle and Königl (1990; see also Chapter by Königl and Ruden) have obtained detailed solutions for the field structure and flow field in the disk, taking into account ambipolar or Ohmic diffusion.

In the present state of the theory, the main uncertainty lies in the mass flux in the wind. As in the case of stellar magnetic winds, the actual amount of mass lost from the disk is sensitive to details of the heating and cooling processes near the disk surface. As the mass loss is increased, the resulting wind becomes slower and less collimated, but it carries more angular momentum away from the disk.

C. Angular Momentum Transport by Spiral Waves

Nonaxisymmetric waves in accretion disks have a spiral shape, due to the differential rotation (axisymmetric waves are also possible but less interesting because they cannot transport angular momentum). Angular momentum exchange by such waves is possible in a number of ways. A companion, if present, exerts gravitational torques on the nonaxisymmetric density distribution in the spirals, adding or extracting angular momentum from the disk. If the disk is massive enough for self-gravity to be important, the perturbations in the gravitational field due to the spirals produce torques on the fluid. Trailing spirals lead to an outward transport of angular momentum (Toomre 1964;

Larson 1984). But even in the absence of self-gravity or companions, angular momentum transport is possible because spiral waves effectively carry angular momentum. That is to say, the total angular momentum of a disk with waves is different from that of the same system without waves. As long as the waves are linear, no interaction takes place with the fluid, and the angular momenta of fluid and waves are conserved separately (for a discussion of wave angular momentum in disks see Narayan et al. [1987]). With dissipation, for example in the form of shock waves, angular momentum is transferred from the waves to the fluid. *Trailing* waves carry a *negative* angular momentum (in the sense described). Where they dissipate, they *reduce* the angular momentum of the fluid, allowing accretion to take place. Waves generated at the outer edge of a disk by a stationary or a corotating perturber are such trailing waves. As they propagate inward, their negative angular momentum provides a sink of angular momentum for the fluid that is available as far as the wave can travel inward.

It may sound counterintuitive at first that a wave source at the edge of a disk can cause matter to accrete in the inner parts of the disk, because the specific angular momentum of the fluid is large at the edge. It can be made more understandable by describing the waves in terms of wave packets or "phonons." Assume that at the outer edge of the disk we have a corotating source of phonons, emitted isotropically. The average momentum of these particles in the corotating frame is therefore zero. A phonon traveling inward meets an increasingly higher rotational velocity. Assuming for a moment that the phonon energy in an *inertial* frame is conserved, its energy measured in the corotating frame increases due to the Doppler effect. At the same time, in a comoving frame the particles have an average momentum *opposite* to the direction of the fluid. Interaction between the particles and the fluid therefore will brake the fluid. The dissipation of the waves thus communicates to the fluid the angular *velocity* of the outer edge, rather than the angular *momentum* there. The energy released in the process comes not from the initial wave energy of the emitted phonons but from the "Doppler-boosted" energy of the waves in the corotating frame, and therefore from the orbital motion of the fluid. The orbiting fluid feels a "friction" that slows it down with respect to the field of phonons emitted at the edge. The continuous inward increase of the orbital speed allows the phonons to continue losing energy by interaction with the fluid while gaining energy by Doppler effect, so that a steady state (in an inertial frame) with a net accretion is possible.

The same process takes place if waves are generated at the inner edge of a disk, for example, by nonaxisymmetries on a slowly rotating central star. This has been proposed by Michel (1984). Such waves could propagate outward, and where they dissipate they would communicate the slow rotation of the central object to the fluid. In this case however, the energy of the waves measured in the comoving frame *decreases* outward. Dissipation of the waves therefore limits their range, and the torque exerted on the disk is limited to the neighborhood of the central object. Numerical simulations of this process

were done by Kaisig (1989*b*).

The wave-particle duality that we appeal to here can be given an exact basis by noting (Whitham 1970; see Lighthill 1978) that wave packets moving in a shearing flow conserve their wave action $s = e/\omega$, where e and ω are the wave energy and wave frequency measured in the fluid frame. One verifies that this conservation property corresponds to the assumed conservation of phonon energy in an inertial frame, if the phonons are treated as particles of zero rest mass. We note that the analogy holds independent of the precise nature of the waves (acoustic or internal gravity waves, for example) as long as one can meaningfully build localized wave packets from them.

D. Self-Gravitating Spiral Waves

In disks of sufficiently high surface density or sufficiently low temperature, clumps can form by Jeans instability if the growth rate is large enough to offset the disruption by the shear in the Kepler flow. In terms of the Q parameter, $Q = c_s \Omega / (G \Sigma)$ this means $Q < 1$, where c_s is the sound speed and Σ the surface mass density. In the absence of (external or internal) heat sources, a disk would cool by radiation and eventually reach instability. The instability will lead to internal dissipation (extracted from the shear), heating the disk again. Paczyński (1978*a*) has proposed that at least certain disks might reach a quasi-equilibrium in this way, in which the heating by the instability balances cooling by radiation. Such disks would have a Q just below unity. Koslowski et al. (1979) and Lin and Pringle (1987, 1990; see also Chapter by Adams and Lin) have calculated models of disks in which the instability is taken to act as a source of effective viscosity, which can be modeled in a way similar to the α prescription. Numerical simulations have been done by Anthony and Carlberg (1988). The angular momentum transport by such instabilities can also be understood in terms of the wave packet description given above. The instability generates waves which propagate some distance away from their origin. Because $Q < 1$, the gravitational torques between the density fluctuations in the waves and the fluid are important and produce an effective coupling between the wave packets and the fluid. At radii inward of their source, the waves extract angular momentum from the fluid in the same way as discussed above; outward of their source, they add angular momentum through this interaction. The net effect is an outwardly directed angular momentum flux, similar to that produced by a viscosity.

E. Angular Momentum Transport by Spiral Shocks

Angular momentum transport by global spiral-shaped shock waves has been proposed by Donner (1979; see also Lynden-Bell 1974), Michel (1984), Sawada et al. (1986), and Spruit (1987). Shu (1970) suggested that in binaries such shocks could be generated by the impact of the mass-accumulation stream on the disk. Suppose that, at the outer edge of a disk, low-amplitude sound waves are generated. As these propagate inward, their energy density increases, as described above, and eventually they form shock waves. The

dissipation in these shocks limits the increase and at the same time transfers the negative angular momentum of the waves to the fluid, so that accretion can take place.

Numerical simulations of mass transfer in a Roche geometry by Sawada et al. (1986), Matsuda et al. (1987, 1990) showed that this process can lead to a steady (in a corotating frame) two-armed shock pattern, and a corresponding steady accretion. In the outer parts of disks formed in this way, rather strong shocks are maintained by tidal forces (at least if a sufficiently massive companion is present). As these waves propagate inward, their strength decreases. In the inner parts of the disks, the tidal effects are small, and the strength of the shocks is determined entirely by the balance between shock dissipation and the inward increase in energy density of the wave. The angular momentum transport in these inner regions is therefore *independent* of the strength of the wave excited at the outer edge (Spruit et al. 1987; Spruit 1989a, b). Low-amplitude waves amplify, high-amplitude waves dissipate, propagating inward until they reach the strength at which amplification and dissipation balance. Spruit (1987) described nonlinear solutions of the hydrodynamic equations that apply to this situation. The efficiency of the accretion process can be measured by comparing the radial drift speed with the standard α description for viscous disks.

The effective α of the process, in regions where there is a balance between amplification and dissipation of the shocks, is of the order $0.01(c_s/\Omega r)^{3/2}$, where c_s is the isothermal sound speed. This dependence was also derived by Larson (1989). It must be stressed that this “effective” viscosity does not imply a real viscous behavior but only measures the accretion rate. In particular, time-dependent processes in spiral-shocked disks may well be very different from those in viscous ones. The main importance of shock wave accretion lies in the fact that it provides a reliable means of angular momentum transport in non-self-gravitating disks in places that are far from the inner and outer edges of the disk. For a moderately “hot” protoplanetary disk ($r = 5$ AU, $T = 800$ K) one gets $\alpha = 5 \times 10^{-4}$, corresponding to an accretion time scale of 10^6 yr. Though this is not a very high value, we nevertheless see that spiral shock accretion could be relevant for angular momentum transport in the giant planet region of a protostellar disk. Figure 5 shows a numerical solution of a self-similar, spiral-shocked flow.

F. Planet-Generated Shock Waves

Embedded objects in disks (protoplanets, for example) are a plausible source of shock waves. The interaction of protoplanets with a disk has been considered by Lin and Papaloizou (1979b) and Goldreich and Tremaine (1980), both having assumed a linear response of the disk to the tidal force. These authors derived expressions for the tidal torque exerted on the disk, and showed that a protoplanet will in general (excepting the case of a very high disk viscosity) clear a gap between its orbit and the disk’s outer edge. The position of this edge is determined by a balance between the tidal forces which extract angular

Figure 5. Self similar spiral shocked flow. The image shows the density distribution (on a logarithmic scale).

momentum from the edge, and the outward diffusion of angular momentum by viscosity. When the viscosity is small, shocks form at the disk edge, invalidating the original assumption of linearity. These shocks have been studied in some detail by Lin and Papaloizou (1986*a*), though the viscosity used was so high that the shocks did not propagate very far into the disk. If we are interested in the angular momentum transport by shocks, and therefore neglect viscosity altogether, the problem of finding the edge of the disk becomes somewhat ill posed. Shocks at the edge of the disk extract angular momentum from it and return it to the orbit of the companion by gravitational interaction. In addition, Lindblad resonances (Goldreich and Tremaine 1980) between the disk and the companion extract angular momentum in a manner that is independent of viscosity (at low, but finite, viscosity). In the absence of an additional "spreading agent," such as viscosity, the disk would continue to shrink until the tidal forces became negligible. One may wonder if this behavior is consistent with the known behavior of disks in binaries. Observational information on the sizes of disks, compared with the orbits of companions is available for cataclysmic variables. The disks in these cases have radii of about 0.3 times the orbital separation, for systems with mass ratio of the order 0.1, in quiescence (Wood et al. 1986, 1989*a, b*; Zola 1988); during outburst the disks are slightly larger. At this size, the tidal forces

produce velocity variations at the edge that are of the order of the sound speed. If this is correct, it suggests that the main factor limiting the disk size is angular momentum extraction through shock waves at the outer edge. Only weak shocks would then propagate inward, and the scenario described for accretion by spiral shocks would give, for the protoplanetary case, the value $\sim 5 \times 10^{-4}$ quoted above. On the other hand, during their outbursts, the disks in cataclysmic variables (CV) definitely increase in size (see, e.g., Zola 1988) on a fairly short time scale. It is not clear at present whether this can result from tidally generated shocks alone; perhaps these observations indicate a truly "viscous" behavior.

Another estimate of the maximum size of a disk in the presence of a companion is that of Paczyński (1978*a*). He calculates the largest orbit that can fit inside a Roche lobe without intersecting other orbits. Orbits larger than this would be impossible because of the formation of strong shocks. The maximum sizes obtained are larger than the quiescent CV disks, but perhaps compatible with the disk sizes (Warner and O'Donoghue 1988; Horne and Cook 1985) at outburst. On the other hand, it is clear that this estimate is an upper limit, as shocks may form well before orbits intersect. This could happen as soon as the tidal perturbations are of the order of the sound speed.

Numerical simulations of disks in binaries should be useful in answering these questions. Current simulations (Schwarzenberg-Czerny and Różycka 1988; Sawada et al. 1986; Matsuda et al. 1987, 1990; Whitehurst 1988*a*; Hirose and Osaki 1990; Różycka and Spruit 1989) do address them, but the interpretation of the results is not entirely unambiguous. Hydrodynamical simulations without viscosity have been done for a gas with constant ratio of specific heats, ignoring radiation losses (Matsuda et al. 1990). Although these calculations start with fairly cool disks, the dissipation in the shocks quickly heats the gas up to a value near the virial temperature. The resulting disks are stationary only in a rather average sense, and do not have well-defined edges. The accretion time scale in these simulations is roughly inversely proportional to the companion mass. It remains to be seen how inviscid disks with more realistic low temperatures behave. Hydrodynamic simulations of a viscous disk have been done by Schwarzenberg-Czerny and Różycka (1988). Particle simulations of disks in binaries have been done by Whitehurst (1988*a*) and Osaki and Hirose (1990). The way in which particle interactions model the hydrodynamic forces in these simulations prevents one from assigning a sound speed to the calculations but it is believed that they represent a highly supersonic, viscous flow. The disks in these simulations are somewhat larger than the observed quiescent disks in CV's, probably as a result of the high effective viscosity.

G. One Armed Spirals, Eccentric Instability

Kato (1983, 1989) and Okazaki and Kato (1985) have pointed out the existence of a class of low-frequency one-armed spiral modes whose frequency (in an inertial frame) is proportional to the disk temperature. The fundamental mode

of oscillation is equivalent to a slow precession of an eccentric disk. In the limit of vanishing temperature (pressureless disk), a disk in this mode is a collection of nested elliptic Kepler orbits. These modes can become unstable in the presence of a companion. This instability so far has been studied in the zero-pressure limit by orbital mechanics methods (Piotrowski and Ziołkowski 1970; Paczyński 1977; Osaki 1989; Osaki and Hirose 1990). The instability is associated with the 3:1 resonance between a disk orbit and the orbit of the companion. For small companion mass, the range of unstable orbits near the resonance shrinks and the growth rate vanishes asymptotically (Hirose and Osaki 1990). Thus, though the instability is very important for cataclysmic variables (Whitehurst 1988a), it is not certain that it is very relevant for the protoplanetary case.

The global $m = 1$ modes studied by Kato can also be destabilized by self-gravity of the disk. Such instabilities have been described by Adams et al. (1989). An important ingredient in the instability mechanism is the motion of both the central object and the disk with respect to the common center of mass. They are discussed in more detail elsewhere in this book. The disk mass required for instability is roughly proportional to the stability parameter Q . ($M_D/M_{\text{tot}} \approx 0.24 Q$; Shu et al. 1990). For disk masses less than 0.24, $Q < 1$ is needed for instability. For $Q < 1$ the disk is also unstable to local self-gravitating instabilities discussed by Paczyński et al. and Carlberg (1988) (see above). For hot ($Q > 1$) massive ($M_D/M > 0.24$) disks the global instability would be important, but for cool ($Q < 1$) less massive disks the local self-gravitating instabilities would be more important.

IV. EVIDENCE FOR TRANSIENT HEATING EVENTS

A. Observational Evidence

Astronomical evidence for heating events exists (see, e.g., Gahm et al. 1989), but it is not clear whether these events are related to stellar or disk activity. We shall not discuss astronomical evidence here, instead we restrict ourselves to information derived from measurements in our solar system.

There are basically three types of evidence for short-term heating events, which are obtained from the study of meteorites. These are chondrules, Calcium-Aluminum-rich-Inclusions (CAIs) and oxygen isotope anomalies. A discussion of the energy problem associated with the chondrule observations is given by Levy (1988). Here we summarize major characteristics of chondrules relevant to understanding the role of rapid heating events in the protosolar nebula.

1. Chondrules are spherical molten droplets. They have a narrow size distribution—typically of the order of a millimeter with masses of the order of a milligram.
2. Chondrules make up a significant fraction of the total mass of all primitive meteorites. Whilst they are a negligible component in the CI meteorites,

they can account for up to 80% by mass in other chondrites. The rest of the meteorite consists of fine-grained (micron to sub-micron-sized) matrix material. In some primitive meteorites another class of objects is found, the so-called "Calcium-Aluminum-rich Inclusions" (CAIs), which we discuss separately later.

3. Chondrules are clearly a nebular product. This is underscored by age determinations and their chemical and textural properties.
4. Dynamical crystallization experiments show that the cooling times of these chondrules are of the order of hours or less (Hewins 1991).
5. By implication, the time scale for heating the prechondrular dust accumulations was shorter, it could have been of the order minutes or seconds; however, this is not clear at present. During the heating events there appears to have been a "stalling" of the temperature at ~ 1800 K. This is inferred from the chemical composition, although it is probably fair to say that this evidence is not conclusive and still subject to debate.
6. The energy requirement for raising the temperature of a chondrule to ~ 1800 K and then melting the material (silicates, e.g., spinel, mellilite, olivine) is $\sim 2000 \text{ J g}^{-1}$. This translates into a time integrated heat flux of at least 400 J cm^{-2} . Losses of heat by radiation and by evaporation increases this value and has consequences for the duration of the heating event.
7. Chondrules are often surrounded by an "accretion mantle" of fine grained material. This mantle was accumulated in the time between formation and incorporation into the parent body.

Additional evidence of rapid nebular heating events seen in CAIs can be summarized as follows:

1. CAIs are aggregates of refractory-rich material, with sizes reaching the centimeter range.
2. In the Allende meteorite (a type CV3 carbonaceous chondrite) they account for about 5% by mass.
3. The cooling times for whole CAIs, as inferred from dynamic crystallisation experiments, are of the order days (cooling rates are 0.5 to 50 K hr^{-1}). These time scales are similar to nebular thermal-convection time scales, so that these objects could be produced in the inner (hot) portions of an accretion disk and then become convectively transported out into cooler regions (Morfill 1983).
4. Practically all CAIs have rims, which have the characteristics of being molten during some intense heating event. The rims are micron-sized; the total mass of a rim is typically about a milligram. High-temperature rims have been reported around chondrules as well (Kring 1991a).
5. Heat conduction and radiative loss considerations give the result that the rim-producing heating events are not longer than a few seconds and subsequent cooling times are also very short.

6. The minimum energy needed to make rims is about 300 J cm^{-2} . The previous statements about cooling and evaporation losses apply here as well, of course.

The evidence from isotopic anomalies is more indirect, but potentially important. During evaporation and condensation, which is a natural consequence of the heating events discussed here, mass dependent fractionation is to be expected purely from, e.g., Rayleigh distillation (see, e.g., Morfill and Clayton 1986*a, b*). In addition, it was shown by Thiemens and Heidenreich (1983) that, in the presence of strong radiation fields, non-mass-dependent oxygen isotope fractionation may be produced. The full physics and chemistry for this effect is not completely understood but seems to be related to the formation of ozone (O_3). Isotopic anomalies of these types are observed in CAI's (see e.g. the reviews by Begemann 1980 and Clayton et al. 1985) and could be further evidence of short-term intense heating events. However, a great deal more experimental and theoretical work is required in order to make this a quantitative connection.

The evidence for short-duration intense heating events is overwhelming. Furthermore, quantitatively it appears as if practically every CAI was exposed to such an event at least once, and a sizeable fraction of chondrule precursor material had the same fate. Based on this observational input, we can estimate the efficiency with which the available energy—basically the gravitational energy of the disk in the field of the central PMS star (or protostar)—is channeled into this particular form of dissipation (see also Levy 1988).

B. Energetics and Frequency of Short-Term Heating Events

Energetically it is immediately obvious that short-term heating events also have to be localized. Let us assume then that these events, irrespective of their possible physical origin, are cylindrical in shape, with radius R and length d . Let us further assume that these events are localized in an "activity zone" in the disk at the radius r , from the center and occupy an annulus of size Δr . The probability that a given dust grain should encounter one of these "events" while it traverses this activity zone is then given by

$$P = \frac{v_\phi}{v_r} \frac{\Delta r}{\lambda} \quad (7)$$

where v_ϕ is essentially the Kepler velocity and

$$\lambda \equiv \frac{1}{N2Rd} \quad (8)$$

is the "mean free path" between encounters of "heating events." The density of these localized hot gas regions in the disk is

$$N = \dot{N}_{tL}/V \quad (9)$$

where \dot{N} is their production rate (s^{-1}), t_L their lifetime and V the portion of the disk volume where these events occur ($V = 2\pi r \Delta r h$, with h the disk thickness).

The lifetime of such events is determined by the cooling of the hot gas (initially at temperature T_H). This in turn is determined by the adiabatic expansion, and is approximately

$$t_L = \frac{R}{c_s(T)} \left[\left(\frac{T_H}{T_M} \right)^{1/2(\gamma-1)} - 1 \right] \quad (10)$$

where c_s is the sound speed in the cold (temperature T) external disk gas and $T_M \approx 1800$ K is the temperature below which melting essentially stops. γ is the adiabatic index of the gas. The production rate of hot gas regions can be estimated from energy arguments. It is equal to \dot{E}/E_H , the total rate of energy release of the disk in the activity zone, divided by the thermal energy content of a single hot region; $E_H = \pi R^2 d \frac{3}{2} k T_H n_H$. There has to be an efficiency factor η for converting energy into this nonlinear localized hot phase, so that

$$\dot{E} \equiv \eta \frac{GM}{2r^2} v_r \rho V. \quad (11)$$

Substituting all these expressions in Eq. 8 yields finally

$$P = \frac{\eta}{\pi} \left[\frac{v_\phi}{c_s(T)} \right]^3 \left(\frac{\Delta r}{r} \right) \frac{T}{T_H} \left(\frac{T_H}{T_M} \right)^{1/(\gamma-1)} \quad (12)$$

where we have made use of the fact that $T_H \gg T_M$. Note that this expression is independent of all "hot spot" parameters with the exception of the initial temperature of the gas T_H . All parameters entering this expression are therefore determined quite well. Putting $\Delta r/r \equiv 0.5$, $v_\phi/c_s = 10$, $T_H/T_M = 100$ and $T_M/T = 3$, i.e., an ambient disk temperature of 600 K, yields

$$P \approx 500 \eta. \quad (13)$$

The meteorite data suggest that the probability of an encounter with a localized rapid heating event is $0.3 \leq P \leq 1$. This implies that the efficiency η with which the available energy dissipation is converted into such events, has to be of the order 0.1 to 1%. This is a high efficiency considering the nonlinear and strongly inhomogeneous nature such processes must possess.

V. DISK ELECTROSTATIC DISCHARGES

A. Charge Production and Separation

In terrestrial thunderclouds lightning is a surprisingly efficient process, in which between 1 and 10% of the kinetic energy of the cloud convective motion

is released. In addition, lightning discharges have all the short duration, localized (etc.) characteristics required by the meteorite observations, hence the speculation, first voiced by Whipple 1966, that electrostatic discharges may be responsible for the production of chondrules, should be investigated seriously. (For comprehensive reading about terrestrial lightning, the reader is referred to a special issue of the *Journal of Geophys. Res.*, Vol. 94, 1989.)

The problem of generating electrostatic discharges in atmospheres can be subdivided into three parts:

1. Generating charges.
2. Separating charges and building up a large-scale electric field.
3. Maintaining a sufficiently low conductivity so that eventually the breakdown potential is obtained.

At some stage there will be a local breakdown somewhere; electrons will be accelerated over one mean free path to energies above the ionization potential, there will be further collisional ionization leading to an avalanche. In the case of H_2 gas, there are additional losses not only due to ionization, but also due to excitation, charge exchange and dissociation. As shown by Cravens et al. (1975), the required energy to which the electrons need to be accelerated (before colliding with the molecules) is ~ 60 eV—otherwise the efficiency of the collisional ionization is too low and the cascade may simply fizzle out.

Figure 6. Illustration of the collisional Lenard effect.

In order that the condition holds that a great deal of charge be separated to build up a sufficiently strong electric field, while at the same time not having the charges so mobile to short circuit the system, it is clear that the charge has to be concentrated on slowly moving dust grains and not on highly mobile ions and electrons. In thunderclouds this role is played by water droplets and/or hail.

There are three major processes that have been discussed in the literature as being relevant for terrestrial lightning. These processes presumably also play a role in Venusian lightning and Jovian lightning—we see no reason, in principle, why these processes should not be expected to operate in protoplanetary disks. The first is the Lenard effect (1904), and is illustrated in Fig. 6. It is found that when a water drop breaks up, the large main residue carries a positive charge whereas the fine spray that has been shed carries a corresponding amount of negative charge. This process has been tested in the laboratory for different conditions such as break-up (ablation) due to drag forces, break-up due to collisions and electrostatic disruption (see Richards and Dawson 1971; Crabb and Latham 1974; Taylor 1964; Latham and Myers 1970).

Figure 7. Illustration of the Findeisen effect.

The second process is the Findeisen effect (1943), illustrated in Fig. 7. This is associated with the freezing of water drops. Initially, a thin surface ice layer forms when a water drop is cooled below the freezing point. Subsequently, as freezing continues, the interior also turns to ice and expands (because the density of ice is less than that of water). This leads to cracking of the surface layer and flaking off of little “chips.” As in the previous case,

the large particle is found to carry a positive charge and the small "chips" a corresponding negative charge.

There is no mention in the available literature whether, for instance, collisional break-up of conglomerate grains also leads to charge production, but based on the above evidence this seems likely. Some experimental work is clearly required here.

The third process is the Elster-Geitel effect (1885), which is illustrated in Fig. 8. This process enhances the charge separation, once it has started, in the following way: consider charge separation by gravitational sedimentation. Large grains sediment faster than small grains because the gas drag, which slows the descent, is proportional to the particle's cross section, whereas gravity acts on its mass. From the previous discussion this naturally produces a large-scale charge separation and the associated electric field. Large dust grains exposed to this electric field will become polarized, the resultant charge distribution is as shown in Fig. 8, with a preponderance of negative charges on the downward-facing side. As these polarized particles sediment, they may overtake and collide with smaller grains. If the collision is elastic, charge transfer during contact may then leave an enhanced charge difference between large and small grains. This electrical induction process can produce large charge separations. It has been found that in an electric field of 1 volt per meter charge separation of 10^5 to 10^6 electron charges per cubic centimeter can be obtained in this way.

If the collision results in coagulation, no net charge separation occurs. On the other hand, if the collision is disruptive, the previously discussed effects will even be enhanced because of the existence of negative surface charges at the impact site.

For the protoplanetary disk there appears to be no problem in generating charges on grains by essentially the same processes that play a role in the terrestrial atmosphere. We must qualify this statement by the constraint that this applies particularly well to the ice transition zone, where central portions of the disk are hotter than the melting (or sublimation) temperature of ice (~ 150 K at the ambient pressures) and the regions closer to the surface are cooler. Ice is of course a major constituent and disk models show that the transition zone is quite large, $\Delta r/r \approx 0.5$ (see, e.g., Morfill 1988). It would be interesting to test the charge generation mechanisms discussed above for other abundant constituents of cosmic dust particles and other gas pressures, to see whether charging might be possible throughout the protoplanetary disk. Here again is a need for experimental effort.

We have seen that the charge production processes on grains automatically lead to charge separation by vertical or radial size sorting. Hence the most obvious charge separation process to be considered for protoplanetary disks is essentially the same as in terrestrial lightning: precipitation. There is a difference, however. In terrestrial lightning we can basically consider a constant gravitational acceleration g and a constant gas density, everything happening in the vertical (z) direction. (This is not true for convective up-

Figure 8. Illustration of the Elster-Geitel effect. This inductive process is able to enhance considerably the charge density—all charges residing on dust particles.

welling, of course, but our meaning will become obvious soon.)

In a protoplanetary disk, particulate material sediments vertically (in the z direction) toward the disk midplane; the gravitational acceleration, almost exclusively due to the mass of the central PMS star (or protostar), is given by

$$g = -\frac{GM}{r^3}z. \quad (14)$$

In other words g is strongly z -dependent, vanishing as z becomes small. The gas density also varies with z .

In addition, there is a radial size sorting due to the effect of gas drag on the particles. For the small grains we consider here, the radial drift increases with particle size, in other words, the positively charged large grains move towards the inner parts of the disk faster than the negatively charged small grains.

These two effects combine to give a charge-separation electric field which has a vertical (z) component and a radial (r) component. Thus, even in the presence of efficient vertical mixing, e.g., by strong turbulence, a net radial charge separation and associated electric field would be present in any case.

A steady-state electrical field strength can be calculated by considering current continuity. Although the radial electric field may be stronger than the vertical component, we illustrate the calculations by the latter in this chapter. A full discussion is given elsewhere.

We consider the general case of free electrons, positive and negative ions, small charged “dust” grains (index S) and large charged “dust” grains (or ice particles, index L) based on the preceding discussions. Free charges

are produced by cosmic-ray interactions or radioactive decay. The equation governing the current continuity is

$$n_L Q_L e \tau_{fL} \left[\Omega^2 z - \frac{e E Q_L}{m_L} \right] = n_S Q_S e \tau_{fS} \left[\Omega^2 z + \frac{e E Q_S}{m_S} \right] + \frac{n_e e^2 E}{m_e \nu_{eo}} + \frac{n_- e^2 E}{M_- \nu_{-o}} - \frac{n_+ e^2 E}{m_+ \nu_{+o}}. \quad (15)$$

The term on the left-hand side of Eq. (16) is the current due to large positively charged dust grains, the four terms on the right are the current due to small negatively charged dust particles, electrons, negative ions and positive ions, respectively. The number densities of the various species are denoted n and the masses are m with the appropriate subscripts added. The resulting electric field is E , the ions are assumed to be singly charged, the dust grains carry charges Q_L and Q_S in units of the electron charge, e , respectively. The conductivity of the free charge species is dominated by collisions with the neutral gas particles, collision frequency is ν , again with appropriate subscripts. Finally, the mobility of the dust grains depends on the frictional coupling to the gas—the appropriate time scales are denoted τ_{fL} and τ_{fS} , respectively. The quantity Ω is the angular Kepler frequency.

In order to build up an electric field of sufficient strength so that breakdown may occur, the conductivity of the medium has to be sufficiently small, because large-scale electric fields cannot be maintained otherwise. In practice this means that the dust grains have to be the dominant charge carriers. From Eq. (16) we can then derive the requirements for the free charge densities of ions and electrons. Based on the production mechanisms (cosmic rays, radioactivity), the speed of ion-molecule reactions and on the recombination processes (gas phase and dust surface recombination) we can then estimate requirements on the disk properties, such as gas density and surface density. We will not discuss such details here, however.

We see from Eq. (16) that the equilibrium solution for the electric field E depends on radial distance (through Ω) and on the vertical distance z . The vertical electric field goes to zero, of course, when z goes to zero—i.e., in the disk midplane, the radial electric field does not. Note that here we are only discussing the average field, not the fluctuating component introduced by, e.g., turbulence or compressive waves. For a discussion of the latter see Pilipp et al. (1992).

We may summarize our results in the following way:

1. For a height z above the midplane, which is between 0.1 and 1 of the disk scale height H , the required electric field strengths of about 1% of the breakdown value can be obtained.
2. This requires two particle populations.
3. Nonlinear charging processes must operate to produce surface potentials on the larger dust (or ice) grains of the order 1 volt.

4. Free charge must be negligible. This may mean significant shielding of even minimum ionizing cosmic rays, i.e., disk surface density in excess of 100 g cm^{-2} . Other nonthermal ionization sources—e.g., from the decay of radioactive nuclides—must also produce negligibly small amounts of free electric charge.

In order to get a breakdown in the gas which carries sufficient power, enough current must flow through the discharge channel. One way of achieving this is that the discharge connects two reservoirs of mobile charges located at different potentials. (Note, however, that on Earth, cloud to cloud lightning occurs as frequently as ground lightning without there being an obvious reservoir of mobile charges.) Clearly there is a surface layer of the disk, being irradiated by cosmic rays, ultraviolet photons, etc. which is such a reservoir. A second reservoir can be obtained in the vicinity of the disk midplane where the dust material (e.g., ices) sublimates and in this way “frees” the dust charges in the form of molecular ions. Thus we envisage breakdown to occur perhaps preferentially, but not exclusively, between these two reservoirs, and expect a tendency for this process to cluster around major sublimation zones of abundant chemical components, particularly ice.

Another requirement is the availability of sufficient energy. This increases with decreasing distance from the central protostar—the implication is that electrostatic discharges should be less frequent in the outer regions of the protoplanetary disk. An interesting consequence is that comets, if they formed sufficiently far outside should not exhibit signs of flash heating—provided electrostatic discharges are responsible for these signatures. On the other hand, if comets formed in the inner solar system and were then scattered out by proto-Jupiter, they might well have sampled major condensation zones and their component particles might therefore show signs of flash heating by electrostatic discharges.

It is widely believed that Jupiter was located at the “ice zone” when it formed (at around 150 K). The evidence comes from disk models as well as planet and satellite composition measurements (see, e.g., Morfill 1985; Stevenson and Lunine 1988).

B. Heating of Dust Grains in the Discharge Channel

Assuming that the energetics and the processes discussed earlier conspire to produce electrostatic discharges, it is then reasonable to ask the question: how does this affect dust grains in the discharge channel and can we reproduce the observed signatures?

We mentioned earlier that a minimum of $300 \text{ to } 400 \text{ J cm}^{-2}$ are required for the time-integrated heat flux. Including losses, e.g., by radiation from the heated grains, latent heat of vaporization, kinetic energy taken away by the evaporated parts of the embedded dust particle, etc., the energy flux has to be raised considerably.

The full physics of dust in a discharge channel is too involved to describe

here. It will be discussed elsewhere. Here it is sufficient to mention some of the stages of development. These are, in terms of increasing time scales: charging of the dust to a negative potential in the hot discharge plasma, heating of dust particles by ion and electron impacts taking account of the effective cross section for each species, electron-ion thermalization, associated change in the grain potential and effective cross section, expansion of the discharge channel, adiabatic cooling, recombination of the plasma in the gas phase, collisional ionization, heating of dust by impact of neutrals as well as ions and electrons, radiative loss, latent heat effects, losses by evaporation, etc.

One of the key results is that the time integrated energy flux turns out to be a constant at around 10^4 J cm^{-2} . Without going into all the details of a full calculation, which leads to this result, we can describe an approximate approach, which illustrates the physics quite well.

The energy flux onto a grain due to collisions with plasma particles of type i is

$$F = \sum_i n_i A_i c_i E_i \quad (16)$$

where n_i is the plasma density, A_i the cross section, c_i the velocity of the particles and E_i their energy at impact. Because of Coulomb effects, the cross sections of different species will be different, too. Integrated over the duration of the heat pulse and normalized to the grain cross section πa^2 , the energy deposition per cm^2 per heat pulse is

$$E_a = \frac{1}{\pi a^2} \int F dt. \quad (17)$$

The discharge channel is assumed to be fully ionized, with initially (after thermalization of electrons and ions) a plasma temperature of about 30 eV. In such a plasma, a dust grain gets charged to a potential $e\phi \approx -2.5kT$. The cross section for ion bombardment is enhanced by the Coulomb forces to a value

$$A = \pi a^2 (1 + e|\phi|/kT) \quad (18)$$

and the energy of the plasma ions, when hitting the dust grains is $|\phi|$, because they are accelerated in the electrostatic field of the grain.

Utilizing our earlier model of an expanding channel, we may write Eq. (17) as

$$E_a = \frac{e|\phi|}{kT_i} \left(1 + \frac{e|\phi|}{kT_i} \right) \int n_i c_i \frac{3}{2} kT_i dt \quad (19)$$

where we only need consider heating by ion impacts. With respect to the initial channel radius R_o , and an initial temperature $T_H (\approx 30 \text{ eV})$ we then get on changing $dt = dR/c_s$, with c_s the sound speed in the unperturbed disk:

$$E_a = 13.1 n c_H k T_H \frac{R_o}{c_s} \int_1^{x_M} \left(\frac{1}{x} \right)^2 \cdot \left(\frac{1}{x} \right)^{3(\gamma-1)} dx. \quad (20)$$

We have defined $x \equiv R/R_o$ and

$$X_M \equiv \left(\frac{T_H}{T_M} \right)^{1/2(\gamma-1)}. \quad (21)$$

The solution is:

$$E_a = 4.38 n c_H k T_H \frac{R_o}{c_s}. \quad (22)$$

For a discharge to take place, collisional ionization must be possible, which means that $T_H \approx 30$ eV. It cannot be much lower than this value, nor should it be much higher.

The size of the discharge channel should be proportional to the mean free path of the electrons in the gas; this means $R_o \sim 1/n$. Scaling this relationship with lightning in the Earth's atmosphere, and correcting for the cross sections (H_2 as opposed to N_2 and O_2) yields

$$E_a = 4.5 \times 10^3 \frac{c_H}{c_s} T_H. \quad (23)$$

We have used the observed thickness of lightning channels of ~ 1 mm in the terrestrial atmosphere with a density of $2 \times 10^{19} \text{ cm}^{-3}$ for scaling. This yields finally

$$E_a = 5.36 \times 10^3 \frac{T_{30}^{3/2}}{T_{300}^{1/2}} \text{ J cm}^{-2}. \quad (24)$$

T_{30} is the temperature corresponding to 30 eV and T_{300} is the ambient disk temperature taken to be 300 K for this quantitative example. The greatest uncertainty in Eq. (24) is the scaling relation used from terrestrial lightning.

The interesting consequence of Eq. (24) is that the result does not depend on the local gas density, only on the temperature (this controls the channel expansion). In hotter regions of the disk, the energy available per cm^2 is less than in cooler regions of the disk. This may be significant in the context of rim formation for CAIs, which is conjectured to occur in the hot inner portions of the disk, as compared to chondrule formation, which is thought to occur in the ice transition zone at greater radial distances.

The time scale for the heat pulse imparted to the grain depends inversely on the gas density. In the Earth's atmosphere it is of the order milliseconds, in the protosolar nebula at a representative gas density of 10^{14} cm^{-3} it is of the order 10 to 100 s. The integrated heat flux is the same, however.

From these considerations and the quantitative estimates associated with them it appears plausible that chondrules may be an observable consequence of nebular lightning. At the same time, it seems acceptable that the rims found on CAI's could also be formed by such a process, albeit at a different location—further in towards the protostar—than the chondrules. The density increases with decreasing distance, which in turn implies that the duration of

the heat pulse decreases. The CAI rims seem to have been produced by a more rapid heat flash than that required for the chondrules.

VI. DISK-CORONAL MAGNETIC FLARES

A. Magnetic Fields in the Protosolar Nebula

Many cosmical systems have magnetic fields that are strong enough to influence evolutionary and dynamical processes. These magnetic influences arise because a magnetic field exerts force on the gas within which it is embedded, through the Lorentz force:

$$\mathbf{F}_L = \frac{1}{c} \mathbf{j} \times \mathbf{B} = \frac{1}{4\pi} (\nabla \times \mathbf{B}) \times \mathbf{B}. \quad (25)$$

Generally speaking, the Lorentz stress has two main effects that are of interest in understanding the behavior and evolution of protoplanetary disks. Because the Lorentz force can exert strong torques and therefore efficiently transmit angular momentum, magnetic stresses can play an important role in the evolution and radial accretion of disks. In addition, magnetic fields distorted away from their equilibrium geometries can store large amounts of energy, which are sometimes released in rapid explosions or flares. Such explosive energy releases are observed to occur in magnetized bodies in the solar system: solar flares and geomagnetic storms are among the most familiar of these manifestations; magnetic flaring is thought to be responsible for observed outbursts also in many distant astrophysical systems.

The empirical evidence for strong magnetic fields in the protosolar nebula is found in primitive meteorites (for reviews, see Levy and Sonett [1978] and Cisowski and Hood [1991], as well as references therein). Remnant magnetism (frequently called "remanence") is found in a wide variety of meteorites, spanning the different meteorite chemical classes as well as the varying degrees of meteorite metamorphism. For the present discussion, the most primitive meteorites—the carbonaceous chondrites—are most pertinent. While other classes of evolved meteorites have been altered by a variety of metamorphic processes on parent bodies, and in some cases may record parent-body magnetic fields, the carbonaceous chondrites appear to be relatively unevolved products of nebular accretion, and their remanence probably records nebular magnetic fields. The remanence of carbonaceous chondrites is very complicated, occurring in the rock at a variety of strengths over a variety of spatial scales. Although significant ambiguities and uncertainties remain in the interpretation of carbonaceous chondrites, some characteristics seem to emerge from the data. Generally speaking, the inferred magnetizing-field intensities are higher for the smaller rock components than for large pieces of the rock. Inferred magnetizing intensities for whole-rock pieces typically range from a tenth of a Gauss to approximately a Gauss. Inferred magnetizing intensities for small components have ranged as high as a few Gauss,

and in isolated cases to as much as ten Gauss or higher, though questions remain about the reliability of the very highest of these intensities, owing to the possibility of magnetic contamination of the samples.

The magnetizing-field intensities inferred from measured meteorite remanence are “model” intensities, the interpretation of which still involves several uncertainties. Most of our understanding of rock magnetism is derived from the much larger body of experience measuring and interpreting paleomagnetic intensities of terrestrial rocks. First, detailed differences between terrestrial rocks and meteorites remain to be fully studied and understood, especially with respect to the physical processes by which meteorites acquired their remanence, whether through thermal, physical, or chemical changes in the presence of magnetic fields. Second, it is important to realize that the remanence does not record the actual magnetic field at some point in space at some time. Rather, what is recorded is the magnetic field in the frame of the magnetized rock, averaged over a time period as long as the time scale of remanence acquisition. Thus, for example, a rotating object acquiring its magnetization over a time scale longer than the rotation period will record only the static component of the magnetic field in the rotating frame, that is to say the projection of the ambient magnetic field along the axis of rotation. Similar considerations apply to the fact that meteorites may accumulate and acquire their magnetization over periods of time longer than the orbit period and even over periods of time comparable to or longer than the oscillation periods of magnetic dynamo modes. These considerations suggest that the most reliable indicators of actual nebular magnetic field strengths should be the highest of the inferred magnetizing fields recorded in the smallest objects, if, of course, both the measurements and the assumed relationship between recorded remanence and magnetizing-field intensity are reliable, and assuming that the magnetizing fields were of nebular origin. Altogether then, leaving aside the most extreme of the inferred magnetizing fields, the meteorite remanence record suggests the presence of magnetizing fields as intense as a few Gauss existing in the nebula at a distance of several AU from the center, at least episodically.

B. The Influence of Magnetic Stresses

The possibility of nebular magnetic fields with intensities falling in the range of a tenth of a Gauss to a few (and possibly, though the evidence is weak only suggestive, ten or more) Gauss (Cisowski and Hood 1991) is very provocative in terms of disk characteristics and disk evolution. This can easily be seen by considering the rate of angular momentum transport induced by such a magnetic field. Consider the angular momentum \mathcal{L} contained in an annulus in Keplerian motion and having radius R , width ΔR , thickness $2h$, and density ρ :

$$\mathcal{L} \sim 4\pi \Delta R h \rho \sqrt{GMR^3}. \quad (26)$$

A magnetic field having toroidal and poloidal intensities B_ϕ and B_p , respec-

tively will exert a torque \mathcal{T} on the annulus given by

$$\mathcal{T} \sim \langle B_\phi B_p \rangle R^2 h. \quad (27)$$

Combining Eqs. (26) and (27), the time scale τ for angular momentum transport is

$$\tau \sim \frac{\mathcal{L}}{\mathcal{T}} \sim \frac{4\pi \Delta R \rho}{\langle B_\phi B_p \rangle} \sqrt{\frac{GM}{R}}. \quad (28)$$

Taking $\rho \sim 10^{-9} \text{ g s}^{-1}$, $R \sim 3 \text{ AU}$, $\Delta R \sim 1 \text{ AU}$, and $M \sim M_\odot$, we find $\tau \sim 10^4 \langle B_\phi B_p \rangle \text{ yr}$. Thus for $\langle B_\phi B_p \rangle^{1/2}$ ranging from a nominal value of about 0.1 Gauss to the limit of plausibility in the vicinity of 10 Gauss, we find τ in the range 10^6 yr to 10^2 yr . Thus the magnetic-torque-induced angular momentum transport times associated with nebular magnetic field strengths inferred from meteorite remanence correspond with the time scales thought to typify protostellar-nebula evolution. Moreover, these magnetic field strengths fall in the range that could plausibly be produced by a dynamo generation process acting in such a nebula (Levy 1978; Levy and Sonett 1978; Levy et al. 1991; Stepinski and Levy 1990).

Now consider the effect of the magnetic pressure. For a nebula with gas density $\sim 10^{-9} \text{ g cm}^{-3}$ and temperature $\sim 300 \text{ K}$, the pressure is about 10 dynes cm^{-2} . In comparison, a five-Gauss magnetic field—near upper end of plausibility for the protosolar nebula—exerts a magnetic pressure of about one dyne cm^{-2} , some 10% of the gas pressure; even a one Gauss magnetic field exerts a pressure approaching 1% of the gas pressure.

Because of the magnetic pressure, a magnetic field tends to induce buoyancy in the gas through which it threads. The origin of this buoyancy is easy to see. For simplicity, imagine a uniform magnetic field of intensity B confined within a straight cylinder, and suppose that both the interior of the cylinder and the surrounding space is filled with an ideal gas having temperature T and exterior number density n_o . Then pressure balance between the interior of the cylinder and the surrounding gas requires that

$$n_o kT = n_i kT + \frac{B^2}{8\pi} \quad (29)$$

where n_i is the number density of the gas within the cylinder. Obviously, from Eq. (29) $n_o > n_i$. By virtue of the lower gas density within, the magnetized cylinder is buoyant in a gravitational field, and, all things being equal, it will rise. Of course, the real situation is more complicated than this simple analysis. The buoyant magnetized gas might be produced in a stratified equilibrium, which can be unstable to breaking up in a kind of magnetically driven Rayleigh-Taylor instability, which has been analyzed in a number of different contexts (see, e.g., Parker 1955, 1966, 1979; Galeev et al. 1979b). This buoyancy is a manifestation of a more general physical property of magnetic fields. It can be seen from a generalized virial theorem (Parker 1954)

that a magnetic field always produces net expansive stress in a system, which, in equilibrium, must be confined by other stresses; in cosmical systems, the confining stress is normally gravity. Because the force of gravity acting on a magnetic field itself is negligible, a gravitating system, partially supported by magnetic stress, can always lower its overall energy by releasing the magnetic field and contracting. Generally speaking, unless thermal effects produce a significant adverse temperature contrast that can negate the buoyancy of the magnetic field (Vainshtein and Levy 1991), we expect that the magnetic flux will bubble buoyantly out of the disk. The strongly magnetized solar corona is one of the most familiar and best studied manifestations of a magnetic field's propensity to bubble out of gravitating systems.

Before passing on to the main topic of this section, it is appropriate to consider briefly the magnetic field's coupling to the nebular gas. Indeed, this is among the most significant and puzzling questions in understanding possible magnetohydrodynamic and plasma effects associated with protoplanetary disks. The primary question involved here is the ionization level (and the resulting electrical conductivity) of the gas. There are several principal sources of ionization in such a nebula: thermal ionization, cosmic-ray ionization, and ionization produced by nonthermal processes intrinsic to the disk gas. In the inner parts of the disk, where the temperature exceeds about 10^3 K, thermal ionization dominates and the magnetic field is inevitably closely coupled to the gas. Farther from the center, however, well beyond an astronomical unit, the temperature is normally so low that thermal ionization plays no significant role. In these regions, both cosmic rays and live radioactive nuclides can, at least in principle, produce enough ionization to couple the gas and the magnetic field (Consolmagno and Jokipii 1978; Levy 1978; Levy et al. 1991; Umebayashi and Nakano 1988). Briefly, two physical questions need to be considered. First it is necessary that the electrical conductivity be sufficiently high that the time scale for Joule dissipation be longer than the time scales characteristic of the fluid motion; this is a purely kinematical constraint, and is necessary in order for any magnetic field to be coupled to the fluid. Second, it is necessary that the time scale for the ions to drift a significant distance through the neutral gas—driven by the magnetic field stress, a phenomenon frequently referred to as ambipolar diffusion—is not shorter than the fluid's relevant dynamical time scales. This latter constraint is a dynamical one, in that it depends on the strength of the magnetic field. Generally speaking, disk magnetic fields of the order of a Gauss in intensity, and consistent with the meteorite paleomagnetic record, seem not be ruled out by either the electrical-conductivity or the ambipolar-diffusion constraints (Levy et al. 1991); however, pinning down the electrical conductivity of protostellar nebulae, as a function of space and time, remains a pressing challenge to understanding the physical processes in these systems.

C. Coronal Flares

If strong magnetic fields occur in protostellar disks—as seems to be indicated

by the meteorite remanence—then it is likely that the disks have magnetized coronae in the tenuous regions above their midplanes. Experience with similar systems suggests that such coronae are likely to be the sites of explosive magnetic flaring. Flares of this kind occur when the magnetic field connects two highly electrically conducting regions of space, in one of which (the fluid body, say) the motion of field is controlled by the fluid, while in the other (the “corona”) the field itself provides the dominating force and controls the fluid motion. If the corona were vacuum, then the magnetic field there would be a potential field, completely determined by the boundary conditions imposed on the surrounding surfaces. As the magnetic field in the fluid body was dragged around by the fluid motion, this boundary magnetic field would change, producing a changing magnetic structure in the corona. The coronal field structure would evolve rapidly, always adopting the unique vacuum structure consistent with the boundary conditions, which structure is also the lowest energy state of the field consistent with the boundary conditions. Changes in the field structure would propagate through the corona at the speed of light.

Now consider the situation when the corona is not vacuum, but rather is filled with tenuous, electrically conducting gas; two differences result in this case. First, changes in the magnetic structure no longer propagate from the boundary at the speed of light; rather they propagate at the Alfvén speed. But more importantly, the coronal magnetic field is no longer able freely to assume a vacuum, potential-field structure in response to changing conditions on the boundary. Under these conditions, the magnetic field lines can be regarded as continuous and ponderable, and as maintaining their topological structures under distortion. Because of this, the field lines cannot freely pass through one another and the coronal magnetic field is prevented from rearranging itself into a potential-field structure matching the boundary conditions imposed from the fluid body below. As a consequence, the magnetic field lines become tangled and distorted away from equilibrium, and the resulting magnetic-field structure stores large amounts of energy in its highly disequilibrated state.

In a protostellar disk, the coronal magnetic field will become distorted both by the radially shearing motions associated with the nearly Keplerian overall motion of the disk as well as by the convective and turbulent movement of the gas within the disk. Inasmuch as flaring release of energy associated with rapid relaxation of distorted magnetic structures seems to be a common manifestation in cosmical systems, it is instructive to explore the possibilities in a protostellar disk.

A variety of specific mechanisms have been explored to account for magnetic flares (see, e.g., the review and references in Spicer et al. 1986), and much remains to be understood about the details. For the purpose of this discussion, we will focus on the possibility of rapid magnetic reconnection as a flare mechanism; this will capture the essential physics of the process and illustrate the magnitudes of energies that can be released. For specificity, consider the classical magnetic reconnection geometry sketched in Fig. 9. Regions of oppositely directed magnetic field are separated by a “neutral

layer." The magnetic field collapses from the sides (in this diagram) toward the neutral layer; magnetic energy is converted and escapes from the system, largely in the form of fast, hot plasma and energetic particles. The energy flowing into the system is largely the energy of the magnetic field, $B^2/8\pi$ erg cm^{-3} . If u is the "merging" speed of the inflow, and if L is the characteristic transverse scale of the system, then the overall rate of energy release is

$$\dot{E} \sim uL^2 \frac{B^2}{8\pi} \text{ erg s}^{-1}. \quad (30)$$

Observations of energy release rates in solar system objects (such as the solar corona and the terrestrial magnetosphere) indicate that the magnetic merging speed u must be of the order of a tenth to several tenths of the Alfvén speed, $B/\sqrt{4\pi\rho}$. Theoretical analyses (Petschek 1964; Sonnerup 1970; Yeh and Axford 1970; Yeh 1976) indicated that such high rates of energy release may occur as the magnetic tension in the reconnected field lines ejects gas from the central layer, allowing rapid collapse of the surrounding magnetic field and gas, though the physical details remain obscure.

Figure 9. Idealized sketch of a magnetic field line reconnection region. Magnetically driven gas flow (heavy vertical arrows), in from the sides, carries the magnetic field lines (light lines). Magnetic reconnection in the central region relieves topological constraints on the field's structure and the resulting relaxation of the stressed magnetic structure releases stored magnetic energy in the ejected fluid (heavy horizontal arrows). The energy conversion essentially takes place in the magnetic reconnection region bounded by the medium-weight lines in the figure.

Here we are concerned with two properties of such magnetic flares: the energy *flux* emerging from the flare and the total energy emitted in a typical event. Using a simple model for reconnection flares (Petschek 1964), which, while it is not likely to represent an exact model for real flares, probably captures the main features of fast reconnection. Levy and Araki (1989)

estimated that the energy flux F emerging from the flare is

$$F \sim \frac{B^3}{8\pi\sqrt{4\pi\rho}} \text{ erg cm}^{-2} \text{ s}^{-1}. \quad (31)$$

Interestingly, the outgoing energy flux corresponds to the magnetic energy density in the incoming fluid, moving at the Alfvén speed. At least within the context of this mechanism, the energy flux is independent of the merging speed u . The total rate of energy release still depends on u in that the fixed flux given in Eq. (31) emerges over a larger area, and is in fact proportional to u .

Inasmuch as magnetic flares are so commonly associated in energetic outbursts in cosmical systems, it is natural to inquire whether such flares could provide the transient heating mechanism that melted chondrules. Imagine that milligram-sized nebular dust accumulations are heated by the magnetic-flare energy flux given in Eq. (31), and that the cooling is by blackbody radiation from the heated droplet, with emissivity ϵ . Crudely, the steady-state temperature to which the chondrule precursor can be heated is

$$T_{\text{eq}} \sim \left(\frac{B^3}{16\pi^{5/2}\sigma\epsilon\sqrt{\rho}} \right)^{1/4} \quad (32)$$

where we have neglected the much lower external temperature into which the heated material is radiating. The maximum temperature to which the chondrule precursor can be heated depends only very weakly on the structure of the particle—both the heating and the cooling rates are proportional to the surface area, and in Eq. (32) we have made the most conservative assumption that the particle is heated from only one side, while it cools into 4π steradians of cold space. In addition, for energy fluxes capable of heating matter into the range of interest for making chondrules, the heating time is very short, of the order of a second or less (Levy and Araki 1989).

Now we turn to consider the conditions that must be satisfied if chondrules are to be the result of magnetic-flare-driven heating events. Taking 1400°C as the temperature needed for incipient melting, and taking the high-plausible end of the magnetic field intensities inferred from meteorite remanence of 5 Gauss, we find from Eq. (32) that the flares would have to occur in an ambient gas density of about $10^{-18} \text{ g cm}^{-3}$. (For this estimate, we have made the conservative assumption that, the emissivity $\epsilon = 1$.) Interestingly, this density is characteristic of the cloud cores from which stars are believed to form (see Boss et al. 1989, and references therein); however, such cores are some 3 orders of magnitude larger in spatial scale than the far more compact nebular disks considered in the present discussion. More relevant perhaps is the variation of gas density with altitude above the midplane of a disk. With $\rho(z) = \rho(0) \exp[-z^2/\Lambda^2]$, $\Lambda^2 = 2kT r^3/GM_\odot m$, and taking $\rho(0) = 10^{-9} \text{ g cm}^{-3}$ and using a disk temperature of 200 K, we find $\rho \sim 10^{-18} \text{ g cm}^{-3}$ at

about 1 AU above the midplane, when $r \sim 3$ AU. Thus, if energy released in magnetic flares is to make chondrules, then the flares must occur at least 1 AU above the disk midplane. And, indeed, it is problematical whether a real disk corona (with its possibly higher temperature and highly dynamical state) will have a number density as low as 10^6 cm^{-3} at that altitude.

D. The Locale of Chondrule Formation

It is important to realize that the low-ambient-density requirement severely constrains the environments in which flares could occur with energy fluxes sufficient to melt chondrules—at least with magnetic-field intensities limited by even the highest values plausible for a nebula. Although there is a range of combinations of field strength and ambient density that can produce the requisite energy fluxes, the restriction on the strength of plausible nebular magnetic fields essentially limits the occurrence of possible chondrule melting flares to very low density regions. The maximum temperature scales roughly as the eighth root of the density. [For high densities and low temperatures, a correction is needed in Eq. (32) to account for the temperature of the background into which the matter is radiating.] A consequence of this dependence on density is that flares embedded in the disk itself are wholly incapable of raising temperatures significantly: at $\rho \sim 10^{-9} \text{ g cm}^{-3}$, T_{eq} given by Eq. (32) is only slightly higher than 100 K, colder than the prevailing ambient temperature.

The form in which energy emerges also constrains the conditions under which magnetic flares could melt chondrules. To estimate the form in which the bulk of the energy emerges from such a flare, consider that the magnetic energy density $B^2/8\pi$ partitioned among the particles with number density $\sim 10^6 \text{ cm}^{-3}$ yields approximately 1 MeV particles for a magnetic field of 5 Gauss. Or looked at another way, with the same parameters, the characteristic Alfvén speed is about $1.4 \times 10^9 \text{ cm s}^{-1}$, which again corresponds to ~ 1 MeV per particle. Thus it is reasonable to expect much of the energy to emerge from these events in the form of 1-MeV protons. These energetic particles will be channeled along the magnetic field lines, down toward the higher-density layers of the disk, where they encounter the bulk of the matter, possibly melting dust assemblages to make chondrules and inducing radiation—analogous to a solar flare or to a terrestrial aurora—which might be an observable manifestation of the flare.

The path length of 1-MeV protons through matter is very short, about 10 mg per cm^{-2} . Thus, although the actual melting of material may occur some distance below the altitude of the flares, there cannot be more than $\sim 10 \text{ mg cm}^{-2}$ of intervening matter. At the ambient densities required, and in the context of a simple nebular model described above, the chondrules melting could happen at about a scale height below the minimum height of the flares. Altogether then, in a strongly magnetized, low-density nebular corona, chondrule-melting flares could occur at about four scale heights above the disk. Energy in the form of energetic particles could be channeled downward to about one scale height below, where the actual chondrule formation would take

place, assuming the presence there of the requisite milligram assemblages of silicate dust. Implicit in the discussion of disk coronal flares is the assumption that the coronal magnetic field strength (at an altitude of about 1 AU above the midplane) is comparable to the stronger of the magnetic fields inferred from the most straightforward interpretation of the meteorite magnetization record. This question is problematical, and requires detailed analysis of the possible structures of disk-corona magnetic fields as they are tangled by motions in the disk and wound up by the disk's differential rotation.

In order for chondrules to have formed in this manner, it would have been necessary for milligram assemblages of precursor silicate dust to have been present at about 3 scale heights above the disk midplane. There are two possibilities. Dust assemblages in the form of very fluffy fractal aggregates could, in principle, be lofted to the necessary altitude. Alternatively, dust assemblages could have been heated during their infall from the precursor cloud core, assuming that such massive assemblages could have grown there in the first place.

Here we will consider the possibility that the material was lofted to high altitude, inasmuch as that seems to offer the greatest freedom in terms of when, during the development of the nebula, chondrule formation might have taken place. In the extreme case, consider assemblages of fractal dimensionality ~ 2 , so that the mass grows as a^2 , where a is diameter of the assemblage. In that case, an assemblage made from $10\ \mu\text{m}$ grains presents about a square centimeter of cross-sectional area to the gas blowing by it. Because the particle and aggregate size is much smaller than the ambient molecular mean-free path, the gas drag is of the order of $a^2 n_g m c_s v$, where n_g is the ambient gas density, m is the mean molecular weight of the gas, c_s is the sound speed, and v is the velocity of the gas blowing by the assemblage. Taking $c_s v \sim 10^{10}\ \text{cm s}^{-1}$, and $m \approx 3 \times 10^{-24}\ \text{g}$, we find that a grain can be lofted against the force of gravity so long as

$$n_g \gtrsim \sigma_m g_v / m c_s v \quad (33)$$

where σ_m is the projected surface density of the precursor dust assemblage. At 3 AU, the vertical component of gravity, g_v is about $10^{-2}\ \text{cm s}^{-2}$, and with $\sigma_m \sim 10\ \text{mg cm}^{-2}$ and $m \sim 10^{-24}\ \text{g}$, we find that the precursor assemblages can be lofted against gravity where $n_g \gtrsim 10^9\ \text{cm}^{-3}$.

In principle then, very fluffy fractal aggregate precursors of chondrules could be lofted by gas motions to altitudes at which they could be melted by energetic particles accelerated in disk coronal flares. However, for this result to be meaningful, it is necessary that the precursors be lofted to such altitudes in sufficient numbers to account for the apparently large fraction of some meteorite material that is found in the form of chondrules—some tens of percent in certain classes of meteorites. To see the magnitude of this problem, consider that a stringent limitation on the altitude of chondrule formation by disk flares comes from the requirement that the flare particles be able to

propagate to the site of chondrule formation without losing their energy. As noted earlier, this requires that the intervening material not exceed more than about 10 mg cm^{-2} . Consider a disk with projected mass density above the midplane of 500 g cm^{-2} . In that case, in order for a dust aggregate to be exposed to a chondrule-melting flare, it must rise to an altitude such that the layer intervening between it and the flare contains only one part in 50,000 of the disk mass. Making the crude assumption that, so long as Eq. (33) is satisfied, the chondrule precursor are more or less tied to the gas, then at any time, only a very small fraction (a part in 50,000) of the potential chondrule material would be at risk of being heated. However, suppose that the convective motions are a few $\times 10^4 \text{ cm s}^{-1}$, then the convective turnover time (for the largest convective eddies) could be of the order of 10 yr. Roughly speaking, with reasonably effective mixing, it would take some 500,000 yr to mix a significant fraction of the potential chondrule precursors to the required altitude. This rate of mixing is sufficient to expose a large fraction of nebular silicates to chondrule melting, assuming that they are assembled into sufficiently large and fluffy assemblages.

Perhaps the more severe constraint involves the formation and persistence of such fluffy, fractal aggregates in the nebula. Numerical simulations suggest that fractal aggregates of dimensionality ~ 2 can be formed as a consequence of Brownian motion dominated accumulation of smaller dust clusters. However, macroscopic motions, such as those associated with turbulence, may prevent the formation of large, low-dimensionality fractal dust accumulations (J. Blum, personal communication). In this case, it may be that dust balls lofted from below cannot provide the raw material for chondrules melted by disk coronal flares. It is possible that dust accumulations entering the disk during accretion from the precursor cloud could provide the raw material that is melted to form chondrules, a suggestion that has been made in a different context by Wood (1984).

E. The Energy Production of Chondrule-Making Flares

Chondrules heated by disk-coronal flares described here have characteristic heating and intrinsic cooling times of the order of a second—short in comparison with the rate of temperature change thought to characterize chondrules as they cool through the solidus. Assuming that the cooling occurs into a cool background, this suggests that the cooling rates were controlled by variations in the heat source. This assumption allows us to estimate the total energy evolved in such flares. Taking τ_f to be the flare duration during the MHD collapse phase, the total evolved energy is (Levy and Araki 1989),

$$E_f \sim \frac{B^5}{64\pi^{5/2}\rho^{3/2}} \tau_f^3. \quad (34)$$

With $B \sim 5 \text{ Gauss}$ and $\rho \sim 10^{-18} \text{ g cm}^{-3}$, we find for the energy of a flare:

$$E_f \sim 3 \times 10^{33} \tau_{f(1000)}^3 \text{ erg} \quad (35)$$

where τ_{f1000} is the duration of a flare measured in units of a thousand seconds. Thus the total energy output of such a flare falls in the range of flares observed to be associated with T Tauri stars (Feigelson 1982).

VII. SUMMARY

In this Chapter we have discussed several nonlinear dynamical behaviors of the protoplanetary nebula that may provide mechanisms capable of explaining some of the major mysteries presented by observations of disks and solar system matter surviving from the time of planet formation. We have concentrated on only a few processes; others are discussed elsewhere in this book. We have focused on the possible influences of nonlinear collective behaviors on angular momentum transport in disks, and on the possible manifestations of electrostatic and electromagnetic effects. Our purpose has been to provide a tentative physical context for a variety of observations, both solar-system derived and astronomical in origin, that is firmly within the confines of known physical phenomena, satisfying the essential constraints on energy, momentum and continuity.

It has become clear that “quiescent” or quasi-linear disk models are unable to account for a number of important observed phenomena—hence the growing interest in nonlinear processes. For example, the rapid temporal evolution of disks is inconsistent with the time scales that could be driven by classical molecular processes. In a related fashion, the observed temperatures of disks point strongly toward mechanisms that tap the disk’s underlying gravitational energy source more rapidly than can classical molecular processes. Therefore, even though the details still remain obscure, it is clear that global disk evolution is driven by collective processes. There are a number of candidate mechanisms, including turbulent transport, collective gravitational effects and magnetic torques.

Among the most provocative observations is the co-existence of chondrules—relics of short-lived hot events—and matrix material—which does not appear to have been similarly heated—in the same meteorites. This observation points strongly toward extremely spatially and temporally heterogeneous thermal structures occurring in the protoplanetary disk. Observations of other protoplanetary disks around young pre-main-sequence stars indicate a cool environment with temperatures less than a few hundred degrees Kelvin. These apparently conflicting observations, together with the assumption that our protoplanetary disk was not in any way special, represent a major challenge in cosmogony.

The observational evidence for short-term heating events is especially provocative. As we have discussed, a protoplanetary nebula has more than sufficient energy to drive the high-temperature episodic events inferred from the meteorite record. With reasonable estimates of the efficiency, the observed abundance of meteorite manifestations (such as chondrules) can be accommodated. However, as we have discussed, a rich selection of physical

phenomena may be needed to account for these things, requiring detailed consideration of the relevant dynamics. A variety of possible chondrule-forming mechanisms have been proposed (see, e.g., Hood and Horanyi [1991] and the review given in Levy [1988]); in this chapter, we have focused on the possibility that chondrules could result from disk lightning or disk coronal flares.

Large electrostatic discharges (lightning) may occur in nebulae with power, frequency and distribution sufficient to account for chondrule formation. However, it should be borne in mind that, so far at least, arguments for the effects of nebular lightning are plausible rather than compelling. On the other hand, it should also be borne in mind that lightning, as an important form of energy dissipation in our own atmosphere, would not have been predicted to occur had it not been for the well-known empirical evidence of its existence. Moreover, evidence for lightning has been found in other planetary atmospheres (Jupiter and Venus, for example), suggesting that it may be a widespread and common phenomenon. In this sense, "nebular lightning" is at least a plausible candidate mechanism for localized, episodic heating events and might furnish an explanation for a significant portion of the thermal complexity observed in meteorites, though considerably more analysis is needed to elucidate fully the mechanisms and effects of possible nebular lightning.

Experience with a wide range of cosmic systems teaches us that magnetic fields are frequently important both for dynamical evolution and for large, transient energetic events. Such "flares" are known to occur in a variety of objects ranging from planetary magnetospheres to stellar coronae, as well as high-energy astrophysical sources. Evidence from primitive meteorites suggests the presence of a strong magnetic field in the protoplanetary nebula. Flares produced in a disk corona during the evolution of this magnetic field provide another possible mechanism that could account for the transient heating events that seem to be recorded in the primitive meteorites. However, even if disk coronal flares are prevalent, chondrule production by such flares presents problems. Two problems stand out. The presence of sufficient quantities of sufficiently massive (~ 1 mg) precursor aggregates at high enough altitudes to be heated by coronal flares is one such problem. The other is the question of the actual magnetic field strengths prevailing in the nebula, especially at several scale heights above the disk midplane.

Altogether, evidence points to the occurrence, in the protoplanetary nebula, of unexpected transient events that released large amounts of energy in localized volumes of space over short periods of time. Such events would, *a priori*, not be expected to occur. However, other cosmic systems with large amounts of free energy to expend are known to exhibit such unexpected and complex behaviors. Provoked by meteoritic and other evidence, we confront the likelihood that nonlinear collective phenomena occurred in the protoplanetary nebula and had important consequences. Our comprehension of these phenomena remains in an early and incomplete state. While final answers are not yet in hand, it seems likely that a complete understanding of the conditions

and processes associated with the formation of stars in general, and of our own solar system in particular, will have to encompass physical processes as complex as those that we confront in such better known systems as the Earth's atmosphere and magnetosphere, as well as the Sun's corona.

METEORITIC CONSTRAINTS ON CONDITIONS IN THE SOLAR NEBULA

H. PALME

Max-Planck-Institut für Chemie

and

W. V. BOYNTON

University of Arizona

Conditions in the early solar nebula may be inferred from the bulk chemical composition of undifferentiated, or chondritic, meteorites as well as from the bulk composition of the planets. Differentiated meteorites, those processed in the interior of planets, may also be useful if reasonable estimates of the chemical composition of their parent bodies can be made. From the bulk chemical compositions of meteorite parent bodies and planets, representative chemical trends can be deduced and some constraints for large-scale conditions in the inner solar nebula at the time of formation of solid matter can be inferred. In contrast, clasts, inclusions and mineral fragments in undifferentiated meteorites provide detailed information about conditions in local environments. All chemical fractionation trends observed in bulk chondritic meteorites require formation temperatures at around the condensation temperature of metallic iron or magnesian olivine (1200–1440 K). The pronounced depletion of moderately volatile elements (Mn, Na, Ga, Zn, S etc.) is a characteristic signature of most chondritic meteorites. Several possibilities for establishing this depletion pattern are discussed, and it is concluded that they are most likely due to fractionation during condensation requiring temperatures of 1200 to 1400 K. Evidence for processing bulk meteorite material at higher temperatures is lacking. Reconstruction of the original composition of planets and parent bodies of differentiated meteorites leads to fractionation trends similar to those observed for chondritic meteorites. It is therefore concluded that the inner solar system, including most of the asteroidal belt, had at one point in the evolution of the solar system experienced temperatures of 1200 to 1400 K. Some Ca, Al-rich inclusions in carbonaceous chondrites require formation temperatures as high as 1600 K. Estimates from trace-element fractionation trends and simple thermodynamic calculations for the growth of refractory metal nuggets in carbonaceous chondrites indicate that these temperatures must have prevailed, at least locally, for tens of years. Refractory-rich rims on Ca, Al-rich inclusions suggest that much more intense heating also occurred, but for times only on the order of one second. Evidence is presented that requires some objects to have formed in rather oxidizing conditions at elevated temperatures. However, it is not clear what fraction of the solar nebula was affected by these processes, in particular when considering that the high-temperature indicators in carbonaceous chondrites only represent a small fraction of the bulk meteorites.

I. INTRODUCTION

Ideally, for meteorites to provide constraints on conditions in the solar nebula, little should have happened to them since they formed. Meteorites, however, have only spent a comparatively short timespan of several Myr as individual bodies in space. Most of the time, for more than 4 Gyr, they were buried in the interior of km-sized planetesimals. The pressure, temperature and oxygen fugacity recorded in the mineralogy of a meteorite is dependent on the type of parent body, i.e., its composition, and the position of the meteorite inside the planetesimal. Meteorites may thus reflect in their chemical and mineralogical compositions a variety of conditions, from complete melting or minor heating to low-temperature alteration by fluid phases (e.g., H_2O).

Clearly, we can only hope to identify relicts of nebular processes in those meteorites that were not exposed to high temperatures in the interior of planetesimals. Either the planetesimals from which these meteorites were derived were not heated to sufficiently high temperatures, or meteorites from them were buried at shallow depths where temperatures were low. Meteorites which have never been exposed to temperatures sufficient for melting are called chondritic meteorites, or chondrites. They may still preserve the original texture and mineralogy that they had acquired in the solar nebula, or they may have a texture and mineralogy adjusted to the new "planetary environment," according to metamorphic conditions or low-temperature alteration. If the low-temperature alteration was isochemical, as often found in carbonaceous chondrites, their bulk chemical composition will still record the nebular origin.

Chondritic meteorites contain all nonvolatile elements in the proportions in which they occur in the Sun, i.e., they have the average solar system composition. This is only true to a first approximation; on a finer scale, compositional variations are found among chondritic meteorites such as variable contents of volatile elements, variations in total iron, variable Mg/Si ratios, etc. In addition, chondritic meteorites also display a wide variety of the degree of oxidation, from water-containing CI chondrites to the completely reduced enstatite chondrites with Si-containing FeNi. These variations (oxygen fugacity and composition) must reflect different environments during condensation or aggregation of solid matter in the solar nebula. For example, different environments could be characterized by small deviations from solar abundances in the local environment (nebula and/or average grain composition) in which they formed. In addition, gas-solid fractionation processes, such as gravitational settling of early-formed grains to the midplane, could have been important. Chondritic meteorites, particularly those of low petrologic type (indicating very little heating inside a larger body) contain components (inclusions, mineral fragments, etc.) that record nebular processes and thus allow one to infer composition, temperature and perhaps pressure of the nebular environment.

In meteorites derived from molten planetesimals (differentiated mete-

orites), as well as in samples from larger planets (Earth, Moon), mineralogical or textural evidence of solar nebular processes is completely erased. There is, nevertheless, some information contained in the chemical composition of individual samples. For example, the composition of basalts (terrestrial, lunar or meteoritic) allows certain conclusions regarding the chemical and mineralogical composition of their source region, and, in some cases, of the bulk chemical composition of their parent planet. In some cases, ratios of incompatible elements, for example, the K/U ratio (see, e.g., Taylor 1988), are constant during igneous fractionations and thus reflect the bulk planet ratio. The composition of a basaltic rock sample from the surface of a planet is also a sensitive indicator of the mineralogy of the source region in the interior of the planet. It is possible by these means to obtain a reasonable estimate of the bulk composition of planets (see, e.g., Dreibus and Wänke 1980,1990).

This approach of using the bulk composition allows one to compare the compositions of the Earth, the Moon and Mars with the composition of a wide range of meteorite parent bodies (differentiated and undifferentiated). Most of the planets and the differentiated planetesimals appear to have compositions that differ slightly from average solar system composition, in particular with respect to volatile elements. These compositional variations are in the same range as those within the group of chondritic meteorites and may also reflect a similar variability in formation conditions in the nebular environment. The advantage of considering the bulk composition of differentiated bodies is that it provides a more representative sampling of the solar nebula. By comparing simultaneously the compositions of the inner planets, meteorite parent bodies, comets (e.g., Halley) and interplanetary dust (results of analyses of interplanetary dust particles, IDPs), it may be possible to identify processes that operated in the inner part of the solar system during formation of solid matter and which are ultimately responsible for the variations in elemental abundances and conditions of formation of planets and planetesimals.

The evidence provided by individual components in meteorites, such as exotic mineral grains, may be more definitive in terms of identifiable solar nebula processes, but the significance of these processes for the bulk matter of the inner solar system may be difficult to evaluate. For example, deducing high temperatures for the conditions of formation of some refractory mineral grains recovered from the Allende meteorite is straightforward, but the extent in space and time of this high-temperature zone is unclear. Was the zone a local phenomenon, or was it a major part of the inner solar system?

In the first part of this chapter (Sec. II) we describe evidence derived from the bulk composition of meteorites, planetesimals and planets and discuss their significance for the evolution of the inner part of the solar nebula. In the second part (Sec. III) we consider evidence for solar nebula processes recorded in individual meteoritic components, such as chondrules, inclusions or mineral grains.

II. BULK CHEMICAL COMPOSITION

A. Significance of Chondritic Meteorites

In cosmochemistry it is useful to arrange elements according to their condensation temperatures (see review by Larimer 1988). Such temperatures are calculated assuming cooling of a hot gas of solar composition at a given pressure under equilibrium conditions. The sequence of elements condensing from this gas is reasonably well known, except for trace elements where, in many cases, a lack of relevant thermodynamic data prevents precise calculations. Condensation temperatures are a convenient measure for volatility, and they provide a useful framework for classification of chondritic meteorites, considering that variations in abundances of volatile elements account for the most pronounced differences among chondrites. According to their condensation temperatures, elements can be divided into four groups:

1. The refractory component (Ca, Al, Ti, Zr, REE, Ir, Os, etc.) which makes up about 5% of the total condensible matter.
2. Mg-silicates (forsterite Mg_2SiO_4 , enstatite MgSiO_3) and metal (FeNi) which represent the major fraction of condensible matter.
3. Moderately volatile elements (Na, K, Cu, Zn, etc.) with condensation temperatures below Mg-silicates and FeNi and above (but including) S (as FeS).
4. Highly volatile elements (In, Cd, Pb, etc.) with condensation temperatures below FeS.

Compositional variations of some representative elements in various groups of chondritic meteorites are shown in Fig. 1. Abundances are divided by Si and normalized to those in CI chondrites (see below). Meteorite groups are arranged in the order of decreasing oxygen content, reflecting increasingly reducing conditions from carbonaceous to enstatite chondrites.

The solar abundances as recently compiled by Anders and Grevesse (1989) are plotted on the left end of the meteorite data in Fig. 1. It is obvious that the best agreement between solar and meteorite data is obtained with CI abundances. This is true for Ca, representing the group of refractory elements, Mg and volatile elements (Na, Zn, S). The solar Fe abundance is an exception being some 50% above the CI abundance. The reason for this discrepancy is not known. It is certainly not due to an overabundance of metal, because the solar abundances of Ni and other siderophile elements agree with the CI abundances (see Anders and Grevesse [1989], for detailed discussion). In a very recent redetermination of the solar iron abundance, Holweger et al. (1991) found agreement between solar and meteorite Fe abundance, suggesting that older solar Fe abundances were in error. Rare gases and some light elements, including C, N and O, are deficient in CI chondrites compared to solar abundances due to their high volatility. The CI-oxygen abundance, for example, is a factor of 3 lower than the solar abundance (Fig. 1), reflecting incomplete water condensation, incomplete formation of

Figure 1. Selected element/Si ratios for all groups of chondritic meteorites. Meteorite groups are arranged in order of decreasing oxygen content (lower right). Solar ratios are indicated on the right side. CI meteorites agree best with solar abundances, e.g., refractory elements (Ca) and volatiles (Zn, S). Oxidized (CI) and reduced meteorites (EH) are both rich in volatiles. Sources of data: Mason 1979; Kallemeyn and Wasson 1981; Anders and Grevesse 1989, unpublished data Cosmochemistry, Max-Planck-Institut für Chemie, Mainz.

hydrous silicates or saturation of silicates with water.

The refractory element Ca (Fig. 1), and the other refractory elements (Al, Sc, Ir, etc.), vary by about a factor of 2 within the group of chondritic meteorites (see difference in Ca between CV and E chondrites in Fig. 1). Ca, Al-rich inclusions in carbonaceous chondrites have, on the average, 20 times higher contents of refractory elements than CI chondrites. This factor of 20 would be expected from complete condensation of all refractory elements, corresponding to 5% of condensable matter (see Grossman and Larimer 1974). These inclusions were, therefore, thought to represent high-temperature condensates. Formation of Ca, Al-rich inclusions as a condensate requires their isolation from equilibrium with the nebula above the condensation temperatures of the more volatile, major components, metallic iron

and the Mg-silicates, i.e., from 1225 K at 10^{-6} bar to 1450 K at 10^{-3} bar. Calculated condensation temperatures of refractory elements at a pressure of 10^{-4} bar are shown in Fig. 2. Methods for calculations are described in Palme and Wlotzka (1976) and Kornacki and Fegley (1986). Major-element condensation temperatures were deduced from data in Kornacki and Fegley (1984). In some refractory inclusions and minerals in carbonaceous chondrites refractory elements with different volatilities are fractionated. For example, highly variable ratios of the very refractory Lu to the less refractory Yb or, similarly, variable ratios of the strongly refractory Zr to the much less refractory Nb are observed. These variations can be explained by incomplete condensation or evaporation of refractory elements as discussed in Sec. III.B.1. Here we wish to emphasize that such fractionations are practically absent in bulk meteorites, i.e., refractory elements always occur in the same relative proportions, despite some variation in absolute contents. This is shown for the Zr/Y and Zr/Nb ratios in Fig. 3. The difference in condensation temperature between Zr and Nb is more than 200 K, while Zr and Y have similar volatilities (Fig. 2). The observation of phases with fractionated ratios in carbonaceous chondrites implies either closed system behavior or a very small proportion of material with fractionated refractory elements. In the first case, high Zr/Nb phases would be balanced by low Zr/Nb phases. Evidence presented later suggests the second possibility, a very small contribution of material processed at high temperatures.

Chondritic meteorites have variable Si/Mg ratios, with maximum variations of about 30% (Fig. 1). These variations may be ascribed to fractionation of olivine, as suggested by Larimer (1979). Forsterite (Mg olivine) has an atomic Mg/Si ratio of 2, as compared to the solar ratio of ~ 1 . Therefore, addition or removal of forsterite has a large influence on the Mg/Si ratio. Isolation of forsterite after condensation requires similarly high temperatures as addition or removal of refractory components.

Parallel variations in Fe and Ni within the different groups of chondritic meteorites are indicated in Fig. 1. Although fractionation of iron as oxide is possible, it is difficult to fractionate Ni as oxide. Simultaneous variations in Fe and Ni contents may therefore be ascribed to addition or removal of metal components established by processes in the solar nebula. Again, similar temperatures as those required for olivine and refractory element fractionations are indicated, because in a gas of solar composition, metal and forsterite have similar condensation temperatures (Grossman and Larimer 1974). Details of the fractionation processes remain unclear, however, as there is no parallel variation of the Mg/Si ratios (reflecting olivine fractionation) with the contents of metallic iron (Kerridge 1979). The evidence for high temperatures is, therefore, indirect. The essential point to emphasize is that variations in Mg/Si ratios and variable metal contents in chondritic meteorites were not established by melting processes, as chondritic meteorites were never molten. Therefore, a nebular formation history with temperatures of 1250 to 1450 K is suggested, although the mechanical separation of metal and

Figure 2. Calculated condensation temperatures of refractory elements at 10^{-4} atm. Hf, Zr, Sc and Y would condense before a major phase condenses. All other elements were assumed to condense in solid solution with perovskite. Ideal solid solution was in all cases assumed. This leads to unrealistically low condensation temperatures for Sr and Ba. Both elements obviously require a different host phase. Elemental fractionations according to differences of condensation temperatures are found in components of meteorites but never in bulk meteorites. Calculations were performed according to programs described by Palme and Wlotzka (1976), Fegley and Palme (1985) and Kornacki and Fegley (1986). Major elements are from Kornacki and Fegley (1984).

forsterite could have occurred at lower temperatures.

The systematics and the significance of abundance trends of moderately volatile elements in chondritic meteorites are discussed in some detail by Palme et al. (1988). Here we review the most important aspects. Abundance trends for several moderately volatile elements are shown in Fig. 1 (Mn, Na, Zn, S). Volatility is increasing, i.e., condensation temperatures are decreasing from Mn through Na to Zn and S, reflecting a tendency for increasing variability in abundances with increasing volatility. In Fig. 4, concentrations of moderately volatile elements in CV3 carbonaceous chondrites (e.g., Allende, Vigarano) relative to CI chondrites and normalized to Si are shown. Elements are arranged according to condensation temperatures. The regular decrease in abundances, independent of the geochemical character of the el-

Figure 3. Constant ratios among refractory elements in the major types of carbonaceous chondrites. Despite large differences in condensation temperatures of Zr and Nb (Fig. 2), the ratio is constant. Data from Jochum et al. (1986).

elements (siderophile, chalcophile or lithophile), suggests a volatility-related process, i.e., condensation or evaporation, as being responsible for this trend. All chondritic meteorites, except CI chondrites with solar abundances, have a similar type of abundance pattern (i.e., a trend of decreasing abundances with increasing volatility) for the moderately volatile elements (Palme et al. 1988).

Under equilibrium conditions condensation and evaporation would lead to the same results. However, evaporation of silicates that occurred after partial or complete dissipation of the nebular gas (equivalent to an enrichment of O_2 -rich dust over H_2 -rich gas) will lead to more oxidizing conditions, primarily due to the absence of H_2 and through decomposition of oxides and evaporation of water. In most cases, therefore, evaporation should occur under more oxidizing conditions than condensation.

Figures 5 and 6 show some results of heating experiments on Allende chips at various oxygen fugacities (Wulf and Palme 1991). The reducing conditions of the solar nebula correspond to an oxygen fugacity indicated at the left of the oxygen fugacity scale of Figs. 5 and 6, at about 10^{-20} bar. On the right, CI-normalized abundances for Allende are indicated, allowing a comparison of the Allende pattern depleted in volatiles to the pattern produced by the volatilization experiments. If the Allende pattern is produced by heating from a reservoir with solar abundances, e.g., Orgueil, then the Allende trace-element pattern should display a similar trend as the pattern produced by the heating experiments. Figures 5 and 6 demonstrate quite clearly that the Allende pattern cannot be produced by evaporation under oxidizing conditions. At oxidizing conditions, the high losses of Au and As and the small losses of Zn and the alkalis preclude any similarity to the observed depletion pattern in Allende. The sequence fits better at low oxygen fugacities, although the absence of Mn depletion in the experiments is not compatible with the ob-

Figure 4. Moderately volatile element abundances in bulk CV chondrites decrease more or less continually with condensation temperatures. The depletion sequence is independent of the geochemical character of the elements, suggesting that a volatility-related process is responsible for the depletion, either evaporation or incomplete condensation. For details and for sources of data see Palme et al. (1988).

served low Mn content. In addition, Se depletions are higher than observed in Allende (in the heating experiments only upper limits could be determined). Heating experiments by Bart et al. (1980) on Allende show that there is no loss of Se at 1000°C , while significant losses are observed at 1050°C similar to what was found in the experiments by Wulf and Palme (1991). This and the Bart et al. data at higher temperatures suggest a sudden increase of the rate of evaporation of S between 1000°C and 1050°C , implying some kind of a threshold temperature. Other elements appear to behave similarly; once the threshold temperature for losing volatiles is reached, a small temperature increase is sufficient to cause extensive losses. Obviously loss of Mn does not occur in the experiments because the threshold is not reached. At the same time, however, Se is almost completely lost, contrary to the observed pattern.

Figure 5. Loss of volatile elements by heating of Allende (1050°C, 4 days) is strongly dependent on oxygen fugacity (Wulf and Palme 1991; Wulf 1990). The oxygen fugacity of the Fe-FeO buffer would give the best fit to the Allende pattern (normalized to CI). Highly oxidizing environments which would be produced by heating after dissipation of the H₂-rich (reducing) gas are excluded. The high Au value for the most reducing sample is probably due to contamination.

An additional problem arises for the highly volatile element abundances (Ti, Pb, Cd, etc.). These elements have similar abundance levels in carbonaceous chondrites as S, Se and Zn (Anders et al. 1976). However, in heating experiments they are much more readily lost than the moderate volatiles (Bart et al. 1980). Partial loss of Na or Zn during thermal metamorphism would therefore imply complete loss of the highly volatile elements. These elements would have to be brought in again after thermal metamorphism. The same trends in volatile element depletions observed in heating experiments on Allende were also found in experiments with Murchison (Wulf 1990). Considering the different texture and mineralogy of this meteorite, it may be concluded that the observed depletions reflect a general trend and are not a result of the specific Allende mineralogy. The results of the heating experiments thus imply that the loss of volatiles occurred in the early solar nebula at a time when the hydrogen-rich, reducing gas was still present, evaporation in the absence of an H₂ atmosphere would have a very different trace-element pattern than that observed.

Anders (1964) and Larimer and Anders (1967) have suggested that moderately volatile and volatile elements are lost during chondrule formation. These authors assume that, for example, Allende parent material initially (before chondrule formation) had the same composition as CI-chondrites, i.e., the full complement of volatiles. By converting three-quarters of this mate-

Figure 6. Heating experiments of Allende (Wulf and Palme 1991; Wulf 1990). In these experiments no loss of Mn is found, although Allende is depleted by nearly 50% (see also Fig. 1). Selenium and S (not shown here) are completely lost in all experiments (below detection limit). Both elements are present in Allende at a level of 0.25 (relative to Si and CI). The pattern of K and Na are, similar to Fig. 5, more compatible with reducing conditions.

rial to chondrules (through the chondrule-forming process), a corresponding fraction of highly volatile elements would be completely lost from this fraction, while moderately volatile elements would only be partially lost, thus producing the abundance pattern of Fig. 4. However, Allende chondrules are, on the average, enriched, not depleted in Na and K (Rubin and Wasson 1987; Spettel et al. 1989), indicating that heating during chondrule formation is not sufficient for losing alkalis. Also, fine-grained matrix material of Allende is, except for a volumetrically insignificant fraction (with grain size $< 1 \mu\text{m}$), not enriched in volatile elements as expected from this model but has similar abundances in bulk Allende (Ireland et al. 1990a). Large compositional variations in chondrules suggest that chondrules are made of coarse-grained precursor materials and not of fine-grained matrix (Grossman 1988). There is, therefore, little evidence that the depletion of volatiles in Allende and other chondrites is associated with chondrule formation.

Alternate explanations for the depletion of moderately volatile elements involve condensation. However, incomplete condensation alone is not sufficient to explain the observed pattern. Removal of a condensate from the solar nebula at a given temperature would lead to a similar pattern as envisioned for evaporation in a hydrogen-rich environment. Wasson and Chou (1974) have, therefore, suggested dissipation of the solar gas during condensation. The abundances of volatiles in the gas, i.e., their partial pressures, would

decrease during condensation as gas would be continually removed, leading to the observed smooth depletion sequence of moderately volatile elements (Fig. 4). The abundance level of the highly volatile elements would then reflect the total fraction of gas lost.

Whatever the origin of the depleted-element pattern, there is little doubt that temperatures up to 1127 K at 10^{-6} bar or 1284 K at 10^{-4} bar, the 50% condensation temperatures of Au (Wai and Wasson 1977), are required. The parent material of most chondritic meteorites must have been processed at this temperature in a solar nebula environment, although it should be emphasized that the duration of the heating event may have been quite short as indicated in Figs. 5 and 6 where significant losses of volatiles are shown to occur within a few days (the time scale for incomplete condensation would depend on kinetics and is thus difficult to predict).

That the loss or incomplete condensation of moderately volatile elements and volatiles occurred very early in the evolution of the solar system is apparent from Sr and Pb isotopic data. At the time of formation of the solar system, chondritic meteorites had $^{87}\text{Sr}/^{86}\text{Sr}$ ratios not very different from that of the lowest measured ratio in Ca, Al inclusions from Allende and slightly lower than the lowest ratio determined in lunar rocks and basaltic achondrites (see review by Tilton 1988). Such data indicate widespread homogenization of Sr isotopes at the time of formation of the solar system. The time of separation of the volatile Rb from the refractory Sr in chondrites cannot be determined precisely because of uncertainties in the Rb decay constant (Minster et al. 1982). However, as data of H, LL and E chondrites fall on a single isochron, it is very likely that the Rb-Sr fractionation is a global event that reflects the general fractionation of volatile elements from a solar reservoir, i.e., condensation of chondritic meteorites. The determination of the isotopic composition of Pb is the most precise dating method for the early separation of volatile (Pb) from refractory (U, Th) elements. Ca, Al inclusions in Allende, for example, have ages from 4.565 to 4.575 Gyr (Manhes et al. 1987). Phosphates in primitive (type 3) chondrites are about 4.55 Gyr old (Göpel et al. 1990). A similar age of 4.551 ± 0.004 Gyr was reported for the differentiated meteorite Angra dos Reis (Chen and Wasserburg 1981*b*). These data indicate a spread of 25 Myr for the separation of Pb from U and the subsequent undisturbed growth of radiogenic Pb. The Pb separation must have occurred very early during the formation of solid material in the early solar system and cannot have been produced in a late reheating event.

B. Differentiated Meteorites and Planets

The depletion of moderately volatile elements is, however, not confined to chondritic meteorites. There is ample evidence that meteoritic basalts (eucrites), lunar and terrestrial basalts are all deficient in moderately volatile elements, as for example, recorded in their K/U ratios (see, e.g., Taylor 1988). More sophisticated models for the bulk compositions of planets lead to similar conclusions: volatile elements when compared to the solar system average

are depleted in the Earth, the Moon, the eucrite parent body and the Shergotty parent body (perhaps Mars) (Dreibus and Wänke 1980,1990).

It is not very likely that the low contents of volatile elements in planets and planetesimals were established during accretion. The extent of the depletions does not depend on the size of the planet. The Moon and the eucrite parent body have lower contents of volatiles than the Earth and the Shergotty parent body, presumably Mars. Volatile element depletions in the Moon may be the result of special conditions during its formation. However, this argument cannot be applied to the much smaller eucrite parent body (*Basaltic Volcanism Study Project* 1981).

The depletion of volatile and moderately volatile elements is also visible in the trace-element pattern of iron meteorites. In their siderophile element abundances, these pieces of planetary cores have retained the signature of the composition of the original planet, i.e., material that accreted to form the planet. A particularly strong depletion pattern is observed in the IVB iron meteorites (see Fig. 7.5.10 in Palme et al. 1988). This is, for example, reflected in the high Pd/Ag ratio (see, e.g., Kaiser and Wasserburg 1983), with a difference in condensation temperatures between Pd and the more volatile Ag of some 400 K (Wasson 1985). Results of the analysis of Ag isotope ratios indicate that the separation of Ag from Pd occurred very early in the history of the solar system. It is, therefore, most likely that the parent body of these meteorites had a fractionated (high) Pd/Ag ratio, i.e., the trace-element pattern may have been established by condensation processes in the solar nebula.

This example also demonstrates the lack of a correlation between heliocentric distance and chemical composition of meteorites and planets. There is no obvious trend for enrichment of volatiles with heliocentric distance. The Earth is richer in moderately volatile elements than the eucrite parent body in the asteroid belt. The IVB iron meteorite parent body, another object of the asteroid belt, is very deficient in volatiles (Kelly and Larimer 1977). Thus, CI chondrites with their full complement of moderately volatile and volatile elements and the volatile poor eucrites and IVB irons are all derived from the asteroid belt. Also, there is no correlation between the amount of volatiles and the degree of oxidation among parent bodies of meteorites. Such a correlation would be expected if volatiles were removed from condensed matter by heating, because water would be removed at low temperatures and oxides would be decomposed at elevated temperatures. Figure 1 demonstrates high Zn and S contents in both, the most oxidized (CI) and in the most reduced (EH) meteorites. The absence of a clear trend of the degree of volatile element depletion with distance from the Sun within different groups of meteorites and between meteorites and planets does not necessarily reflect the original structure of the solar system. Meteorite parent bodies may have formed at very different places than their present location would indicate. However, there is always the difficulty to understand the formation of the volatile-rich and completely reduced enstatite chondrites within the framework of the equilibrium condensation model. Additional assumptions such as an enhanced C/O ratio

are required (Larimer and Bartholomy 1979).

It appears that each group of chondritic meteorites was formed in its own separate nebular reservoir that was slightly different from the average composition of the solar system, i.e., the Sun, producing a characteristic chemical signature for each group.

Depletion of volatiles, however, has occurred in almost all matter of the inner solar system. Consequently, conditions prevailing in the inner solar system through at least part of the asteroidal belt, included a H_2 -rich gas with temperatures on the order of $1100^\circ C$. The CI meteorites, in particular Orgueil, are exceptional; either this material is derived from comets, or it has escaped the high-temperature event, or it was added to the asteroid belt after the high-temperature event was over. Mixing of unheated material to the inner solar system is required by recent findings of unprocessed interstellar material (Anders 1988; Zinner 1988). However, at least some interplanetary dust particles (IDPs) may have the full complement of volatile elements, even including carbon (Schramm et al. 1989). Those particles may be derived from comets. The high contents of volatile elements in Comet Halley supports this assumption (Jessberger et al. 1988).

Other chemical fractionation trends in chondritic meteorites discussed earlier, such as variations in Mg/Si ratios or in the content of metal (NiFe) also seem to be present in planets. These fractionations would also require temperatures of around 1200 K. However, because the estimation of bulk planet compositions are not always unambiguous, and because variations in these ratios are small, they will not be discussed further.

Although there is widespread evidence for loss of volatiles, there is very little evidence for gain of volatiles as pointed out by Palme et al. (1988). Except for a few volatile-rich clasts in chondrites, there is no meteorite class with abundances of moderately volatile elements or volatiles clearly in excess of the solar photospheric level. This may be an important clue in identifying the process that caused the volatile element depletion. If it occurred during condensation, the uncondensed volatiles may have been blown out of the inner solar system. However, as mentioned before, they did not recondense in the asteroid belt, at least not in that part that is sampled by meteorites present in our collections.

An upper limit to the temperature where the bulk of protoplanetary material has been processed may be deduced from a lack of fractionation among refractory elements. Bulk planet ratios of Zr/Nb and Hf/Ta are essentially the same as ratios in primitive chondritic meteorites as shown by Jochum et al. (1986), despite large differences in the volatilities of Zr and Nb and Hf and Ta, respectively (Fig. 2). Such fractionations are, however, observed in high-temperature components of carbonaceous chondrites as is discussed in the next section.

III. CONDITIONS IN THE SOLAR NEBULA DERIVED FROM COMPONENTS IN METEORITES

A. Chondritic Meteorites are Complex Mixtures of Components Formed Under Highly Variable Conditions

As techniques for chemical and isotopic analyses have improved over the years, a continuous decrease in the amount of material required for precise chemical and isotopic analysis of meteorites and their constituents allows one to study meteorites in great detail. A fascinating body of data on minerals and inclusions of unequilibrated meteorites, particularly from carbonaceous chondrites, has been obtained. Sophisticated techniques of chemical dissolution of meteorites have led to the identification of extremely small amounts of pre-solar material in these meteorites (see Chapter by Ott). On the other hand, isolation of refractory materials in carbonaceous chondrites has provided abundant evidence for processing material at temperatures of 1600 to 1800 K (at 10^{-4} bar; see Fig. 2). These meteorites contain a bewildering variety of components that require very different conditions of formation, from low temperature phases such as carbonates to mineral grains that record gas-solid equilibria at rather high temperatures. In many cases, processing of these materials must have occurred in distinctly nonsolar environments, characterized by high $\text{H}_2\text{O}/\text{H}_2$ ratios, i.e., excess oxygen.

The multitude of components assembled in these meteorites reflect the absence of equilibration processes in a parent body. This mixture of high- and low-temperature materials formed under both extremely reducing and highly oxidizing conditions, comprising mineral grains and clasts which are in apparent disequilibrium, has nevertheless a well-defined chemical composition, which is basically solar for nonvolatile elements and shows systematic trends for volatile elements (see Fig. 4). This apparent paradox may be resolved by assuming a nearly closed system with respect to chemical composition that provides a variety of local environments but allows the addition of only a very small fraction of chemically unusual material. Small amounts of isotopically unusual material found in meteorites, presumably of pre-solar origin, does not show up in bulk analyses. On the other hand, chondrules and matrix, both produced by very different processes, are significant components in the Murchison CM2 meteorite needed to account for the "primitive" bulk composition (Wood 1985), suggesting the nearly closed system behavior.

An example of this mixture of materials formed under different processes can be seen in Fig. 7, which shows a thin section of the Murchison meteorite. In the lower half of the figure, there are two granular olivine chondrules. Extremely fine-grained matrix, rich in FeO, appears to have accreted with these FeO poor chondrules. In the upper right, there is a large olivine crystal, some of these olivine crystals are almost free of FeO and may have formed by condensation from the solar nebula. Thus the Murchison meteorite is a breccia containing a variety of lithic and mineral fragments that were mechanically mixed on the surface of a parent body. The components of this meteorite

formed at different temperatures and under very different oxygen fugacities. Low- and high-temperature components (e.g., calcite vs forsterite) display large differences in the composition of the oxygen isotopes, excluding a common single source of the oxygen in these minerals (Clayton and Mayeda 1984). Despite the chaotic nature of this meteorite and the apparently random mixing of various components, the chemical composition of Murchison is well defined, resembling average solar system composition.

Figure 7. Ultra-thin section of Murchison, a CM meteorite. The brecciated character of this meteorite is obvious. Several olivine crystals are clearly visible (e.g., upper right). Chondrules appear to be surrounded by fine-grained rims probably formed during accretion in space. There is no thermodynamic equilibrium among the various components of Murchison. They formed under different oxygen fugacity (Si-bearing metal and H_2O -containing phyllosilicates), and they show large variations in oxygen isotopic composition (Clayton and Mayeda 1984). The bulk chemical composition of this meteorite is, however, well defined. Long side 2.4 mm. Source: R. Beauchamp, Battelle-Institut, NW.

Recently Kring (1988) and Metzler et al. (1992) have shown that chondrules and fragments in CM meteorites are often surrounded by fine-grained matrix material compositionally similar to CM matrix. The authors suggest that these "dust mantles" formed by accretion in space and not by processes

Figure 8. A Type B Ca, Al-rich inclusion from the Allende meteorite, consisting primarily of melilite (bright) and fassite (dark). The dark area in the lower middle inside the inclusion is matrix. Diameter of the inclusion is 1 cm.

in the regolith of a parent body. This supports the view that CM components formed independently in space and that there is very little processing after assembling of the meteorite parent body.

We will now give some examples to illustrate the variety of local environments that are required to explain the diversity of components identified in carbonaceous chondrites.

B. High-Temperature Components

1. Ca, Al-Rich Inclusions (CAIs) and Their Components. There exists a large body of literature on these inclusions, and the reader is referred to review papers by Grossman and Larimer (1974) and by MacPherson et al. (1988). Here we will restrict the discussion to a few aspects that bear on the question of temperature, pressure, oxygen fugacity and time scale of the environment in which they formed.

One of our best sources of information on high-temperature processes are the Ca, Al-rich inclusions found in carbonaceous chondrites. A large Ca, Al-rich inclusion from the Allende meteorite is shown in Fig. 8. The high content of refractory elements, including low-vapor-pressure metals, such as W, Ir, Pt, etc. (see Fig. 2), and the absence of igneous trends in the trace-element pattern leave no doubt that these objects are composed of material formed at high temperatures, either by condensation from a gas of solar composition or by vaporization of chondritic material. Figure 9, for example, demonstrates the uniform enrichment of refractory elements in Allende inclusion A4. Often, however, more complicated patterns are found, such as the pattern of A10 in Fig. 9. These puzzling patterns were interpreted by Boynton (1975) as condensates from a gas that has suffered previous removal of a first very refractory condensate. This first condensate is expected to be rich in Hf, Zr, Y, Sc, Lu and Dy, according to condensation temperatures (see Fig. 2). Removal of such a condensate from equilibrium with the solar gas would leave the residual gas depleted in Hf, Zr, and other refractory elements in low abundance in A10. Any component formed by subsequent condensation would lack these elements just as it is observed in the A10 inclusion in Fig. 9. This picture may seem complicated and somewhat contrived; any other explanation, however, is even more complex. These so-called group II patterns are common in certain types of fine-grained inclusions in Allende, but the complementary "superrefractory pattern" (enriched in Hf, Zr, etc.) indicative of the first condensate was never found in Allende.

Inclusions with this superrefractory pattern have been found in other meteorites, however. Boynton et al. (1980) found such a pattern in a spinel-hibonite inclusion from Murchison, and Palme et al. (1982) isolated a tiny grain (about 1 μg) from the Ornans meteorite that had an even more extreme super-refractory pattern (Fig. 10). Condensation of only the most refractory elements, for example in perovskite (CaTiO_3) or hibonite ($\text{CaAl}_{12}\text{O}_{19}$) as suggested by Boynton (1975) requires thermodynamic equilibrium between gas and solid at high temperatures. The rare-earth element, Lu, should practically completely condense, while the six-times more abundant and geochemically similar rare-earth element Sm, with a condensation temperature of only 50 K lower, would remain in the gas (Fig. 10). Effects due to supersaturation must have been absent or were not important. Perhaps pre-solar, tiny, unvaporized grains acted as condensation nuclei.

Removal of most of Lu from a given volume requires time in the order of days to years as a simple calculation demonstrates. Given grains of perovskite with 1 μm diameter, the number of encounters per second of Lu with these grains is given by:

$$Z = n_{\text{Lu}} n_{\text{gr}} \pi (d_{\text{Lu}} + d_{\text{gr}})^2 \sqrt{v_{\text{Lu}}^2 + v_{\text{gr}}^2}. \quad (1)$$

n_{Lu} and n_{gr} are number densities of Lu atoms and perovskite grains, d_{Lu} and d_{gr} are the sizes of the Lu atom and the perovskite grain the v 's are the

Figure 9. Refractory elements in bulk Allende, a Type B inclusion with uniform enrichment factors (about 20), and a fine-grained inclusion with a Group II pattern. These patterns reflect solid-gas equilibrium after removal of a super-refractory component (see Fig. 2 for volatilities of refractory elements). Sources of data: Cosmochemistry, Max-Planck-Institut für Chemie, Mainz (unpublished).

corresponding mean velocities, given by

$$v = \sqrt{8 \frac{kT}{\pi m}}. \quad (2)$$

The time between two encounters of Lu atoms with perovskite grains is $1/Z$ and the lower limit in time for accumulating as many Lu atoms as would correspond to the Ti atoms in the perovskite grain, assuming a chondritic Ti/Lu ratio, is $(1/Z)cl_{Ti}(a_{Lu}/a_{Ti})$ where a_{Lu} and a_{Ti} are the cosmic abundances of both elements and cl_{Ti} is the number of Ti atoms in a $1 \mu\text{m}$ grain of perovskite. With some simplification, such as unity sticking coefficients and no consideration of depletion of the gas in Lu during condensation, a time of 4 days for Lu condensation on perovskite is obtained for a temperature of 1600 K and a pressure of 10^{-4} bar. Because of the assumptions made, this should be considered a lower limit only. After condensation of Lu and other trace elements, additional time is required for the perovskite grains to have been removed, perhaps by settling to the midplane, so that the other refractory elements could condense on other phases and produce the peculiar Group II pattern.

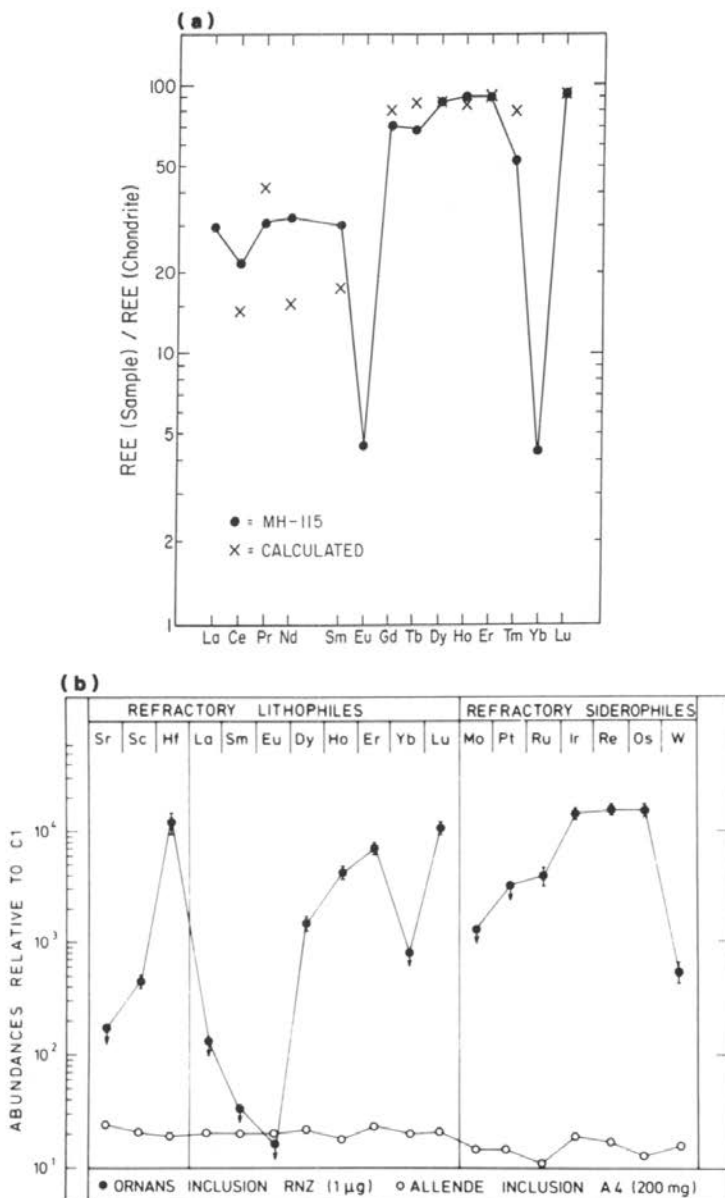

Figure 10. (a) Super-refractory pattern in a spinel-hibonite inclusion from Murchison. (b) Super-refractory pattern of a tiny (1 μ g) grain in Ormans. These patterns are complementary to the Group II pattern in Fig. 9 and are thought to represent the most refractory material that was isolated from the gas before Group II inclusions began to condense.

Ireland et al. (1988) have shown that the Group II pattern is commonly found in very refractory mineral grains, such as hibonite and perovskite from the Murchison meteorite. The time significance for formation of components carrying the Group II pattern may be similarly constrained because similar times are needed to grow the Group II grains yet leave in the gas the less refractory elements, such as Eu and Yb. The equilibrium distribution of refractory trace elements between gas and solids thus requires a rather slow cooling from high temperatures (days to perhaps years).

It is therefore clear that rapid heating, provided by lightning for example, is not a suitable mechanism for explaining these gas-solid equilibria. In some of the refractory grains analyzed by Ireland (1990), isotope anomalies were found, suggesting that interstellar grains may have acted as condensation nuclei. Ireland et al. (1990b) analyzed the isotopic composition of lead in perovskite grains and found ages of around 4.56 Gyr, indicating that these are solar nebula products, at least heated at that time to temperatures required to completely vaporize lead.

There is good evidence that refractory metals (Re, Os, Ir, etc.) condensed as alloys in the solar nebula. Tiny refractory metal grains either contain all refractory metals in chondritic relative proportions or they have a volatility-dependent pattern of refractory metals, suggesting a condensation origin. An origin as evaporative residue is less likely. Under moderately oxidizing conditions W and Mo will be lost from the alloy, because both elements form volatile oxides. Conditions during evaporation are likely to be more oxidizing than a solar gas as stated before. There are inclusion and metal grains with depletions in W and Mo. Fegley and Palme (1985) have, however, argued that even these grains formed by condensation, but under more oxidizing conditions than assumed for the solar nebula.

A similar, simplified calculation as the one indicated before was made for the time required to condense these alloys (see Palme and Wlotzka [1976] for details). For example, for the growth of an Os cluster with a diameter of $10\text{ }\mu\text{m}$ by collisions of Os atoms with the growing cluster a time of 1500 yr is calculated for a pressure of 10^{-4} bar and a temperature of 1600 K. The corresponding time for growing $1\text{ }\mu\text{m}$ and $0.1\text{ }\mu\text{m}$ grains are 150 and 15 yr, respectively. These times are longer than those calculated for condensation of Lu, simply because in the Lu case we have assumed that existing perovskite grains capture the Lu atoms, while in the Os case the metal-clusters are built up by addition of single Os atoms. As there is evidence that refractory metals condense as alloys, Os is used in the calculations as representing all refractory metals. In a few cases, the isotopic composition of some of the refractory metals has been determined (Hutcheon et al. 1987). No anomalies larger than 1% were found, suggesting that the alloys are solar nebula products.

2. Isolated Olivine Crystals. There are other coarse-grained components in carbonaceous chondrites that may be linked to condensation. Forsterite is the first major Mg silicate to condense from a cooling gas of solar composition. Isolated FeO-poor olivine grains found in CM, CV and CO chondrites

have indeed morphologies and trace-element contents that strongly suggest a condensation origin (Steele 1988, and references therein). Recent data on the oxygen isotopic composition of forsteritic cores showed that they are rich in ^{16}O and different from chondrules (Weinbruch et al. 1989), excluding formation of forsteritic olivine grains inside chondrules, thus supporting a condensation origin. Without making detailed calculations, it is clear that time scales of at least days are needed to produce these 100 to 1000 μm objects (Fig. 11).

3. Oxidizing Conditions in the Solar Nebula. The FeO contents of even the most Mg-rich olivines, however, are still too high for condensates from a gas of solar composition (Wood 1985; Kring 1991b; Palme and Fegley 1990). These olivines must have condensed from a gas considerably enriched in oxygen compared to a solar gas. Still higher oxygen partial pressures are required for the formation of broad (10 μm) rims of FeO-rich olivine commonly observed in Allende. There is now a large body of evidence suggesting that these rims formed by condensation in an environment far more oxidizing than generally assumed for the solar nebula (Peck and Wood 1987; Kring 1988; Hua et al. 1988; Weinbruch et al. 1990). Condensation of the FeO-rich rims must have occurred rapidly to retain the sharp boundary (steep compositional gradient) between FeO-rich and FeO-poor lithologies (Fig. 11). The FeO-poor olivine grains were either transported into a region of the nebula that had higher oxygen partial pressure or a gas more enriched in oxygen arrived at the location of these mineral grains. A high-temperature formation at oxidizing conditions for FeO-rich matrix grains was earlier postulated by Kornacki and Wood (1984).

Additional evidence for oxidizing conditions at high temperatures is recorded in Ca, Al-rich inclusions from type 2 and 3 carbonaceous chondrites (see Rubin et al. [1988] for a comprehensive discussion):

- a. Some inclusions have a negative Ce anomaly. Lack of condensation of Ce can be explained by gas-solid equilibrium at high temperatures and oxidizing conditions (Boynton 1978b; Davis et al. 1982).
- b. Among the first phases to condense in a gas of solar composition is a refractory metal alloy containing W, Os, Ir, Ru, Mo, etc. Such alloys were observed in Ca, Al-rich inclusions (see, e.g., Palme and Wlotzka 1976), but many of these inclusions have lower W and Mo contents than expected. The deficit of Mo and W can be explained by high-temperature condensation in an oxidized gas (Fegley and Palme 1985).
- c. Similarly, oxidation of existing metal alloys led to formation of tungstate and molybdate. There are good reasons to assume that this process occurred at high temperatures (Bischoff and Palme 1987).

These examples should demonstrate that the high-temperature stage experienced by mineral grains and metals was not caused by a local fast-heating event, such as impacts or lightning. In these cases, it is unlikely that the

Figure 11. Single olivine grain (~ 0.3 mm diameter) from the Allende meteorite. The sharp transition from the FeO-poor interior (dark) to the FeO-rich rim (bright) reflects late condensation of FeO-rich olivine under oxidizing conditions (see text). Several earlier episodes of oxidation are reflected in the variable brightness of the interior, reflecting variable FeO- contents (SEM-image, S. Weinbruch).

temperature would have stayed high sufficiently long to enable equilibrium distribution of trace elements between gas and solid, and furthermore, there is not enough time to form solid condensates that were either removed later or are still present as refractory metal alloys.

Direct evidence for evaporation processes is provided by the isotopic fractionation of Si and Mg in some inclusions from the Allende meteorite (Clayton et al. 1985). The enrichment of heavy isotopes of Mg and Si in these inclusions is most likely the result of preferential evaporation of the light isotopes. This process most likely requires liquid residual phases where isotopic equilibrium is possible, as demonstrated for olivine by Davis et al. (1990). Therefore, temperatures near or above the liquidus temperatures are necessary. These temperatures may be as high as 1700° C. Also the time for evaporation must be comparatively slow to allow isotopic re-equilibration in the residual liquid. In many cases complex processes of evaporation and condensation are required to produce the observed fractionations of Si, Mg and Ca (Clayton et al. 1985).

At this point, it must be emphasized that, contrary to general belief, only

a small fraction (20–30%) of the refractory elements in the type 3 carbonaceous chondrites are residing in Ca, Al-rich inclusions or minerals. The major fraction of refractories is sited in a very fine-grained component, intimately associated with olivine, as chemical data on grain-size fractions from the Allende meteorite have shown (Ireland et al. 1990a). The fine-grained mixture of olivine, chromite, sulfide and refractory phases may have formed by rapid condensation, reflecting fast cooling, quite different from conditions experienced by large mineral grains and coarse inclusions discussed before. Because the oxygen isotopic composition of the coarse-grained high-temperature materials and the fine-grained matrix material are also different, two separate reservoirs are required for the formation of both components, at least with respect to oxygen.

4. Chondrule Formation. As most of the processes discussed above are restricted to Ca, Al-rich inclusions in carbonaceous chondrites, a relatively small fraction of the bulk meteorites is actually involved. Another high-temperature event, the formation of chondrules, has affected major fractions of most chondritic meteorites. Chondrule formation may, however, be different from processes discussed above in that heating and cooling may be much faster than estimated for gas-solid equilibria. The extent of Si isotopic variations in Allende chondrules is, for example, six times smaller than that observed in Ca, Al-rich inclusions (Clayton et al. 1985), suggesting a shorter heating period for chondrules. Estimates by Hewins (1988) indicate chondrule formation temperatures of up to 1600 K and cooling rates from 100 K to 2000 K hr⁻¹, too slow for cooling by radiation into space but faster than the time scale of Ca, Al-rich inclusions discussed above. It is therefore likely that the chondrule-forming process records a different event than the high-temperature gas-solid equilibria.

In addition, there is good evidence that the formation of chondrules affected pre-existing compositionally heterogeneous matter, suggesting that the formation of chondrules occurred later, after solid solar system material was formed by condensation processes (see, e.g., Grossman 1988). This suggestion is supported by the rather high contents of alkali elements in Allende chondrules. Na and K must have condensed in order to be associated with solid chondrule precursors, and most models for chondrule formation assume solid coarse-grained precursor materials. Chondrule formation, therefore, is likely to be caused by a transient heat source which locally transformed assemblages of mineral grains into melt spherules, and thus chondrule formation must have occurred some time after condensation of moderately volatile elements. Attempts to date chondrule formation, relative to the formation of other meteorite components, by the I-Xe method have not been successful. It can only be stated that components of unequilibrated meteorites formed within about 10 Myr of each other (Swindle and Podosek 1988).

5. Formation of Refractory Rims on CAIs. A much more rapid heating event may have also affected many Ca, Al-rich inclusions from Allende. This event is the flash heating that formed rims on most of the coarse-grained CAIs.

Like the chondrule formation process, this process also acted on pre-existing matter, but it is not clear what relationship, if any, this heating event has to the formation of the CAIs.

Wark and Lovering (1977) showed that most coarse-grained CAIs are surrounded by thin $\sim 50\ \mu\text{m}$ rims that are made up of several layers of different minerals. Many speculations were advanced on the origin of these rims including several episodes of condensation (Wark and Lovering 1977), crystallization from a thin layer of melt (Bunch and Chang 1980a; Wark 1981; Korina et al. 1982), metasomatic alteration (MacPherson et al. 1981; Nord et al. 1982), and nonequilibrium condensation (Korina et al. 1982; Wark 1983), but each of these mechanisms has difficulties in explaining the data.

Boynton and Wark (1987) showed that the rims were enriched in refractory elements by uniform factors of 3 to 6 relative to the interior of the CAIs. An important observation was that the chondrite-normalized patterns of the refractory element patterns in the rim were always identical (except for the uniform enrichment ratio) to that of the underlying CAI. This was true even for CAIs in which the underlying pattern was formed as a Group II condensate from a refractory-depleted nebular gas or was formed as an igneous fractionation product. Because the rims reflected the elemental abundances in the original CAIs, it was clear that they formed from the interior, and because they were more refractory, it was clear they formed by heating with the loss of the more volatile elements such as Mg and Si. Finally, because the rims were thin, and the rest of the CAI seemed unaffected by the event, it must have been brief—on the order of a few seconds at most.

Murrell and Burnett (1987) considered six different possibilities for the origin of rims on CAIs but did not choose a preferred mechanism. They did not endorse the flash-heating hypothesis of Boynton and Wark (1987) because they felt it would not account for the Mg isotopic data of Fahey et al. (1987), who showed that the $^{26}\text{Mg}/^{24}\text{Mg}$ ratio was higher in the rim than in the interior of a CAI from Efremovka—in the opposite direction to that expected from volatilization during the flash heating. An important part of the Mg data not considered by these groups was the fact that the $^{26}\text{Mg}/^{24}\text{Mg}$ ratio in the rim had the normal solar system value, but that the interior was lower than normal. The flash-heating hypothesis, however, predicts that most of the Mg was lost from the proto-rim during the vaporization event, and that a later metasomatic diffusion, which formed the different layers now observed in the rim, was the source of the rim-sited Mg. The normal Mg isotopic composition of the rim is thus expected if the metasomatic reservoir had normal Mg isotopic composition.

Boynton (1988) calculated that the time scale was, indeed, about one second or less and showed that the energy required to vaporize enough mass to account for the observed enrichments of refractory elements was about $300\ \text{J cm}^{-2}$. He also noted the difficulty in providing this heat source in an astrophysical environment. Heating by photons, electromagnetic discharge, and atmospheric entry were considered and dismissed. Recently, Morfill et

al. (see their Chapter) showed that lightning, if it can occur, has both the appropriate time scale and energy flux to account for the rim observations.

IV. DISCUSSION AND SUMMARY

The inner part of the solar system, including most of the asteroid belt, was heated to temperatures of about 1300 K at the beginning of the formation of the solar system. The evidence is derived from the low volatile-element contents of meteorites and planets, possibly caused by dissipation of gas during condensation. There is no evidence for systematic variations in volatile-element contents with heliocentric distance. Variations in Fe-metal and in Mg/Si ratios among meteorites and planets, require separation of components that formed at high temperatures, similar to those necessary to produce the volatile-element variations.

Midplane temperatures obtained from theoretical modeling of planetary formation by Tscharnuter and Boss (see their chapter) are about 1500 K in the inner nebula with a flat profile and a steep gradient at a distance of 4 AU where temperatures drop to 150 K. These results were calculated for a time when the central protosolar mass had reached $0.84 M_{\odot}$. The upper temperature limit in this model is determined by the stability of metallic iron through a buffering effect caused by reduction in opacity on the evaporation of silicates and iron grains.

It is obvious that there is some agreement between constraints derived from meteoritic evidence and the calculated temperature profiles. It may be mere coincidence. However, both temperatures are associated with the stability of the major phase forsterite and metallic iron and the only elements affected are those with condensation temperatures below the condensation temperatures of the major phases. During the high-temperature stage and later cooling, uncondensed nebular gas could be blown out of the inner part of the nebula, producing the reduction in partial pressure required by the low contents of volatile elements.

In contrast to this global picture, temperatures and oxygen partial pressures inferred from individual components in meteorites, particularly in the unequilibrated carbonaceous chondrites, reflect local environmental conditions. Fractionations among refractory elements indicate temperatures up to 1800 K. Time scales required to establish the gas-solid equilibria range from days to years.

Similarly high temperatures but much faster cooling is registered by the melting of chondrules. Even faster and more sporadic events are recorded in sudden melting of rims of Ca, Al-rich inclusions. These violent events may have been caused by lightning (Chapter by Morfill et al.).

CHEMISTRY AND EVOLUTION OF GASEOUS CIRCUMSTELLAR DISKS

RONALD G. PRINN

Massachusetts Institute of Technology

The chemical and physical processes which determine the composition and evolution of gas-rich circumstellar disks are discussed. The composition of accreted interstellar material is an important determinant of subsequent chemical evolution. Elemental composition (e.g., C and O abundances) and molecular composition (e.g., N_2 vs NH_3 and hydrous vs anhydrous silicates) are both significant in this respect. Major disk chemical processes are thermochemistry (not necessarily equilibrium) and shock chemistry (during accretion and by lightning). Strong mixing in a thermoclinic environment like an accretion disk leads to thermochemical disequilibrium due to "kinetic inhibition" induced by chemical time constants becoming longer than outward mixing (or equivalently cooling) time constants. In this case, species thermodynamically stable at high temperatures but not at low temperatures (e.g., CO, N_2) dominate at all temperatures in the disk. Nonaxisymmetric accretion of material at hypersonic speeds is a major forcing mechanism for mixing in the disk and can produce eddy speeds of 1% of the sound speed. Typical resulting mixing times for trace species are about 10^{10} s compared to a typical disk lifetime of 10^{13} s. Nonlinear processes yield much longer mixing times for momentum than for trace species. Kinetic inhibition in the carbon, nitrogen and anhydrous/hydrous silicate families has major implications for the compositions of the terrestrial planets, giant planets, ice-rich satellites, Pluto, comets, meteorites and asteroids which are discussed. Ice-rich bodies in the outer solar system have rock-to-ice ratios which can be explained by formation in either the CO- and hydrocarbon-rich circumsolar disk or a CH_4 - and CO-rich circumJovian planetary disk with some post-formation ice loss being required in some cases. The CO, CH_4 , NH_3 and H_2O abundances in comet Halley can be explained by its formation in the circumsolar disk. Observations of key species like CO, CH_4 , NH_3 and H_2O in gaseous circumstellar disks could provide important information about these disks (and thus about the original circumsolar gaseous disk).

I. INTRODUCTION

The advancement of our understanding of the chemistry of the gaseous and dusty circumsolar nebular disk in which the planets formed has been guided traditionally by a combination of observations of the composition of the planets, planetary satellites, meteorites and comets together with development of *a priori* models of the circumsolar disk. More recently, astronomical observations of circumstellar disks have begun to provide an important new

source of information on disk structure and constraints on both circumsolar and other circumstellar disk models.

In view of the interdisciplinary goals of this book, this chapter will focus more on the general principles determining the composition and chemistry of gas-rich circumstellar disks. A more specific (and very detailed) discussion of the chemistry of the circumsolar nebula already exists (Prinn and Fegley 1989) and these details will not be repeated here. However, the conclusions in the latter paper will be updated where necessary, based on more recent results.

As a preface to the chapter it is useful to paraphrase the principal conclusions from Prinn and Fegley (1989):

1. The starting materials for forming the circumsolar disk were gases and grains in interstellar clouds.
2. As the circumsolar gaseous disk formed and evolved, these gases and grains were at least partially reprocessed with the greatest reprocessing occurring near the proto-Sun.
3. Thermochemical reactions (using thermal energy and shock heating) constitute the major chemical processing mechanism.
4. The gas-rich and later dust-rich circumsolar disk was highly opaque limiting severely the influence of ultraviolet radiation from the proto-Sun in chemically processing the body of the disk.
5. The reduction of N_2 and CO to NH_3 and CH_4 was kinetically inhibited in the circumsolar disk but not in higher pressure disks like circumJovian planetary disks. Thus the circumsolar disk was rich in N_2 and CO (and organics formed from it) while the circumJovian planetary disks were rich in NH_3 and CH_4 .
6. Vapor-phase hydration of silicates is kinetically inhibited in the circumsolar disk but not in circumJovian planetary disks.
7. Regular satellites can form in circumJovian planetary disks with distinctly different compositions than bodies formed in the circumsolar disk.
8. Thus certain volatile ratios (e.g., CO/CH_4 , N_2/NH_3 , H_2O ice/silicate) in ice-rich bodies are diagnostic of their origin.
9. After dissipation of the gaseous circumsolar disk, collisions between objects formed in the circumsolar disk and those formed in circumJovian planetary disks imbedded within it are inevitable and can lead to hybrid heterogeneous objects.

This chapter attempts to generalize the above ideas about the circumsolar nebula disk to other circumstellar nebula disks by addressing the underlying chemical and physical processes. There are five sections devoted respectively to: chemical theories; chemical-dynamical theories (kinetic inhibition); comparison between theory and planetary, satellite observations; comparison between theory and observations of comets, meteorites and asteroids; and finally key new astrophysical observations to test and extend current theories.

II. CHEMICAL PROCESSES

A. Initial Composition and Its Relevance

The *elemental* composition of a circumstellar disk (or equivalently its precursor interstellar cloud) is obviously important in determining the chemical state of the disk. Observations of the gaseous component of dense interstellar clouds show a complex mixture of hydrogen-, oxygen-, carbon-, nitrogen-, and sulfur-containing compounds while observations of the dust component suggest the presence of various silicates, magnetite, carbon-containing compounds (including graphite), and water ice. As reviewed by Irvine and Knacke (1989), hydrogen and helium are generally dominant in interstellar clouds with oxygen, carbon, neon and nitrogen being of the order of 10^{-4} to 10^{-5} by number of the H abundance and silicon, magnesium, sulfur and iron being of the order of 10^{-6} of the H abundance. Two estimates of the elemental abundances in a solar composition medium are given in Table I. In this chapter we will denote the number density of an element or compound i by $[i]$.

TABLE I^a
Ratios Relative to H₂ of the Ten Most Abundant
Elements in Solar Composition Material

	Anders and Grevesse	Cameron
H ₂	1.0	1.0
He	0.195	0.135
O	1.17×10^{-3}	1.38×10^{-3}
C	7.24×10^{-4}	8.35×10^{-4}
Ne	2.47×10^{-4}	1.95×10^{-4}
N	2.24×10^{-4}	1.74×10^{-4}
Mg	7.70×10^{-5}	7.97×10^{-5}
Si	7.17×10^{-5}	7.52×10^{-5}
Fe	6.45×10^{-5}	6.77×10^{-5}
S	3.69×10^{-5}	3.76×10^{-5}

^a Table uses the abundance estimates of Anders and Grevesse (1989) and Cameron (1982).

Certain elemental ratios are extremely important in defining the disk chemistry. In particular, if carbon equals or exceeds oxygen, the majority of the oxygen can end up as CO leading to: relatively very low H₂O (vapor or ice) abundances (Lewis and Prinn 1980); an excess of carbon leading to abundant graphite and hydrocarbons; and very reducing conditions leading to formation in thermochemical equilibrium of CaS, Fe₃C, MgS, SiC and TiN (Larimer 1975). Conversely, if oxygen significantly exceeds carbon (as it did on the average for the circumsolar nebula), H₂O (vapor or ice) is abundant even if essentially all the carbon is in CO (Lewis and Prinn 1980) and the oxidation state of the nebula is much higher making minerals such as SiC

thermochemically unstable if [O] exceeds [C] by more than 10% (Larimer 1975).

The [C]/[O] ratio also potentially affects the density of ice-rich condensates in circumstellar disks through its control of the H₂O to silicate ratio. For the circumsolar nebula disk the precise [C]/[O] ratio is controversial with Anders and Grevesse (1989) and Stone (1989) reporting the solar [C]/[O] ratio ≈ 0.42 and Cameron (1982) recommending [C]/[O] ≈ 0.60 . If CO is the dominant C compound ([CO]/[C] ≈ 1) and if we model anhydrous rock as SiO₂, MgO, FeO and FeS, then the ratio of the oxygen abundances in CO, H₂O and anhydrous silicates (i.e. [CO]:[H₂O]:2[Si] + [Mg] + [Fe] - [S]) is 3.2:1.1:1.0 for [C]/[O] = 0.60 and 2.9:3.0:1.0 for [C]/[O] = 0.42. Thus there is 3.0/1.1 = 2.7 times more water available for forming ice-rich bodies when [C]/[O] = 0.42 than when [C]/[O] = 0.60. Water availability is also sensitive to the oxidation state of carbon because if [CO]/[C] ≈ 0 (i.e., CH₄ and/or organics are the major forms of carbon), then [CO]:[H₂O]:2[Si] + [Mg] + [Fe] - [S] is 0.0:4.3:1.0 for [C]/[O] = 0.60 and 0.0:5.9:1.0 for C/O = 0.42. Thus there is 4.3/1.1 = 3.9 ([C]/[O] = 0.6) or 5.9/3.0 = 2.0 ([C]/[O] = 0.42) times more water available for forming ice in a CH₄-rich or organic-rich region than in a CO-rich region.

The *molecular* composition and *physical state* of interstellar material collapsing onto the disk are also important in determining the susceptibility of this material to chemical processing during accretion and later processing within the disk. Highly refractory solid material (e.g., Al₂O₃, CaTiO₃, Ca₂MgSi₂O₇, Fe-Ni alloy, Mg₂SiO₄) is more likely to survive than less refractory solid material (e.g., graphite, hydrated silicates, polycyclic aromatic compounds, FeS) and both are much more likely to survive than volatile solids (H₂O ice, NH₃·H₂O, CH₄·7H₂O, CO·6H₂O). Survival of solids will also depend on grain size, and on whether compounds are in crystalline or amorphous states. In the gas phase, strongly bound molecules like N₂ are more likely to survive processing than more weakly bound species like NH₃. Some of the organic material in some meteorites may be unaltered interstellar material and one certainly expects a greater probability for survival of such unaltered material in bodies in the least explored outermost regions of the solar system, particularly comets.

B. Energy for Chemical Reactions

Potential sources of energy to drive chemical reactions include the internal thermal energy of the disk, shock heating due to impact of hypersonic interstellar material accreting onto the disk, lightning discharges and thundershocks associated with convection in the disk, ultraviolet photons from the central protostar and the surrounding proximal stars, and very high energy photons and particles from decay of radioactive elements (especially ²⁶Al) in the disk. As discussed by Prinn and Fegley (1989), it is useful to compare the usable energy fluxes ϕ available from the various sources to drive chemical reactions to the net outward flux $\phi_T = sT_e^4$ in the disk where s is Stefan's constant and

$T_e(R)$ is the effective temperature of the disk at radius R . For conditions at $R = 1$ AU in the circumsolar nebula disk they compute

$$\phi(\text{thermal})/\phi_T \approx \exp(-E/NkT) = 4 \times 10^{-5} \quad (1)$$

$$\phi(\text{thundershock})/\phi_T \approx 4 \times 10^{-6} \quad (2)$$

$$\phi(\text{solar photons})/\phi_T \approx 10^4 \times F \exp(-\tau)/\phi_T \approx 0 \quad (3)$$

$$\phi(\text{stellar photons})/\phi_T \approx 10^{-9} \quad (4)$$

$$\phi(\text{radioactivity})/\phi_T \approx 3 \times 10^{-12} \quad (5)$$

where $E = 5 \times 10^4$ J/mole is a typical activation energy of a chemical reaction quenching at $R = 1$ AU, k is Boltzmann's constant, N is Avogadro's number, τ is the optical depth for solar ultraviolet photons between the proto-Sun and radius R , and F is the present-day solar ultraviolet energy flux at $R = 1$ AU. Evidently for these five energy sources, thermal energy dominates at 1 AU except for reactions with very large E (for which thundershocks could be significant). Solar photons (due to the very large τ value resulting from abundant H_2O , dust, etc., in the disk) and radioactivity (due to the low abundance of ^{26}Al) are negligible at 1 AU. As we approach the proto-Sun ($R \ll 1$ AU) thermal energy dominates even more while thundershocks become relatively more important further from the proto-Sun ($R \gg 1$ AU). Stellar photons are unimportant for $R \leq 1$ AU but could be relatively significant for $R \geq 10$ AU. Very close to the protoSun ($\tau \approx 0$, $R \approx 0$), protosolar ultraviolet photon fluxes will be very large but due to the large opacity, the photons are absorbed wholly in the very hot (temperature $\gg 2500$ K) relatively dense innermost part of the gaseous disk. Here, large thermochemical reaction rates involving abundant thermally produced atoms, free radicals, electrons and ions will generally overwhelm the dissociative and ionizing effects of the ultraviolet photons. For this purpose, efficient thermal ionization requires temperatures about 1000 K greater than thermal dissociation. We note parenthetically that protosolar photons emitted in directions other than into the disk (e.g., in polar directions) may suffer little or no absorption and therefore be remotely observable. Thus observations of ultraviolet emissions from T Tauri stars do not provide evidence for photochemistry driven by photons from the central star occurring other than in the innermost regions of a protosolar-type gaseous disk.

The sixth energy source mentioned above, namely shock heating during accretion onto the disk, was not considered quantitatively by Prinn and Fegley (1989). To obtain a measure of the intensity of the shock heating which can occur, we use here the Hugoniot shock relation in an ideal polytropic gas (see Courant and Friedrichs 1976) to obtain the temperature T_s of the shocked disk

gas relative to the temperature T_o of the pre-shocked gas

$$\begin{aligned}
 T_s &\approx T_o[\mu^2(1 - M^{-2}) + 1][\mu^2(M^2 - 1) + 1] \\
 &\approx 1031 \text{ K}(\mu^2 = 0.18, T_o = 60 \text{ K}, R = 10\text{AU}) \\
 &\approx 1847 \text{ K}(\mu^2 = 0.17, T_o = 120 \text{ K}, R = 5\text{AU}) \\
 &\approx 8224 \text{ K}(\mu^2 = 0.16, T_o = 600 \text{ K}, R = 1\text{AU})
 \end{aligned} \tag{6}$$

where μ^2 is the average over the interval between T_o and T_s of the gas constant divided by the sum of the heat capacities at constant volume and constant pressure, $M \approx 22$ is the Mach number of the shock front which we equate to the Mach number of the free falling impacting interstellar material, and T_o is a representative solar nebula temperature profile allowing ice condensation in the Jovian formation region. Note that because the free fall speed varies as $R^{-0.5}$, the sound speed varies as $T_o^{0.5}$ and T_o varies approximately as R^{-1} , then the latter Mach number is independent approximately of distance R . Evidently, the disk gas (and to a lesser extent the lower-temperature-impacting interstellar gas) is intensely shock heated for $R \leq 1$ AU but only mildly shock heated for $R \geq 10$ AU. Thus, quite apart from any subsequent processing within the disk, the disk accretion process itself probably led to significant thermochemical reprocessing of disk (and to a lesser extent impacting interstellar) material inside $R = 10$ AU. Depending on the relative magnitudes of the mass per unit area (in the direction of impact) for the accreting gas mass and the nebula disk, the accreting material will be decelerated and force strong mixing near the surface of the disk or throughout its thickness. Chemical reprocessing will occur in both the region of deceleration and beyond this region through propagating shock waves.

C. Equilibrium Products of Thermochemical Reactions

The *potential* products of thermochemical reactions are conveniently summarized by addressing the predicted composition in *thermochemical equilibrium*. As discussed later, such equilibrium is possible only if the relevant cooling time (dynamical or radiative) for the gas exceeds the relevant chemical reaction times and it is thus most likely to occur at high temperatures in the disk where reactions are fast (e.g., near the protostar or in a region shock heated by an impact or lightning). Figures 1, 2 and 3 illustrate how three key ratios CO/CH_4 , N_2/NH_3 and CO_2/CO vary in thermochemical equilibrium as a function of pressure and temperature in a gas with solar H, O, C and N ratios. Sample disk adiabatic pressure-temperature profiles are shown for the circumsolar nebula disk (Lewis and Prinn 1980) and the circumJovian planetary nebula disk (Prinn and Fegley 1981). Pressure-temperature profiles for any arbitrary near-solar-composition circumstellar disk may also be drawn on these diagrams to illustrate the composition of these disks if thermochemical equilibrium is attained. Similarly, shock heating of the disk gas can be illustrated on these diagrams by imagining a temporary excursion of

Figure 1. Thermochemical equilibrium $\log_{10} ([\text{CO}]/[\text{CH}_4])$ values in a solar composition medium with $[\text{C}]/[\text{O}] = 0.6$. Also shown are illustrative temperature-pressure profiles for the circumSolar and circumJovian disks and the quench temperature T_q for homogeneous (gas-phase) conversion of CO to CH_4 assuming an upper limit for $t_{\text{mix}} = 10^{13}$ s. Heterogeneous (iron-catalyzed) conversion is possible between the lines designating the iron condensation temperature labeled “Fe(s,liq)” and the temperature where oxidation of Fe to FeO is complete, labeled “FeO complete.”

the shocked gas up an adiabat (as shown) or up a shock-Hugoniot (which would be closer to vertical than the adiabats shown) to higher temperatures and pressures. Evidently, for all these near-adiabatic temperature-pressure profiles the transition to higher temperatures and pressures is accompanied by a shift of the three major equilibria

to the right to yield CO, N_2 and CO_2 until temperatures become high enough (≥ 3000 K) for atomization and ionization to begin. In addition, the equilibria

Figure 2. As in Fig. 1 but for the $[N_2]/[NH_3]$ ratio and conversion of N_2 to NH_3 .

also shift to the right for $T \leq 3000$ K yielding trace amounts of HCN, C_2H_2 and C_2H_6 (see, e.g., Prinn and Fegley 1989, Figs. 5, 6, 9, 10). Figures 1–3 use a $[C]/[O]$ ratio of 0.6 and are quantitatively but not qualitatively altered for $[C]/[O] = 0.42$.

The equilibrium composition of solid materials under circumstellar disk conditions is also of considerable interest (see Fig. 4). At sufficiently high temperatures, silicates exist in anhydrous forms (olivine $(Fe,Mg)_2SiO_4$; pyroxene $(Fe,Mg)SiO_3$; etc.) and Fe exists as the metal or (as FeO) in olivines and pyroxenes. As the temperature is lowered, Fe oxidation to FeO which is incorporated into olivines and pyroxenes and to FeS which forms troilite depletes this metal, specifically

Figure 3. As in Fig. 1 but for the $[\text{CO}_2]/[\text{CO}]$ ratio and conversion of CO to CO_2 .

Also, as the temperature is lowered further, hydration of olivines and pyroxenes to form hydrated silicates like serpentine and talc and hydroxides like brucite occur. For example,

Because these latter hydrated silicates and hydroxides are 8 to 16% by weight H_2O they lower the density of the rock material in equilibrium from about 4 g cm^{-3} (anhydrous) to 3 g cm^{-3} (hydrated).

At even lower temperatures (Fig. 4), the following transitions occur in order: H_2O condenses as ice; NH_3 (the major form of N in equilibrium) condenses as the hydrate $\text{NH}_3 \cdot \text{H}_2\text{O}$; CH_4 (the major form of C in equilibrium) condenses as the clathrate $\text{CH}_4 \cdot 6\text{H}_2\text{O}$; and finally, excess CH_4 condenses as the pure solid.

For both the gas and condensed phases, we emphasize again that the rates of the above conversions must be fast relative to changes in temperature and pressure for the thermochemical equilibrium products to be relevant. As discussed in the next section, this condition is not always met.

Figure 4. Thermochemical equilibrium stability fields for condensed solid material in a solar composition medium. Also shown are illustrative temperature-pressure profiles for the circumsolar and circumJovian disks.

III. DYNAMICAL-CHEMICAL PROCESSES

Chemistry circumstellar disks is profoundly influenced by sufficiently strong circulation and mixing if it occurs in the disk. Mixing processes in disks are often discussed in the context of a standard model (see, e.g., Pringle 1981; Lin and Papaloizou 1985; Morfill et al. 1985). This model parameterizes the radial angular momentum flux which is fundamentally quadratically nonlinear in velocity solely by a gradient eddy or viscous diffusion expression which is linear in velocity. This simplification (or oversimplification) has enabled conclusions to be reached by simply choosing a viscosity which ensues evolution of the disk on the observed time scale (10^5 to 10^6 yr). A particular difficulty arises when this viscosity is considered applicable also to the transport of trace materials in the disk.

There are arguments (albeit not universally accepted) favoring strong trace material mixing in the circumsolar disk and by analogy probable strong mixing in other circumstellar disks. First, there is considerable observational evidence for extensive inner circumsolar nebular mixing and reprocessing contained in chondritic meteorites. Specifically, these meteorites are an inhomogeneous mixture of materials (chondrules, refractory inclusions, matrix)

which formed in distinctly different nebula environments in which they underwent varying degrees of condensation, vaporization and recondensation (see, e.g., review by Wood 1988). Formation of this mixture requires strong mixing of these materials with different histories (although the timing and spatial scale of the mixing is ill defined in part because the separation of these nebula environments is unknown).

Second, the time scale for mixing can be much shorter than the time scale for disk evolution because basic nonlinear acceleration processes enable the shear in an accretion disk to be maintained against viscous dissipation (plus gravitational torques if applicable), so that trace constituents in these disks can be well mixed without momentum being well mixed (Prinn 1990). Stevenson (1990) presents an opposing viewpoint. He concludes that momentum and trace constituents are approximately equally (and in this context both weakly) mixed. These arguments are based on an acceptance of the standard model which as discussed above neglects the nonlinear (in velocity) nature of momentum transport compared to the linear (in velocity) nature of trace material transport. Prinn (1990) argues that the poor trace constituent mixing predicted in accretion disk models which omit nonlinear processes is an artifact of this omission. This is almost certainly true when the system is externally forced by the disk accretion process but the Stevenson (1990) case cannot be ruled out when accretion ceases. An important question to be answered is, therefore, whether the material which formed the present solar system was defined while accretion onto the disk was still proceeding or afterwards.

Third, as we discuss in Sec. III.B, the disk accretion process itself provides an important and perhaps dominant forcing mechanism for strong mixing.

A. Kinetic Inhibition Models

The major effect of strong mixing in the disk is to cause chemical disequilibrium. The so-called “kinetic inhibition” theory for thermochemical disequilibrium induced by rapid mixing in a thermoclinic environment was first proposed by Prinn and Barshay (1977) to explain the unexpected discovery of CO in the CH₄-rich Jovian atmosphere. It was later applied also to the circumsolar nebula disk (Lewis and Prinn 1980) and to circumplanetary disks around the Jovian planets (Prinn and Fegley 1981). The disequilibrium results specifically when the cooling time due to transport in a medium with a temperature gradient becomes shorter than the relevant chemical reaction time for maintaining equilibrium.

In a hot thermoclinic environment like a gaseous circumstellar disk one can define for each chemical species a quench radius (R_q) inside which the temperatures are high enough (and thus thermochemical reactions fast enough) to ensure that the species concentration $[i]$ is essentially equal to that in thermochemical equilibrium (see Fig. 5). To a sufficient approximation R_q is the radius at which the chemical destruction time $t_{\text{chem}} = -[i]/(d[i]/dt)$ for the species equals the radial mixing time t_{mix} . Also, since temperature, pressure and hence $[i]/t_{\text{chem}}$ generally decrease with altitude z above the disk plane,

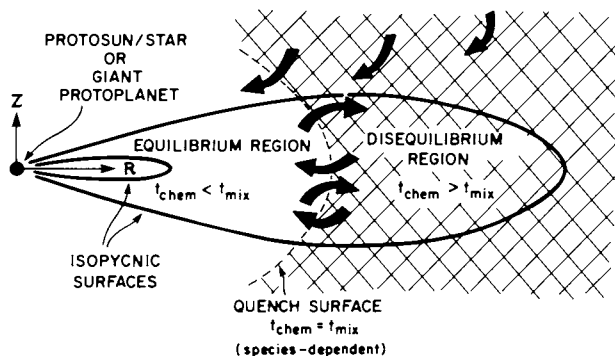

Figure 5. Illustration of the species-dependent quench surface separating thermochemical equilibrium and transport-induced-disequilibrium regions in gaseous circumsolar or circumJovian planetary disks.

the equilibrium region bounded by the quench surface is convex as shown in Fig. 5. We use the mixing ratio form of the species continuity equation in cylindrical coordinates in the region $R > R_q$ with the assumption that the gas is quenched chemically by moving outward a distance l_{chem} from R_q which is much less than the characteristic length L of eddy circulations in the disk. This leads to the solution that the mixing ratio f in the disequilibrium region ($R > R_q$) equals approximately the equilibrium value of f at the quench radius R_q (see Eqs. (13)–(18) of Prinn and Fegley [1989] for details). This latter solution is the one appropriate to reactions with large activation energies such as the conversions of CO to CH₄ and N₂ to NH₃ in the hydrogen-rich circumsolar nebula disk. Referring back to the thermochemical equilibrium calculations in Figs. 1 to 3, the general approach is to compute t_{chem} values for the relevant conversion using equilibrium concentrations and then to compare them to estimates of t_{mix} (see next section). Then we define the quench radius to be where $t_{\text{chem}} = t_{\text{mix}}$. The temperature at the quench radius is referred to as the quench temperature T_q and it is often more convenient to define the quench position in the disk by T_q rather than R_q . Sample T_q values defined by considering only homogeneous gas-phase conversion reactions to define t_{chem} and equating t_{mix} to the approximate lifetime of the circumsolar disk (10^{13} s) are shown in Figs. 1 to 3. The actual t_{chem} values are shorter (lowering T_q) than the homogeneous ones due to heterogeneous catalysis reactions on Fe particles but this is countered by the t_{mix} values also being less than 10^{13} s (raising T_q). The importance of knowing t_{mix} is clear and in the next section we deduce t_{mix} values for a disk mixed by eddies forced by nonaxisymmetric accretion of interstellar material.

B. Accretionally Forced Turbulence

The forcing of turbulence in circumstellar accretion disks by the infalling ma-

terial itself has been recognized by Cameron (1978*a*) and Prinn (1990), but it has not been quantified and indeed has received remarkably little attention. As summarized by Prinn (1990), the thermodynamics of accretion involves the conversion of the initial gravitational potential energy into kinetic energy (mostly orbital but some radial). Next, a large fraction of the kinetic energy is converted into internal (thermal) energy by compression or frictional dissipation as the accreting material collides and merges with the gaseous disk. Some of the latter thermal energy is then lost by radiation to space and some is converted back to kinetic energy by various internal instabilities. Convective instability has received some attention but there are many other instabilities (baroclinic, barotropic, etc.) yet to be considered. However, these internal instabilities cannot reduce the temperature gradient or the absolute temperature to zero and they are capable therefore of converting only a very small fraction of the internal energy back to kinetic energy. Hence the production (through internal instabilities) of disk kinetic energy from disk internal energy is expected to be considerably less than the production of disk kinetic energy (through accretion) from initial gravitational potential energy (Prinn 1990). An approximate estimate of the speed in eddy circulations forced in the disk by accretion is provided here by considering the eddy angular momentum equation in cylindrical polar coordinates for the disk (Prinn 1990, Eq. 4):

$$\frac{1}{R} \frac{\partial}{\partial R} (R^2 \sigma \langle V'U' \rangle) + R \sigma \langle V \rangle \frac{1}{R} \frac{\partial}{\partial R} (R \langle U \rangle) = R (\langle U_a \rangle - \langle U \rangle) \left(\frac{d\sigma}{dt} \right)_a \quad (21)$$

where R is the radius, σ is the surface density, $(d\sigma/dt)_a$ is the rate of change of σ due to accretion, V and U are the radial and azimuthal components of velocity, respectively, U_a is the azimuthal velocity of infalling material, t is time and $\langle i \rangle$ and i' denote, respectively, the azimuthal average and deviation from this azimuthal average of the quantity i . Assuming the radial advective flux is small relative to the radial eddy flux of azimuthal (angular) momentum, equating $\langle U_a \rangle - \langle U \rangle$ to the product of the free-fall velocity $(2GM/R)^{1/2}$ of accreting material and a constant α of order unity, and neglecting any small radial dependence for σ , we have:

$$\frac{2}{R} \langle V'U' \rangle + \frac{\partial}{\partial R} \langle V'U' \rangle = \frac{\alpha}{\tau} \left(\frac{2GM}{R} \right)^{1/2} \quad (22)$$

where $\tau = (d \ln \sigma / dt)^{-1}$ is the evolution time for mass in the disk. Assuming in Eq. (22) the scaling relations $\langle V'U' \rangle \approx v^2$ and $\partial \langle V'U' \rangle / \partial R \approx v^2 / L$ where v and L are the characteristic speed and length scale of the eddy circulations, we obtain the following simple expression for the eddy speed

$$\begin{aligned} v &= \left[\frac{GMR\alpha^2}{2\tau^2(1+R/2L)^2} \right]^{1/4} \\ &= 18 \left(\frac{M}{M_s} \right)^{1/4} \left(\frac{R}{R_o} \right)^{1/4} \left(\frac{\tau_o}{\tau} \right)^{1/2} \alpha^{1/2} (1+R/2L)^{-1/2} \end{aligned} \quad (23)$$

in m s^{-1} where M_s is the mass of the Sun, $R_o = 1 \text{ AU}$, and $\tau_o = 10^{13} \text{ s}$ is the approximate lifetime of the gaseous circumsolar disk. The nominal eddy speed (v_o) of $18/(1 + R/2L)^{1/2} \text{ m s}^{-1}$ is $0.95\%/(1 + R/2L)^{1/2}$ of the sound speed in H_2 (1900 m s^{-1} at 600 K). For all L exceeding about $5 \times 10^{-3}R$ this speed equals or exceeds the maximum speed expected from free convection in the disk (Cabot et al. 1987b). This v_o also implies nominal radial eddy mixing times $t_{\text{mix}} = R_o/v_o$ of $6 \times 10^9/(1 + R/2L)^{1/2} \text{ s}$. Thus for all L exceeding about $4 \times 10^{-7}R$, $t_{\text{mix}} < \tau_o$ so that the disk is well mixed. Finally, we note parenthetically that the advective velocity $\langle V \rangle$ estimated by equating the right-hand side of Eq. (21) to the second (rather than the first) term on the left-hand side and using the Keplerian velocity for $\langle U \rangle$ is

$$\begin{aligned}\langle V \rangle &= 2^{3/2} \frac{\alpha R}{\tau} \\ &= 0.04 \frac{R \tau_o}{R_o \tau} \alpha \text{ m s}^{-1}\end{aligned}\quad (24)$$

which is evidently much less than the eddy speed v .

C. Kinetic Inhibition Results

The quench points for the conditions in Figs. 1 to 3 are located at the intersections of the disk temperature profiles and the quench temperature curves. Remembering that the species mixing ratios at the quench points determine the ratios at all points exterior to them (i.e., at all $T < T_q$ or all $R > R_q$), we conclude from Figs. 1 and 2 that $[\text{CO}] \gg [\text{CH}_4]$ and $[\text{N}_2] \gg [\text{NH}_3]$ for all T in the circumsolar nebula disk. Conversely, $[\text{CH}_4] \gg [\text{CO}]$ and $[\text{NH}_3] \gg [\text{N}_2]$ in the circumJovian planetary nebula disk. From Fig. 3, $[\text{CO}_2]$ is 0.2 to 1% of $[\text{CO}]$ in both disks but as $[\text{CO}]$ is negligible in the circumJovian planetary disk, it is only in the circumsolar disk that CO_2 becomes an important carbon-containing compound. These conclusions from the above simplified approach using Figs. 1 to 3 are qualitatively similar to the conclusions from the more detailed approaches which take into account both homogeneous and heterogeneous (catalyzed) reactions and a wide range of feasible mixing times (Lewis and Prinn 1980; Prinn and Fegley 1981; Prinn and Barshay 1977; Prinn and Olaguer 1981; Prinn and Fegley 1989).

The chemical lifetimes and quench temperatures for formation of hydrated silicates (e.g., serpentine, tremolite in Fig. 4) in the solar nebula have been considered by Prinn and Fegley (1989). They conclude that even the simple hydration (reaction 19) of $0.1 \mu\text{m}$ radius forsterite (Mg_2SiO_4) grains has $t_{\text{chem}} \geq 10^{18} \text{ s}$ (which certainly exceeds t_{mix} and even exceeds the lifetime of the solar system) at the 225 K temperature at which its hydration to serpentine and brucite becomes thermodynamically possible in the circumsolar nebula disk. Formation of tremolite from hydration of enstatite plus diopside at around 500 K and of serpentine from hydration of enstatite plus forsterite at around 350 K requires solid-solid diffusion leading to even longer t_{chem}

times. Tremolite is in any case a minor predicted mineral in the nebula and rare in meteorites. The anhydrous silicates accreted onto the circumsolar disk or produced from thermal reprocessing of accreted interstellar hydrated silicates are expected therefore to be very stable in the disk. In contrast, Fegley and Prinn (1989) conclude that the 100 K higher temperatures (325 K) and 10^5 times greater H_2O concentrations at the serpentine formation point in the circumJovian disk mean that $t_{\text{chem}} \approx 10^9$ s which may feasibly be faster than the mixing time due to convection in this disk. Thus unlike in the circumsolar disk, the formation of hydrated silicates may not be kinetically inhibited in the circumJovian disk.

Fegley and Prinn (1989) discussed for the solar nebula the conversion of Fe to FeS (in troilite) and FeO (in olivine and pyroxene) and concluded that FeS formation is not kinetically inhibited at the FeS stability point (≈ 690 K) whereas the oxidation of Fe and its incorporation into magnesium silicates was almost certainly kinetically inhibited. In this case, the excess Fe not converted to FeS could thermodynamically begin to react with H_2O vapor at about 380 K to form magnetite (Fe_3O_4) but laboratory data are not available to determine if this reaction is not also inhibited.

The kinetic inhibition of the $\text{N}_2 \rightarrow \text{NH}_3$, $\text{CO} \rightarrow \text{CH}_4$ and anhydrous \rightarrow hydrous silicate transitions in the circumsolar disk but not in the circumJovian planetary disks means that low-temperature condensation of ice-rich phases in the two disks are distinctly different (Lewis and Prinn 1980; Prinn and Fegley 1981). In the solar disk, we expect at successively lower temperatures formation of anhydrous rock, H_2O ice, NH_4HCO_3 salt, $\text{NH}_4\text{COONH}_2$ salt, CO_2 (dry) ice, $\text{CO} \cdot 6\text{H}_2\text{O}$ clathrate, $\text{N}_2 \cdot 6\text{H}_2\text{O}$ clathrate, CO solid and N_2 solid. Conversion of some of the CO through Fischer-Tropsch-type reactions to involatile carbonaceous compounds (condensing at higher temperatures than ice) and light hydrocarbons and hydrocarbon clathrates (condensing coincident with or at lower temperatures than ice) is also possible particularly if the metallic Fe catalyst required is not completely oxidized or sulfurized as discussed above or de-activated by organic coatings. If volatilization of interstellar involatile carbonaceous compounds was kinetically inhibited during accretion shock heating and within the circumsolar nebula disk then this would add to the involatile carbon component.

In the circumJovian planetary disks in contrast we have the condensation sequence: hydrous rock, H_2O ice, $\text{NH}_3 \cdot \text{H}_2\text{O}$ hydrate, $\text{CH}_4 \cdot 6\text{H}_2\text{O}$ clathrate, CO solid and N_2 solid. This looks superficially like the condensation sequence if chemical equilibrium prevailed in the circumsolar nebula but on closer examination it is clearly recognized as different due to the presence of some C and N as CO and N_2 . The significant differences between the circumsolar and circumJovian planetary condensation sequences which are summarized in Table II lead to the conclusion that low-temperature condensates in ice-rich bodies may be diagnostic of the type of nebula disk in which they formed (Prinn and Fegley 1981).

Certain caveats concerning the formation of the clathrates in the above

TABLE II^a
Condensation Sequences Predicted in the Circumsolar Gas-Dust Disk and CircumJovian Planet Gas/Dust Disk^b

CO-Rich	Circumsolar Disk	CO + Hydrocarbons	CircumJovian Planet disk CH ₄ -Rich
Largely anhydrous rock ^c	Largely anhydrous rock ^c Involatile carbonaceous compounds ^(e,f)		Largely hydrous rock ^d
H ₂ O (150 K)	H ₂ O		H ₂ O (235 K)

^a Prinn and Fegley 1989.

^b Condensation temperatures in models (Lewis and Prinn 1980; Prinn and Fegley 1981) are given for each condensate where available. For the circumsolar disk the CO-plus-hydrocarbons sequence is preferred with the condensation temperatures being slightly below those in the CO-rich case (the precise temperatures will depend on the degree of CO to hydrocarbons conversion).

^c Olivine, pyroxene, troilite, unoxidized Fe, feldspar, etc.

^d Serpentine, talc, magnetite, troilite, tremolite, etc.

^e These compounds contain $\leq 10^{-2}$ of the total C or N.

^f Exemplified by organic material in chondrites, and formed by nebular Fischer-Tropsch-type reactions and/or of interstellar origin.

^g Exemplified by the light (C₁-C₃) hydrocarbons formed as initial products in high H₂; CO environments (see Prinn and Fegley 1989). Precise condensation or enclathration temperature depends on the chain length and hydrocarbon abundance.

^h There is insufficient H₂O to allow condensation of all C and N as CO and N₂ clathrates.

sequences are in order. For the Anders and Grevesse [C]/[O] ratio and even more so for the Cameron [C]/[O] ratio, there is insufficient H_2O to enclathrate the majority of the CO let alone the N_2 in the circumsolar disk. Lunine and Stevenson (1985) give theoretical arguments and Davidson et al. (1987) give experimental evidence that $\text{CO}\cdot 6\text{H}_2\text{O}$ is more stable than $\text{N}_2\cdot 6\text{H}_2\text{O}$ so the latter clathrate may be very rare indeed. Similar difficulties exist for CO and N_2 clathrates in circumJovian planetary disks where there is insufficient water to enclathrate even the majority of the CH_4 . Fegley and Prinn (1989) also point out possible kinetic inhibition of clathrate formation in the circumsolar (but not circumJovian planetary) disk unless the activation energy for diffusion of gas into the ice is very small. Lunine (1989*b*) argues in reply that this activation energy is indeed small. However, if for CO one equates it (arguably) to the recently reported binding energy for CO on H_2O ice ($14.5 \text{ kJ mole}^{-1}$; Sandford and Allamandola 1990*b*) this is indeed large enough to cause $\text{CO}\cdot 6\text{H}_2\text{O}$ formation to be kinetically inhibited in the circumsolar nebula. Specifically, we compute $t_{\text{chem}} = 1.6 \times 10^{17} \text{ s}$ for conversion of ice particles ($2 \mu\text{m}$ dimension) to $\text{CO}\cdot 6\text{H}_2\text{O}$ at its formation temperature of about 60 K in the circumsolar nebula (Table II). Conversely, this large activation energy would lead to efficient *adsorption* of CO on ice provided the ice is sufficiently *amorphous* to expose a large enough surface area to enable [CO]/[H_2O] stoichiometries like the 1/6 value in the clathrate to be realized. This may be the way in which CO was incorporated into ice to explain its presence in comets. Note also that the salts ammonium bicarbonate (NH_4HCO_3) and ammonium carbamate ($\text{NH}_4\text{COONH}_2$) will enable up to 1% of the solar abundances of C and N to be incorporated into ice.

IV. PLANETS AND SATELLITES

The amounts of H, O, C and N in the terrestrial planets, giant planets, satellites of giant planets, Pluto/Charon, and comets provide crucial tests of theories of their origin. This subject is thoroughly discussed by Prinn (1982), Lewis and Prinn (1984), Prinn and Fegley (1987, 1989) and Lunine (1989*a, c*) so here we present only a brief summary and update (the latter focusing on recent observations of ice-rich satellites and comets).

A. Terrestrial Planets

It has been understood ever since Urey (1952) proposed the idea (based on evidence such as the observed depletion of noble gases like Ne relative to reactive elements like N) that the volatile elements on the terrestrial planets originated not from accretion of disk gas but from accretion of disk solids (before and after disk gas dissipation). Fegley and Prinn (1989) and Prinn and Fegley (1987) review the evidence that the major source of carbon and some hydrogen in the terrestrial planets was accretion of material rich in organic compounds (e.g., of the type produced from CO by Fischer-Tropsch reactions) with thermochemical equilibrium sources like carbon dissolved in Fe-Ni alloy

being secondary. This argues in favor of the CO plus hydrocarbons sequence in Table II. The small amount of nitrogen in these planets is easily provided by the same organic compounds. As noted earlier, the kinetic inhibition of hydrous silicate formation in the circumsolar nebula makes the most likely source of H₂O for the terrestrial planets to be accretion of ice-rich material in the post-gas-rich phase of the circumsolar disk (this material could also include hydrous minerals formed in asteroid-sized bodies once these evolved).

B. Giant Planets

It is also well understood that the giant planets are composed of circumsolar disk gases plus additional solid material either contained in a precursor core or accreted later during both the gas-rich and post-gas-rich epochs (see the review by Pollack and Bodenheimer [1989]). Prinn and Fegley (1989) conclude that the solid material must have been 9 to 30% (Jupiter) and 3 to 12% (Saturn) carbon by mass to explain the bulk properties and atmospheric composition of these two planets. This also argues in favor of the CO plus hydrocarbons sequence in Table II because the CO-rich sequence has insufficient carbon at the formation temperatures for Jupiter and Saturn which certainly exceeded 60 K. Similar conclusions for large carbon inputs pertain to Uranus and Neptune with the organic carbon content of the added solid material being at least comparable to the carbon in (solid or clathrate) carbon monoxide (Pollack et al. 1986; Fegley and Prinn 1986; Simonelli et al. 1989).

C. Ice-Rich Satellites and Pluto

The ice-rich satellites of the outer planets and Pluto provide a wealth of significant information on the circumsolar nebula disk. The information refers not only to the outer regions of the nebula disk but also to inner regions as kinetic inhibition of $\text{CO} \rightarrow \text{CH}_4$, $\text{N}_2 \rightarrow \text{NH}_3$, and anhydrous rock \rightarrow hydrous rock, and catalytic conversion of CO to light or heavy hydrocarbons are inner nebula processes impacting the composition of outer nebula objects (Lewis and Prinn 1980; Prinn and Fegley 1981, 1989; Lunine 1989*a, c*).

Using observations and models for satellite interiors, Johnson et al. (1987), Johnson (1990), McKinnon and Mueller (1988, 1989), and Simonelli et al. (1989) have computed the ratio $r = (\text{rock mass})/(\text{rock mass} + \text{ice mass})$ in various ice-rich bodies in the outer solar system and these are shown in Fig. 6. To compare with these "observed" r values, we have computed models for a variety of kinetic inhibition scenarios and for the C and O abundances A_{C} and A_{O} (measured relative to $A_{\text{Si}} = 10^6$) of both Anders and Grevesse (1989) and Cameron (1982). We model the rock as $\text{SiO}_2 + \text{MgO} + \text{FeO} + \text{FeS}$ (i.e., anhydrous) and noting the similarity of the Si, Mg, Fe and S abundances of Anders and Grevesse (1989) and Cameron (1982), we use the average of these two abundance estimates for these latter 4 elements. We consider carbon in three forms: CO (noncondensing), light hydrocarbons including CH₄ (noncondensing), and heavy hydrocarbons (condensing). We model the heavy condensing hydrocarbons as CH₂ and add them to the ice mass in the

Figure 6. Ranges of $r = (\text{rock mass})/(\text{ice plus rock mass})$ for ice-rich bodies in the solar system deduced from observations by Johnson et al. (1987; filled circles), Johnson (1990; open circles), Simonelli et al. (1989; crosses), McKinnon and Mueller (1988; filled triangles) and McKinnon and Mueller (1989; open triangles). Also shown are predicted r values for condensates in a CO-rich solar-composition environment (solid horizontal lines) and a CH₄-rich solar-composition environment (dashed horizontal lines). Predictions are shown for solar C and O abundances from Cameron (1982; labeled "C") and from Anders and Grevesse (1989; labeled AG). The dot-dashed horizontal lines at $r = 0.52$ and $r = 0.70$ are predictions from a variety of models discussed in the text.

definition of r . We define the mole fractions of total carbon in CO, light hydrocarbons, and heavy hydrocarbons as α , $1 - \alpha - \beta$, and β , respectively. Thus the CO-rich nebula of Lewis and Prinn (1980) has $\alpha \approx 1 - \beta$, $1 - \alpha - \beta \approx 0$, and $\beta < \alpha$ (allowing for some conversion of CO to heavy hydrocarbons by Fischer-Tropsch-type reactions). Conversely the CH₄-rich nebula of Prinn and Fegley (1981) has $\alpha \approx 0$, $1 - \alpha - \beta \approx 1$, and $\beta \approx 0$, respectively.

With the above definitions, we obtain

$$r = 9.755 \times 10^6 [A_O - \left(\alpha - \frac{14}{18} \beta \right) A_C + 6.296 \times 10^6]^{-1}. \quad (25)$$

Note that r does not depend on the $[C]/[O]$ ratio A_C/A_O alone but on the separate values of A_O and A_C .

In Fig. 6, we see distinctly lower values of r for the satellites of Jupiter, Saturn and Uranus ($r \approx 0.52$) than for Triton, Pluto and Charon ($r \approx 0.7$). For A_C and A_O from Anders and Grevesse (1989), we could approximately explain the Jovian, Saturnian and Uranian satellites as objects formed in a CO-rich ($\alpha = 1$, $\beta = 0$) solar nebula disk but must then rely on *ad hoc* explanations

(e.g., massive post-formation water loss) to explain Triton, Pluto and Charon. Conversely for A_C and A_O from Cameron (1982), we could easily explain Triton, Pluto and Charon as objects formed in a CO-rich ($\alpha = 1$, $\beta = 0$) solar nebula disk but must then rely on *ad hoc* explanations (e.g., massive post-accretional water addition) to explain the Jovian, Saturnian and Uranian satellites.

To address this failure of the simplest models to fit the data, we can use Eq. (25) to deduce the values of $\alpha - (14/18)\beta$ which will fit the apparent r values (0.52, 0.7) of the above two classes of objects. We thus obtain for the Anders and Grevesse (1989) abundances

$$\begin{aligned}\alpha - \frac{14}{18}\beta &= 1.104 \text{ (Jovian, Saturnian, Uranian)} \\ &= 1.586 \text{ (Triton, Pluto, Charon)}\end{aligned}\quad (26)$$

and for the Cameron (1982) abundances

$$\begin{aligned}\alpha - \frac{14}{18}\beta &= 0.349 \text{ (Jovian, Saturnian, Uranian)} \\ &= 0.831 \text{ (Triton, Pluto, Charon)}\end{aligned}\quad (27)$$

As $\alpha + \beta \leq 1$, we see that for the Anders and Grevesse (1989) abundances no values of α and β will suffice (consistent with both the Anders and Grevesse values being less than 0.52 in Fig. 6).

The almost ubiquitous presence of some dark presumably carbonaceous material in ice-rich bodies in the outer solar system argues either that $\beta \neq 0$ or that the bodies contained some CH_4 which was photochemically converted to carbonaceous material (i.e., $1 - \alpha - \beta \neq 0$). Also, the presence of CH_4 on Titan, Triton (Spencer et al. 1990; Broadfoot et al. 1989), and Pluto argues either for $1 - \alpha - \beta \neq 0$ or for thermochemical conversion of organic material in object interiors to form CH_4 (i.e., $\beta \neq 0$). Therefore we can fit the observations in Fig. 6 with the Cameron (1982) abundances if we make the following reasonable assumptions: (a) the Jovian, Saturnian and Uranian satellites formed in a CH_4 -rich circumplanetary disk with the carbon being 65% CH_4 , 35% CO, and only trace amounts of heavy hydrocarbons (i.e., $\alpha = 0.349$, $1 - \alpha - \beta = 0.651$, $\beta \approx 0$), and (b) Triton, Pluto and Charon formed in a CO-rich circumsolar disk with the carbon being 90% CO, 9% heavy hydrocarbons and 1% CH_4 (i.e., $\alpha = 0.9$, $\beta \approx 0.0887$, $1 - \alpha - \beta = 0.0113$).

Alternatively, we can assume that the C and O abundances are unknowns and ask what values of A_C and A_O in Eq. (25), would allow the Jovian, Saturnian and Uranian satellites to form in very CH_4 -rich circumplanetary nebulae ($\alpha = 0$, $\beta = 0$) while Triton, Pluto and Charon formed in the CO-rich environment discussed in the previous paragraph ($\alpha = 0.9$, $\beta = 0.0887$, $1 - \alpha - \beta = 0.0113$). This requires $A_O = 1.25 \times 10^7$ and $A_C = 0.59 \times 10^7$ which are each significantly less than either the Cameron (1982) or Anders and Grevesse (1989) values. This explanation would therefore require the C

and O abundances in the circumsolar disk to be much less than the current solar values due to some unforeseen evolutionary process which seems very unlikely.

Finally, we can model the data by postulating post-formation water loss. Using Anders and Grevesse (1989) abundances, the Jovian, Saturnian and Uranian satellites could have formed in a CH_4 -rich ($\alpha=0$, $\beta=0$) environment if they subsequently suffered 56% loss of their original ice content while Triton, Pluto and Charon could be explained as being formed in a CO-rich ($\alpha = 1$, $\beta = 0$) environment if they subsequently lost 59% of their ice content. For the Cameron (1982) abundances, formation of the Jovian, Saturnian and Uranian satellites in the same CH_4 -rich environment requires 41% post-formation loss of ice while formation of Triton, Pluto and Charon in the same CO-rich environment requires essentially no post-formation water loss.

In summary, a variety of explanations can be put forward to explain the r values of ice-rich bodies. To differentiate between them, more knowledge is needed about current A_{O} and A_{C} values, the possibility, if any, of evolution of A_{O} and A_{C} over time, and mechanisms for post-formation evolution of r .

V. COMETS, METEORITES AND ASTEROIDS

A. Comets

Comets also contain important information on the circumsolar nebula disk. Prinn and Fegley (1989) concluded that the analyses of Halley observations available at that time which indicated the presence of several percent CO, a few percent CH_4 , and up to 1% NH_3 relative to H_2O could be explained by this comet being a heterogeneous mixture. Specifically, they proposed a mixture of a small amount of condensate containing CH_4 and NH_3 from a circumJovian planetary disk (Prinn and Fegley 1981) and a large amount of condensate containing CO from either the processed circumsolar disk (Lewis and Prinn 1980) or from unprocessed interstellar material. Engel et al. (1990) proposed an alternative model in which CH_4 was provided by partial conversion of CO to CH_4 in the inner circumsolar disk followed by outward mixing and the NH_3 was of interstellar origin. The Prinn and Fegley (1989) proposal involves ejection of circumJovian planetary disk material out into the solar system through (post-gas-phase) collisions but the process has not been quantified. The Engel et al. (1990) proposal requires catalysis of the $\text{CO} \rightarrow \text{CH}_4$ conversion down to temperatures of 600 to 800 K which is unlikely (Fegley and Prinn 1989), and also survival by interstellar NH_3 condensate of accretional shock heating.

Recent Halley analyses indicate that the two above proposed mechanisms for producing heterogeneous mixtures may not be necessary. Boice et al. (1990) have specifically reanalyzed the Giotto mass spectrometer data for Halley and concluded that abundant CH_4 is not required because the hydromonocarbon ions observed can be explained by the presence of heavier organic compounds (e.g., polymerized formaldehyde) on Halley. Specifically,

they conclude that CH_4 is $<0.5\%$ of CO which is consistent with its origin exclusively in the CO-rich circumsolar nebula disk (Lewis and Prinn 1980). As noted earlier, up to 1% of the solar C and N is predicted to condense as $\text{NH}_4\text{COONH}_2$ and NH_4HCO_3 in a CO-rich circumsolar disk so that provided there are no kinetic barriers to their formation these species are potential sources of NH_3 , CO_2 and HCN. Also Boice et al. (1990) note that organics could also be the sources of the HCN and inferred NH_3 in the Halley coma. Thus sources of NH_3 beyond those expected in circumsolar disk condensates may also not be required.

Finally, on the issue of interstellar material being present in comets Tokunaga and Brooke (1990) have compared infrared spectra of comets and interstellar dust and gas in molecular clouds and found significant differences in both the silicate and organic band profiles and in the relative abundances of some molecules (CH_4 , CH_3OH). They conclude that comets did not therefore form from unaltered interstellar grains in agreement with the Boice et al. (1990) conclusion.

B. Chondritic Meteorites

Chondritic meteorites provide the rare luxury of detailed laboratory chemical, physical and isotopic analyses of ancient material in the solar system. A detailed review of current knowledge is provided in a recent Space Science Series book (Kerridge and Matthews, eds. 1988). We focus here only on a few results relevant to the preceding discussion. The reader should be aware, however, that there are many detailed aspects of meteorites not easily explained by current models (e.g., origin of chondrules).

One idea which can be addressed through meteorites is whether the CO-rich nebula predicted by kinetic inhibition theory is conducive to organic synthesis. As reviewed by Hayatsu and Anders (1981), Fischer-Tropsch-type reactions in the circumsolar disk could have led to some of the organic material in these meteorites. For example, CI1 and CM2 chondrites contain organic material light in ^{13}C and carbonates heavy in ^{13}C and this pattern has been reproduced in organics and CO_2 synthesized by Fischer-Tropsch reactions from CO and H_2 (note that this has not yet been done in laboratory environments appropriate to the circumsolar disk). On the other hand, Yang and Epstein (1983) and Pillinger (1984) note that the D/H ratio in chondritic organic matter can be up to 50 times that in solar composition requiring equilibration of organic material with the major D reservoir (HD) at very low temperatures (e.g., $<100\text{ K}$). Such low-temperature equilibration is undoubtedly kinetically inhibited in the circumsolar nebula but may proceed over much longer time scales in (ionized) interstellar clouds. How much of the organic material in meteorites is circumsolar and how much is interstellar remains an open question.

Petrographic evidence (see, e.g., Barber 1985) favors an origin for the hydrous silicates found in CI1 and CM2 meteorites in environments which are expected in "asteroid-like" meteorite parent bodies but not expected in

the circumsolar disk. This is in accordance with the prediction discussed earlier that the hydration of silicates in the circumsolar disk is kinetically inhibited. Concerning the origin of the water needed to carry out hydration on the parent bodies, Bunch and Chang (1980*b*) presented water ice as a possibility. Prinn and Fegley (1989) concurred noting that the D/H ratio in the meteoritic hydrated silicates (Yang and Epstein 1983; Pillinger 1984) was consistent with (but did not demand) the source of this water being simply ice condensed at about 200 K.

C. Asteroids

Asteroids have so far been investigated only by remote sensing but these studies have already provided insight into circumsolar nebula processes. Jones et al. (1990) have recently presented results of laboratory and telescopic observations of the low-albedo outer-belt asteroids (the C, P and D asteroids between 2.4 and 5.2 AU). Some 66% of the C asteroids have hydrated silicate surfaces. In contrast, the P and D asteroids appear to have anhydrous silicate surfaces. They conclude that their data is consistent with the initial asteroidal composition being anhydrous silicates, water ice and complex organics (i.e., the expected asteroidal composition in the CO-plus-hydrocarbons sequence of Prinn and Fegley [1989] as summarized in Table II), with subsequent evolution forced by solar wind induction heating leading to selective silicate hydration reactions. The latter reactions would maximize in the nearest C asteroids and minimize in the most distant P and D asteroids thus explaining the observed variations in the degree of surface silicate hydration.

VI. CONCLUSIONS

Observations of solar system objects have already provided much significant information on the gaseous circumsolar disk environment in which they originated. Current observations of many volatile-rich bodies, though impressive in some cases, are still however insufficient to totally constrain current models. The need is great ultimately to sample and analyze unperturbed material from comets, asteroids, and ice-rich satellites as well as to continue work on remote sensing of these bodies and on meteorites. A great deal of information is contained in the trace compounds as well as the dominant compounds in these bodies. Such information may be necessary, for example, to differentiate definitively between pristine interstellar material and reprocessed disk material in these solar system objects.

Future observations of certain key chemical species in circumstellar disks obtained with sufficient sensitivity and spectral and spatial resolution could yield very significant new information about the chemistry and physics of these disks. Answers to the following key questions would be especially revealing:

1. Is the $[\text{CO}]/[\text{H}_2]$ ratio constant over the disk or does it decrease with radius due to conversion of CO to light (e.g., CH_4) or heavy hydrocarbons?
2. Is NH_3 detectable and if so is the $[\text{NH}_3]/[\text{H}_2]$ ratio constant over the disk or does it increase with radius due to conversion of N_2 to NH_3 ?
3. Are silicates in the disk in anhydrous forms (olivines, pyroxenes, feldspar, etc.) as expected in the circumsolar disk or hydrous forms (serpentine, talc, etc.)? Are there changes with radius?
4. Is iron present as the metal, as FeO in olivines and pyroxenes, or as magnetite? Are there changes with radius?
5. Is there evidence for a sudden large drop in the $[\text{H}_2\text{O}]/[\text{H}_2]$ ratio at a particular radius indicating condensation of ice? Is there evidence for the expected increase in the ratio of condensate mass to gas mass at this radius?
6. What is the $[\text{CO}]/[\text{H}_2\text{O}]$ ratio at temperatures above the H_2O condensation point in the disk? If $[\text{CO}]/[\text{H}_2\text{O}] \gg 1$ indicating reducing conditions, one would expect to find also abundant graphite and hydrocarbons and exotic minerals like SiC.

Finally, we still lack quantitative laboratory studies of the kinetics and mechanisms of a wide range of homogeneous and heterogeneous reactions (e.g., Fischer-Tropsch-type reactions) under conditions relevant to circumsolar, circumJovian planetary, and circumstellar gas-rich disks. This knowledge is essential to further development toward more realistic models of circumstellar disk chemistry.

Planetesimals and Planets

FORMATION OF PLANETESIMALS IN THE SOLAR NEBULA

S. J. WEIDENSCHILLING

NASA Ames Research Center

This chapter describes the evolution of solid particles in the solar nebula (or other circumstellar disk). Motions of bodies \lesssim km in size were dominated by gas drag rather than gravity. An original population of microscopic grains had to produce $>$ km-sized planetesimals before gravitational accretion of planets could begin. Planetesimals probably formed by coagulation of grain aggregates that collided due to differential settling, turbulence, and drag-induced orbital decay. Growth of such aggregates depended on sticking mechanisms and their mechanical properties, which are poorly understood. Their growth was aided by concentration of larger bodies toward the central plane of the disk. The nebula could remain optically thick during this process. It is unlikely that a particle layer formed by settling would undergo gravitational instability, as a small amount of turbulence (e.g., $\alpha \sim 10^{-4}$ in a convective disk) would keep the particle layer from reaching the critical density. This conclusion is independent of the particle size, as even large bodies do not effectively decouple from the gas. Even in a laminar disk, shear in the particle layer would generate enough turbulence to keep it stirred up. This shear-induced turbulence produces complex flow patterns that could result in radial transport and size sorting of particles.

I. INTRODUCTION

The most widely accepted theory of the origin of planets is that they formed by accretion from an initial population of small solid bodies, or planetesimals, in orbit about the Sun. When their orbits intersected, collisions and binding by self-gravity resulted in growth of larger bodies, which eventually reached planetary size. The usual assumption, used as the starting a point for most calculations of planetary accretion (cf. Chapter by Lissauer and Stewart), is that planetesimals had initial sizes in the range 1 to 10 km. This is large enough so that they moved in Keplerian orbits, relatively unaffected by forces other than gravity. In a dynamical sense, there was little difference between a km-sized planetesimal and a planet some 10^4 times larger. In contrast, smaller bodies were dominated by their interactions with nebular gas, while it was present. Planetesimals must have formed from smaller bodies, i.e., surviving

presolar grains and/or condensates from the gas of the solar nebula. With presently available observational techniques, dust is the dominant, perhaps only, detectable solid matter in protostellar disks and surrounding newly formed stars (see Chapter by Strom et al.). The dust is the principal source of opacity in optically thick disks. The presence of larger bodies, either planetesimals or planets, must be inferred indirectly. We cannot tell whether dust means that large bodies have not yet formed, or that they are merely hidden within a dusty cocoon.

At one time, it was generally accepted that planetesimals formed by gravitational instability. In that model, dust grains settled to the central plane of the gaseous disk, forming a layer of enhanced concentration. This dust layer became thinner until its density reached a critical value about equal to the Roche density:

$$\rho_c \simeq 3M_\odot/2\pi r^3 \quad (1)$$

where M_\odot is the solar mass, and r the distance from the Sun. At this density, the layer would become unstable to perturbations by its own self-gravity, and develop condensations with a characteristic size

$$\lambda_c \simeq 4\pi G\sigma_s/\Omega^2 \quad (2)$$

where G is the gravitational constant, σ_s the surface density of the dust layer, and $\Omega = (GM_\odot/r^3)^{1/2}$ the Kepler frequency. The mass of a condensation would be $\sim\sigma_s\lambda_c^2$; plausible values of σ_s imply that the resulting planetesimals would have sizes ~ 1 to 10 km. The quantitative aspects of this model were developed independently by Safronov (1972) and Goldreich and Ward (1973).

The simplicity of this model is appealing, but there are problems that render it untenable, at least in the extreme form of direct conversion of μm -sized dust grains to km-sized bodies by gravity alone, without any other sticking mechanism. Wetherill (1980a) warned that “. . . it would be a mistake to conclude that the solar system *must* have developed dust-layer instabilities simply because this does not require specification of sticking processes that are poorly understood, but that quite possibly may have occurred anyway.” Weidenschilling (1988) pointed out that gravitational instability depends on quiescent nebula. An extremely small amount of turbulence in the gas would prevent the dust layer from reaching the critical density; in order to do so, its thickness must be $\lesssim 10^{-6}r$. This condition implies turbulent velocities \lesssim one particle diameter s^{-1} , which are implausible for dust grains and unlikely even for macroscopic bodies. Over the last two decades both theory and observations have led away from the simple picture of the solar nebula as a passive reservoir of raw material for making planets. Rather, it was a dynamic, evolving, and sometimes violent place. Small solid bodies were more strongly affected by drag of nebular gas than by gravitational forces, and gas was probably turbulent. Formation of planetesimals must have involved some collisional sticking, at least to form bodies large enough to settle toward

the central plane and begin to decouple from the gas. In the follow sections we describe briefly some of the effects of particle/gas interaction in the solar nebula (for a fuller account, see Adachi et al. [1976], Weidenschilling [1977a,1980,1984,1988] and Nakagawa et al. [1981,1986]).

II. STRUCTURE OF THE NEBULAR DISK

A zero-order description of the solar nebula is a flattened disk of gas in orbit about the proto-Sun. The process of formation of planetesimals was dominated by the first-order corrections to this picture, i.e., the disk had a finite thickness; its mean rotation was not strictly Keplerian, and may have had turbulent motions; and most importantly, some small fraction of its mass consisted of solid matter. Present observational methods do not constrain the structures of protostellar disks at this level of detail; of necessity, the "solar nebula" described here is essentially schematic.

For simplicity we assume that the surface density Σ has a power law distribution:

$$\Sigma(r) = \Sigma_0(r/r_0)^{-n} \quad (3)$$

where Σ_0 is the value at some arbitrary radius r_0 . The masses and orbital radii of the planets are roughly consistent with $n = 3/2$ (Weidenschilling 1977b). We assume the disk's structure is in equilibrium between gravitational, centrifugal, and pressure forces. If Σ is low enough (disk mass $\leq 0.1 M_\odot$), the disk's gravity can be neglected, and the force normal to the plane of the disk is simply the vertical component of solar gravity:

$$g_z = \frac{GM_\odot}{r^2} \left[\frac{z}{r} \right] = \Omega^2 z \quad (4)$$

where z is the distance from the midplane. If the local temperature T is independent of z , then the gas pressure at the midplane is (Safronov 1972)

$$P_c = \Omega \Sigma c / 4 \quad (5)$$

where c is the mean thermal velocity of the gas molecules (nearly equal to sound velocity), and at other values of z is

$$P(z) = P_c \exp(-z^2/H^2) \quad (6)$$

where $H = \sqrt{\pi} c / 2\Omega$ is the characteristic half-thickness of the disk. Other plausible temperature profiles, e.g., adiabatic gradient in the z direction, yield similar values. Typical model disks have $H \leq 0.1r$.

Equation (5) implies a radial pressure gradient. Most disk models have both Σ and T (hence c) decreasing with r , while $\Omega \propto r^{-3/2}$. If we assume that $T(r) = T_0(r/r_0)^{-k}$, then

$$P_c(r) \propto r^{-(n+k/2+3/2)} \quad (7)$$

and $\partial P/\partial r < 0$, unless Σ actually increases with r more rapidly than $r^{(3+k)/2}$. The pressure gradient partially supports the gaseous disk against the Sun's gravity; for equilibrium, its rotation must be slightly slower than the Kepler velocity V_k . The fractional deviation is (Weidenschilling 1977a)

$$\frac{\Delta V}{V_k} = \frac{-(n + k/2 + 3/2)}{2} \frac{\Re T/\mu}{(GM_\odot/r)} \quad (8)$$

where \Re is the gas constant and μ the mean molecular weight. Thus, $\Delta V/V_k$ is of order c^2/V_k^2 , or the ratio of the thermal energy of a gas molecule to its orbital kinetic energy. This quantity is typically only a few times 10^{-3} , but even this small deviation from Keplerian rotation has important consequences for solid bodies within the disk.

A. Turbulence

The solar nebula must have been turbulent during its formation from the collapsing protostar, because of velocity discontinuities as the infalling matter struck the disk (Cassen and Moosman 1981). The infall probably did not stop suddenly, but decayed, not necessarily monotonically, over some interval. Another possible source of turbulence was a massive outflow from the proto-Sun, impinging on the surface of the disk (Elmegreen 1978b).

Some researchers (ter Haar 1950; Safronov 1972; Hayashi et al. 1985) have concluded that in the absence of such extrinsic stirring mechanisms any residual turbulence would have decayed quickly. This conclusion was based on the stability of a rotating disk against convection in the radial direction. This stability would allow a quiescent period of indefinite length, during which planetesimals, or even planets, could form. However, the concept of a laminar nebula was challenged by Lin and co-workers (Lin and Papaloizou 1980; Lin and Bodenheimer 1982; Ruden and Lin 1986), who developed a self-consistent model for turbulence driven by the differential rotation of the disk. If convection occurs normal to the plane of the disk, eddies cause the effective viscosity to be large. Shear in the viscous, differentially rotating disk causes dissipation of energy, and the resulting heating drives the convection. Lin and Papaloizou showed that the disk is unstable to convection in the z direction if it is optically thick and the opacity increases sufficiently rapidly with temperature; both conditions are met if the opacity is due to small grains suspended in the gas. The ultimate energy source for the turbulence is the disk's potential energy in the solar gravity well (viscous spreading causes a net inward flow of gas).

Published models of turbulent accretion disks generally define the turbulent viscosity $\nu_t = \alpha H c$, where α is a coefficient chosen to make this expression correct (cf. Weidenschilling 1988a). This expression is appropriate for turbulence acting on the full vertical scale (H) of the nebular gas. If H is taken to be the length scale of the largest turbulent eddies, then the maximum random velocities of gas in those eddies is of order αc , but this should

be regarded as no more than a crude estimate. Lin's early models suggested $\alpha \simeq 1/3$, with convective velocities a significant fraction of the sound speed. A more elaborate analysis of convective instability modes in a rotating disk led Cabot et al. (1987*a, b*) to conclude that likely values of α were in the range 10^{-4} to 10^{-2} , or $v_t \sim 10^{13}$ to $10^{15} \text{ cm}^2 \text{ s}^{-1}$. The corresponding turbulent velocities V_t , are $\lesssim 0.01 \text{ c}$, or less than a few tens of meters per second in the inner part of the disk, and less in the outer regions.

The size of the largest eddies is set by the dimensions of the disk. The energy in those eddies cascades through a spectrum of smaller eddies, down to a size where they are damped by molecular viscosity. Dimensional arguments (Tennekes and Lumley 1972) imply that the rate of dissipation per unit mass is of order

$$\epsilon \sim V_t^3/L \quad (9)$$

where V_t , and L are the velocity and length scales of the largest eddies. The smallest eddies have the so-called "inner scales" of velocity, length and time given by

$$\begin{aligned} u_i &\sim (\nu\epsilon)^{\frac{1}{4}} \\ \ell_i &\sim (\nu^3/\epsilon)^{\frac{1}{4}} \\ t_i &\sim (\nu/\epsilon)^{\frac{1}{2}} \end{aligned} \quad (10)$$

where ν is the molecular viscosity. On smaller scales, the flow is locally laminar, though varying with time. For example, if $V_t = 10 \text{ m s}^{-1}$ and $L = H \simeq 0.05 \text{ AU}$, then u_i, ℓ_i, t_i are respectively a few cm s^{-1} , a few hundred meters, and a few hours.

III. AERODYNAMICS OF SOLID BODIES IN THE NEBULA

The behavior of an individual solid body in the nebular gas (laminar or turbulent) is largely determined by a single parameter, its response time to the force exerted by gas drag:

$$t_e = mV/F_d \quad (11)$$

where m is the particle's mass and V its velocity relative to the gas. The drag force F_d depends on V and two dimensionless parameters, the Reynolds and Knudsen numbers. The Reynolds number Re is the ratio of inertial to viscous forces; for a particle of diameter d , $Re = Vd/\nu$. The Knudsen number Kn is defined as λ/d , where λ is the mean free path of the gas molecules. At the low gas densities in the solar nebula, λ is typically $> 1 \text{ cm}$, so Kn is large for typical grains and even aggregates of many grains. In this regime, t_e has the simple form

$$t_e = d\rho_s/2\rho c \quad (12)$$

Figure 1. View of a fractal aggregate of dimension $D \simeq 2.1$, generated by a computer model of P. Meakin (cf. Weidenschilling et al. 1989). Fluffy structures resembling this aggregate are found in laboratory studies of particle coagulation (Meakin and Donn 1988), and should have been produced in the solar nebula.

where ρ is the gas density and ρ_s is the particle's density. Expressions for t_e in other regimes are given by Weidenschilling (1977a).

Equation (12) refers to a spherical particle of diameter d . However, coagulation of solid grains does not produce spherical particles, but rather aggregates with highly irregular shapes (Fig. 1). Such structures have fractal-like properties, i.e., their bulk densities decrease with increasing size (Meakin and Donn 1988), with $\rho_s \propto d^{D-3}$, where D is the fractal dimension of the aggregate. Particle aggregates typically have $D \simeq 2$, so density varies inversely with size. In the regime of large Kn , t_e is proportional to the ratio of particle mass to its projected area. Computer models by P. Meakin (cf. Weidenschilling et al. 1989) give the mass/area ratio for fractal aggregates with $D \simeq 2$ shown in Fig. 2. As one would expect, a low-density aggregate of irregular shape is more strongly coupled to the gas (has smaller t_e) than a dense, compact body with the same mass. The larger cross section also means that the opacity due

Figure 2. Mass/area ratio (or response time t_e) for aggregates of different fractal dimension D , vs number of grains (or mass). $D = 3$ corresponds to a spherical particle of constant density. Aggregates with $D \simeq 2$ have larger cross sections and smaller t_e , i.e., are more closely coupled to the gas by drag forces than are compact particles of the same mass.

to grains remains relatively high, despite their coagulation.

Solar gravity affects the particle's motion on a time scale of $1/\Omega$, the inverse of the Kepler frequency. If $t_e < 1/\Omega$, drag force dominates and the particle moves with the angular velocity of the gas. A solid body is not supported by the pressure gradient in the gas, and so there is a residual gravitational force in the radial direction. The particle drifts radially inward (relative to the gas) at a terminal velocity

$$V_r = -2\Omega t_e \Delta V. \quad (13)$$

Similarly, the vertical component of solar gravity (Eq. 4) causes a particle at distance z from the central plane to settle vertically at a rate

$$V_z = -\Omega^2 z t_e. \quad (14)$$

A sufficiently large body has $t_e \gg 1/\Omega$; its motion is dominated by gravitational forces. Such a body follows a Keplerian orbit, moving faster than the gas. This "headwind" of magnitude ΔV causes the orbit to decay. A circular orbit of semimajor axis a decays at a rate

$$V_r = da/dt = -2\Delta V / (\Omega t_e). \quad (15)$$

The radial velocity has a maximum value of ΔV when $t_e = 1/\Omega$ (Weidenschilling 1977a). Bodies of different sizes (or t_e) have relative velocities that are readily found from Eqs. (13–15). Effects of drag on eccentric and inclined Keplerian orbits are discussed by Adachi et al. (1976).

In addition to these systematic motions induced by the nebula's non-Keplerian rotation, particles may have other motions driven by turbulence in the gas. The relevant parameters controlling their behavior are the response time t_e , the inner time scale of the turbulence t_i , and the turnover time of the largest eddies, t_0 . If $t_e < t_i$, a particle is effectively coupled to all motions of the gas, down to the smallest eddies. If $t_e > t_0$, it is decoupled from the turbulence at all scales, and can cross the largest eddies. For intermediate values of t_e , the particle responds to eddies larger than some size between the smallest and largest scales. The smallest scales are given by Eqs. (10), while in a rotating system it is generally a good assumption that $t_0 \sim 1/\Omega$.

Diffusive transport of particles relative to the mean (nonturbulent) component of gas flow is accomplished mainly by the largest eddies. The viscosity ν_t due to gas turbulence can be expressed as $\bar{v}^2 t_0$, where \bar{v}^2 is the mean square of the fluctuating part of the gas velocity, and t_0 is the mean eddy mixing time. A particle acquires its random velocity v_p by drag interactions with fluid eddies, described by the equation $\dot{v}_p = (v - v_p)/t_e$. Because $\dot{v} \sim v/t_0$, v_p/v should depend on the time scale ratio t_e/t_0 , known as the Stokes number (Crowe et al. 1985, 1988). The Schmidt number is defined as $Sc \equiv \bar{v}^2/\bar{v}_p^2$ and, by analogy with the fluid viscosity, a particle diffusion coefficient $D = \nu_t/Sc$ may be written \bar{v}_p^2 , where \bar{v}_p^2 is the mean square fluctuation of the particle velocity (see Appendix below). Safronov (1972) assumed that $t_0 \simeq 1/\Omega$, and also argued that a particle would build up a typical velocity $v_p = V_t/(1 + t_e/t_0)$, implying $Sc = (1 + t_e/t_0)^2$. A more careful analysis, including averaging over a size spectrum of rotating eddies, indicates that the Schmidt number becomes simply (Völk et al. 1980)

$$Sc = 1 + t_e/t_0$$

or

$$v_p = V_t/(1 + t_e/t_0)^{\frac{1}{2}}. \quad (16)$$

For small Stokes numbers, Sc is near unity since the particles respond to the eddies almost immediately, like the fluid molecules themselves. The Schmidt number becomes large at high Stokes numbers because of the reduced coupling of the particles to the eddies.

The relative velocity between two particles embedded in turbulent gas is more complex, and depends on t_0 , t_i , and the value of t_e for each particle. These relative velocities are needed to study collisions between particles and accretion that may result (Sec. V). A first solution by Völk et al. (1980) neglected the inner cutoff scale of the turbulence spectrum. An improved solution by Mizuno et al. (1988) takes this cutoff into account; its effect is to decrease the relative velocities of small grains for which $t_e < t_i$. Two bodies with the same value of t_e have no systematic relative motion, but will have nonzero relative velocities due to turbulence (small particles may have significant thermal motion as well). Relative velocities as a function of

Figure 3. Relative velocities between two particles of unit density vs size in a laminar nebula. The nebular parameters are those of the model of Hayashi et al. (1985) at $r = 1$ AU, $z = 0$: $\rho = 1.4 \times 10^{-9}$ g cm $^{-3}$, $T = 280$ K, $\Delta V = 5400$ cm s $^{-1}$. Relative motions are due to thermal motion and radial and transverse velocities induced by non-Keplerian rotation of the gas. Thermal motion dominates for $d \lesssim 0.01$ cm; relative velocities are low for equal-sized bodies.

particle size are shown in Figs. 3 and 4 for one set of nebular parameters, with the gas assumed to be either laminar or turbulent.

IV. COUPLED MOTIONS IN A PARTICLE-GAS LAYER

Goldreich and Ward (1973) recognized that if a particle layer reached a density greater than that of the gas, the particles would dominate. Their velocities relative to the gas would not be given by Eqs. (13–15); rather, the particle layer would tend toward Keplerian motion, and the gas within that layer would be dragged with it. Weidenschilling (1980) showed by dimensional arguments that such shear would be unstable, and should produce turbulence in the particle layer. Any density gradient in the z direction is too small to prevent the dust layer from becoming turbulent. This localized shear-

Figure 4. Same as Fig. 3, but with turbulence added; $V_t = 1000 \text{ cm s}^{-1}$. Bodies with $d \approx 100 \text{ cm}$ have $t_e \approx 1/\Omega$; in this size range relative velocities are $\approx V_t$ even for equal-sized bodies.

induced turbulence would occur even if the gaseous disk had no other source of turbulence, such as convection.

Nakagawa et al. (1986) developed an analytic solution for the coupled equations of motion for a two-phase inviscid system of particles and gas. The solutions are expressed as functions of the mass loading, i.e., the ratio of densities of the particle layer and the gas. To a good approximation, if the particles are small, the deviation from Keplerian motion within the layer is given by

$$\Delta V' = \Delta V / (1 + \rho_p / \rho) \quad (17)$$

where ρ_p and ρ are the space densities of the particles and gas, respectively. Nakagawa et al. assumed purely laminar motions; their solution is inappropriate if such a layer became turbulent. The presence of sufficiently large ($\gtrsim 1 \text{ cm}$) particles could cause some damping of turbulence, but it is not clear whether it is possible to have particles that are simultaneously large enough and abundant enough to damp the turbulence effectively. This question is

clearly a fruitful subject for future work.

The shear due to collective motion of the particle/gas layer becomes significant for mass loadings of order unity. Weidenschilling (1988*b*) speculated that this effect could lead to a quasi-stable, long-lived state. Formation of a layer with solids/gas mass ratio of order unity might induce enough turbulence to prevent further settling. Any decrease (increase) in layer's thickness would increase (decrease) the intensity of shear and turbulence, tending to restore its original state. It appears that the only escape from such a state would be a change in the particles themselves, i.e., coagulation into bodies large enough to decouple from the gas and settle in spite of the turbulence. This scenario needs to be tested by numerical modeling; preliminary results of such an effort are described in Sec. VI.B.

A. Viscosity in the Boundary Layer

The particle layer interacts with the surrounding gas primarily in a region of limited thickness, or boundary layer, in which the shear velocity and particle concentration vary most strongly. In a boundary layer of thickness δ surrounding the particle layer, the orbital velocity of the nebular gas changes by an amount ΔV . Shear flows with velocity scale ΔV and length scale δ develop turbulence when their Reynolds number $Re = \Delta V \delta / \nu$ exceeds a critical value $Re^* \sim 50$ to 500. The difference in orbital velocity is typically tens of meters per second and $\delta \sim 10^3$ km. For these values, the boundary layer is indeed turbulent. Thereafter the turbulent viscosity in the boundary layer becomes

$$\nu_t \sim (\Delta V \delta / Re^*). \quad (18)$$

In a system rotating at angular velocity Ω , the boundary layer thickness itself depends on the viscosity as

$$\delta \sim (\nu_t / \Omega)^{\frac{1}{2}} \quad (19)$$

leading to a crude mixing length estimate of the boundary layer viscosity:

$$\nu_t \sim \Delta V^2 / \Omega Re^{*2}. \quad (20)$$

For eddies with length scale δ , this implies turbulent velocities of order $\Delta V / Re^*$ in the boundary layer.

Shear flow has been studied in laboratories for decades, and the thickness of the boundary layer and the properties of the turbulence have been well characterized. In fact, numerical techniques now exist for modeling the structure of individual eddies and coherent structures within the turbulence. Canuto and Battaglia (1988) have derived expressions for turbulent viscosity and particle velocities that take into account anisotropic turbulence in a rotating system. However, for the purposes of modeling the nebula, homogeneous, isotropic turbulence in the shear-generated boundary layer is not a bad assumption. Several parameterizations exist for obtaining its magnitude. Champney and

Cuzzi (1990) have used two such parameterizations to study the turbulence induced by the particle layer in an otherwise laminar nebula. A simple model due to Prandtl, which is still an improvement over Eq. (20), is

$$\nu_t = C\delta^2(\nabla \times \mathbf{V}_g) \quad (21)$$

where $C \sim 0.1$ is a constant determined in the laboratory and \mathbf{V}_g is the (vector) gas velocity. In more sophisticated models in computational fluid dynamics, a “two-equation” model is often used, in which the turbulence at a point is a balance between ongoing creation and dissipation processes, and is transported as is any other quantity. This latter model may be adapted to a two-phase environment in which the particles can damp turbulence, as well as generate it by maintaining the velocity gradient. Champney and Cuzzi (1990) have made preliminary studies of the merits of these two models, and further work is underway. The overall conclusion, at present, is that in the boundary layer $\nu_t \sim 10^{10} \text{ cm}^2 \text{ s}^{-1}$. The turbulent viscosity calculated in this way for the boundary layer alone is much less than the values $\sim 10^{13}$ to $10^{15} \text{ cm}^2 \text{ s}^{-1}$ for turbulence through the entire thickness of the disk with $\alpha \sim 10^{-4}$ to 10^{-2} . The viscosity is confined to a boundary layer surrounding the particle layer, with thickness rather well estimated by Eq. (19).

Given the viscosity in the boundary layer, one may calculate the shear torque between the particle layer as a whole and the surrounding, more slowly rotating pressure-supported nebular gas. Goldreich and Ward (1973) assumed the particle layer acted as a rigid, impermeable rotating disk embedded within the gas. This situation, the Ekman problem, has been thoroughly studied in theoretical and laboratory work, and inspection of the analytical solutions leads to considerable insight into the more complex nebula problem (see, e.g., Batchelor 1967). The shear torque exerted between the disk and the fluid is

$$S = \rho \nu_t \Delta V / \delta = \rho \Delta V^2 / Re^*. \quad (22)$$

The result of this torque is a loss of angular momentum by the particle layer, which causes it to drift inwards at a rate that depends on the boundary layer’s turbulent viscosity ν_t . Goldreich and Ward considered the orbital decay of a dust layer due to shear between it and the more slowly moving gas on either side. They did not discuss the effects on the gas, possibly thinking of it as merely providing a vast reservoir of angular momentum and not significantly affected by the particle layer. Nevertheless, interesting dynamical structure is present in both the particles and the gas in this important region of interaction, driven primarily by the turbulence that the particle layer itself generates. For example, the angular momentum lost by the particle layer is transferred to the gas in the boundary layer, which must then move outward (Weidenschilling 1980). Study of these motions in more detail requires a numerical model. Such a model is described in Sec. VI.B.

V. COAGULATION AND SETTLING OF PARTICLES

For an assumed structure of the nebular disk, the expressions in Sec. III yield the velocities of particles as functions of their sizes and location. In principle, one can use these values to compute the evolution of their spatial distribution in the disk. Also, by assuming mechanical properties (i.e., whether particles stick together in collisions), the evolution of the size distribution from some assumed initial state can be computed. Of course, the spatial and size distributions are coupled, and their evolution must be calculated simultaneously. In practice, all such efforts are subject to simplifying assumptions to render the problem tractable for analytic or numerical solution.

A. Coagulation in a Laminar Nebula

Safronov (1972) derived the settling velocity of a particle (Eq. 14). Because $V_z \propto z$, the distance from the central plane decreases exponentially with an e -folding time of $(\Omega^2 t_e)^{-1}$. If there is no turbulence and the particles do not coagulate, the entire dust layer becomes thinner and denser uniformly, in homologous fashion. Safronov considered settling with coagulation, in which a single large particle falls through a field of small grains and grows by sweeping them up. If only vertical motion of the particle is considered, it can grow to a maximum size $d_{\max} = \sigma_s / 4\rho_s$, where σ_s is the surface density of the grain component of the disk. Plausible values of σ_s and ρ_s give d_{\max} of the order of a few cm. The initial growth rate of the particle is exponential with a time constant $\lesssim 4\rho c / \sigma_s \Omega^2$. It reaches d_{\max} (and $z \rightarrow 0$) in a few thousand orbital periods. Goldreich and Ward (1973) independently derived a similar result. These analytic models refer only to the first (and largest) particles to "rain out" to the central plane of the disk. Modeling the subsequent buildup of a particle layer and depletion of the smaller particles at large values of z requires numerical simulation. Nakagawa et al. (1986) described the settling and coagulation in a model that included collective effects of the particles upon the gas; i.e., ΔV varied with particle concentration. In order to make this problem analytically tractable, they had to make two mutually inconsistent assumptions: that growth was by the sweeping up of the small particles by the largest ones, and that settling was uniform, as if all particles had the same size.

Numerical models were developed independently by Weidenschilling (1980) and Nakagawa et al. (1981). These were one-dimensional models that computed the vertical distribution of particles at a given radius in the disk. The evolution of the size distribution due to coagulation was calculated in a series of levels, with mass transported between layers by settling (both assumed a laminar nebula, with transport only toward the central plane). Their results were very similar; assuming perfect sticking, a dense particle layer forms in the central plane within a few times 10^3 yr at $r = 1$ AU. The largest bodies grow to 10^2 to 10^3 cm in size, much larger than Safronov's value of d_{\max} , because the radial motion of the particles allows more growth. A modest

(but still significant) fraction of the mass of solids remains as small particles suspended in the gas to much later times (10^4 – 10^5 yr), due to their slow settling velocities. Thus, the disk could remain optically thick long after planetesimals formed. Both Weidenschilling and Nakagawa et al. assumed that settling of the large aggregate bodies would eventually result in gravitational instability of the particle layer, but neither model had fine enough spatial resolution to show this result directly. Also, they neglected the possibility of turbulence in the disk.

B. Turbulent Coagulation

Although it is widely accepted that the solar nebula passed through a stage as a turbulent accretion disk, there has been relatively little study of the consequences of turbulence for planetesimal formation. Most cosmogonical scenarios assume that planetesimals either formed despite turbulence (even values of α as large as $1/3$), or else that any turbulence eventually decayed completely, and they formed after the disk became perfectly laminar. Particle coagulation in a turbulent disk has been considered by Wieneke and Clayton (1983), Morfill (1983, 1988), Mizuno et al. (1988) and Mizuno (1989). These studies concerned radial transport of solid matter in the disk, while averaging the distribution and properties of particles vertically through the thickness of the disk. Only Mizuno computed actual size distributions of particles, rather than some effective mean size. The formation of planetesimals, whether by gravitational instability of a particle layer or direct collisional growth, appears to be intimately linked with concentration of particles toward the central plane of the disk. Thus, averaging through the disk thickness can cast little light on planetesimal formation.

Weidenschilling (1984) modeled the vertical distribution of particles at a given radius in a turbulent disk. The numerical method was based on the one-dimensional model described above (Weidenschilling 1980), but particles were allowed to settle toward the central plane only if they were large enough so that their settling velocities exceeded their turbulent diffusion velocities. The nebular model used had high turbulent velocities ($\alpha \sim 1/3$), as suggested by the convective disk models of Lin and Bodenheimer (1982). The vigorous turbulence resulted in high collision rates, and if perfect sticking was assumed, large particles would accrete much more rapidly than for a laminar disk. However, this assumption of perfect sticking seems unrealistic. If the particles were assigned plausible impact strengths, in the range 10^4 to 10^6 erg cm $^{-3}$, accretion came to a halt after a few centuries, with the largest aggregates (<1 cm in size), being destroyed in collisions as rapidly as they formed. Battaglia (1987) performed a similar calculation for the low- α disk model of Cabot et al. (1987*a, b*). He concluded that even for the lower turbulent velocities in that model nebula, unrealistically high strengths were required to allow aggregates to grow large enough to decouple from the gas and settle to the central plane.

The results of Weidenschilling and Battaglia can be readily understood

in terms of their assumptions about the collisional behavior of the particles. They assumed that for a given material there exists a critical energy density E_c , such that the target is shattered if an impact yields a higher value. For lesser impact energies, "cratering" erosion excavates and removes some amount of mass that is proportional to the impact energy; the excavated mass is then C_{ex} times the impact energy, where C_{ex} is the excavation coefficient. Then the excavated mass exceeds the projectile mass, i.e., there is net erosion, if the impact velocity V_i is $>(2/C_{ex})^{1/2}$, and net mass gain occurs at lower V_i . E_c and C_{ex} are related by the condition that there is a largest cratering impact that the target can sustain without shattering. If the largest crater contains a fraction f of the target's mass, then $C_{ex} = f\rho_s/E_c$; typically, $f \approx 0.1$ (Weidenschilling 1984).

Solid particles embedded in turbulent gas have relative velocities that increase with size, up to a maximum value roughly equal to the eddy velocity V_t for bodies with $t_e \approx t_0$. It is significant that a body of this size has velocity of $\approx V_t$ relative to *all* smaller bodies, up to those of its own size. This means that the target body will be eroded by collisions with smaller particles, losing mass rather than gaining, if V_t is $\gtrsim (2/C_{ex})^{1/2} = (2E_c/f\rho_s)^{1/2}$, or unless E_c exceeds the critical value $f\rho_s V_t^2/2$. If E_c is smaller than this value, solid bodies can never grow large enough to decouple from the turbulence ($t_e > t_0$). If E_c is $\gtrsim \rho_s V_t^2/2$, even collisions of equal-sized bodies will not disrupt them. For $f\rho_s V_t^2/2 < E_c < \rho_s V_t^2/2$, a body will grow due to impacts of much smaller bodies, but may be shattered by large impacts; its fate will depend on the size distribution of those it encounters. Taking $\rho_s = 2 \text{ g cm}^{-3}$, $f = 0.1$, we see that, e.g., $V_t = 10^3 \text{ cm s}^{-1}$ requires $E_c \gtrsim 10^5 \text{ erg cm}^{-3}$ for collisional growth to occur. This simple model explains why Weidenschilling (1984) and Battaglia (1987) required high values of E_c in order to form large bodies by collisional coagulation. For any value of E_c we can find the maximum value of turbulent velocity that allows coagulation (although lower values of V_t do not necessarily assure it, unless the particles also stick when they collide).

Similar results can be obtained for the systematic velocities due to non-Keplerian rotation of the disk. However, bodies of comparable size (or t_e) have low relative velocities. The maximum relative velocity between bodies of very different sizes is $\approx \Delta V$, so collisions always result in mass gain if $E_c \gtrsim f\rho_s \Delta V^2/2$. For typical values of ΔV ($\sim 10^4 \text{ cm s}^{-1}$ at 1 AU), growth is assured if $E_c \gtrsim 10^7 \text{ erg cm}^{-3}$. This value is quite high, of the order of values measured for solid rock (Fujiwara et al. 1989). However, the model of impact behavior was extrapolated from experiments involving solid projectiles and targets; even for these, there is some indication that impact strength does not correlate with more conventional properties such as compressive strength (Fujiwara et al. 1989). It is possible that C_{ex} is much smaller than assumed by Weidenschilling, or even zero, i.e., that fluffy aggregates stick rather than "crater" each other below some critical velocity or energy density, as in the model of Donn (1990), discussed below.

C. The Problem of Particle Sticking

The major unsolved problem is the degree to which particles stick together in collisions, and the mechanism (or mechanisms) by which they adhere. It is common experience under a wide range of laboratory condition that very small ($\lesssim \mu\text{m}$ -sized) particles stick together into larger aggregates. The dominant sticking mechanism in this size range is van der Waals bonding; this force is relatively insensitive to the compositions of the particles. Electrostatic forces may also play a role in coagulation. Weidenschilling (1980) argued that van der Waals forces alone would suffice to produce $\sim\text{cm}$ -sized aggregates of grains in a laminar nebula, where relative velocities are due to thermal motion and differential settling. This conclusion should be valid for a nebula with moderate turbulence ($\alpha \lesssim 10^{-2}$); particles in this size range are strongly coupled to the gas, so their turbulent motions are correlated and have little effect on their relative velocities.

The growth of larger bodies poses more of a problem. Relative velocities increase with size and differences in size (cf. Fig. 3), and there is a real possibility of outcomes other than sticking: rebound, erosion with net loss of mass, and even disruption of the colliding bodies. There are few relevant experimental data on the collisional behavior of weakly bonded aggregates. Weidenschilling (1988c) performed drop tests of unconsolidated pumice dust into a dust target and concluded that net mass loss would occur for impact velocities approximately $> 10^3 \text{ cm s}^{-1}$. Pinter et al. (1989) and Blum (1989) have conducted experimental collisions of sub-cm-sized fluffy aggregates at relative velocities up to a few meters per second. They found coagulation occurred with sticking probabilities of a few tens of percent. Their estimate that fragmentation would occur at relative velocities $\gtrsim 600 \text{ cm s}^{-1}$ implies impact strengths of order 10^5 erg cm^{-3} . The aggregates consisted of glass spheres bonded by a coating of hydrocarbons; their degree of similarity to actual nebular material is uncertain.

Donn (1990) argues that collisions of porous bodies would result primarily in their interpenetration, with essentially complete agglomeration up to relative velocities of $\simeq 10^3 \text{ cm s}^{-1}$, and net mass gain to $\simeq 5 \times 10^3 \text{ cm s}^{-1}$. His analysis is based mainly on the behavior of porous materials under static compression, and needs to be verified by collisional experiments. Donn assumes very high porosities, making the aggregate bodies very compressible. We note that in most solar nebula models, peak velocities relative to most other particles are reached for roughly meter-sized bodies. Thus, bodies of this size are likely to be fairly well compacted, and may not coagulate as effectively as Donn's model implies.

As seen in Figs. 3 and 4, relative velocities decrease for bodies with sizes larger than $\sim 10^2 \text{ cm}$, so if meter-sized bodies can form by collisional coagulation, then there is no obstacle to the formation of km-sized planetesimals. The crucial gap is in the centimeter-to-meter range. The collisional strengths that seem necessary for growth in this size (or velocity) range are higher than

expected for aggregates composed of small grains. There are alternatives to assuming that the aggregates are extremely strong. The relative velocities are caused mainly by differential motion due to non-Keplerian rotation of the gas. The maximum velocities are $\simeq \Delta V$, so there is less of a problem in the outer part of the disk where velocities are lower (Eq. 8). It is possible that the nebula's temperature and radial structure were such that ΔV was lower than implied by most nebular models. Less plausibly, accretion might have produced a narrow size distribution so that relative velocities of particles comprising most of the mass were less than ΔV . The most probable explanation is that a concentration of small (cm-sized?) aggregates decreased ΔV in a layer near the central plane (Eq. 17, cf. Sec. VI.B), allowing growth to proceed with lower relative velocities and minimizing collisional breakup.

VI. RECENT RESULTS OF NUMERICAL MODELS

The formation of planetesimals involves complex feedbacks between all of the processes described above, and no current model describes the full situation. Recent work has approached the problem from complementary perspectives, by emphasizing or suppressing different aspects of the problem. Below, we describe two such efforts which together paint a fairly realistic picture of, at least, the scope of possible situations. As a natural outgrowth of the discussion above, we first describe a model of particle growth by coagulation, which neglects coupling of the mean flow regimes and treats the gas eddy velocity in an *ad hoc* fashion. We then describe a complementary model of the fully coupled gas-particle flow dynamics near the midplane, which neglects particle growth and treats only a single typical particle size. The results of the two approaches are instructive and illustrate the variety of possible states in which a protoplanetary nebula might be found (possibly all, at different times). In the coagulation models, it is seen that (depending on the assumed turbulent gas velocity) a flattened state in which the particle mass density significantly exceeds that of the gas may or may not occur. In the coupled flow models, it is seen that even in a globally laminar nebula, relatively flat (thousands to tens of thousands of km vertical thickness) particle layers of mass density which exceeds that of the gas by 1 or even 2 orders of magnitude are stable against gravitational settling for particles smaller than tens of meters or so, due to shear-induced turbulence.

A. Coagulation and Settling with Turbulence

Weidenschilling has recently developed an improved code for modeling coagulation and settling in a turbulent disk. As in the earlier models (Weidenschilling 1980, 1984) this is a one-dimensional computation, with the nebula divided into a series of layers at a given radial distance. The size distribution of particles in each layer is computed as it evolves due to collisions; sources of relative velocity include thermal motion, systematic settling, and turbulence.

In contrast to the earlier models, transport between layers by turbulent diffusion is computed explicitly. Particles can diffuse upward if their turbulent diffusion velocity (cf. Eq. 16) exceeds the settling velocity (Eq. 14). The spatial resolution (number and thickness of layers) is improved over earlier work, as is the resolution of the size distribution. A complete description of the model and results is published elsewhere (Weidenschilling 1993).

Figure 5. Size distribution at different levels for a laminar nebula, at $r = 1$ AU, at the time when the solids/gas mass ratio reaches unity at $z = 0$. Numbers give values of z in units of scale height H . At the highest level, aggregates reach a maximum size $\approx 10^{-3}$ cm; the low density (4×10^{-3} times that at $z = 0$) allows rapid settling of larger particles. At $z = 0$, most of the mass is in bodies $\sim 10^2$ to 10^3 cm in size.

Because of uncertainties in the mechanisms for producing turbulence and its consequent strength, calculations are performed for “generic” turbulence. The largest eddies are assumed to have an arbitrary velocity V_t and size H , with a Kolmogorov spectrum of smaller eddies down to the appropriate inner scale (Eqs. 9 and 10). In the examples shown here, aggregate particles are assumed to have fractal properties with dimension 2.11 (Meakin and Donn 1988; Weidenschilling et al. 1989) in the size range 10^{-4} to 10^{-2} cm. At sizes > 1 cm, their density begins to increase again to a limiting value of 1 g cm^{-3} at sizes $> 10^2$ cm. The qualitative justification for this variation is that while grain assemblages formed by low-velocity collisions will be fluffy, higher-

velocity collisions of larger aggregates will cause compaction (the qualitative results are not affected by these assumptions about particle density).

Figure 6. Vertical distribution of solids/gas mass ratio with time. At $t = 0$, the ratio is assumed to be 4.2×10^{-3} , independent of z . Contour interval is 200 yr.

In these calculations and those in Sec. VI.B, the nebular parameters are taken from the model of Hayashi et al. (1985). In the two examples shown here, an initial population of single grains, all of size 10^{-4} cm, is initially uniformly mixed with the gas. Perfect sticking is assumed in order to set a lower limit on the evolution time. The calculations are carried out until the particle/gas mass ratio reaches unity at $z = 0$, at which time collective effects become important, and a different method must be used (Sec. VI.B).

Figures 5, 6 and 7 illustrate the results for a purely laminar, nonturbulent disk. Figure 5 shows the size distribution at the various levels when the solids/gas ratio reaches unity, after a model time of 1677 yr (the much longer settling time reported by Weidenschilling et al. [1989] appears to be an artifact of the coarse resolution of their size distribution). Several peaks in the

Figure 7. Cumulative distribution of normal optical thickness above a given value of z , vs time. Rosseland mean opacities from Pollack et al. (1985) are used. Opacities due to particles smaller than the peak emission wavelength are assumed proportional to the mass loading, with geometric extinction by (opaque) particles of larger size. The optical half-thickness drops from the initial value of $\simeq 800$ to $\simeq 100$ after 2000 yr, for perfect sticking of particles.

distribution correspond to sizes at which thermal motion (10^{-4} to 10^{-3} cm), vertical settling ($\sim 10^{-2}$ to 10^{-1} cm), and radial motion (~ 10 cm) dominate the collision rate. A fourth peak at 10^2 to 10^3 cm, appears at $z = 0$, where the largest bodies have settled. The changing vertical distribution of the dust/gas ratio is shown in Fig. 6, through most of the disk; the solids are depleted by $\simeq 1$ order of magnitude in this time. Figure 7 shows the distribution of the optical thickness.

Turbulence with velocity of 10^3 cm s $^{-1}$ has very little effect on relative velocities and coagulation rates of small particles, because their motions are highly correlated. However, the vigorous vertical diffusion of small particles affects the overall rate of growth and settling. There is very little variation of the size distribution with z (Fig. 8). The time to reach a high mass concentration at the central plane is much longer than for the laminar

Figure 8. Same as Fig. 5, but for turbulence with velocity 10^3 cm s^{-1} through the thickness of the nebula. The size distribution has less variation with z , due to diffusion of particles between levels. Most of the mass is in large bodies $\sim 10^3$ to 10^4 cm near the central plane. The computation was halted after 10^4 yr , when solids/gas $\simeq 0.4$ at $z = 0$ (see text).

case, partly because particles must grow larger to settle appreciably, and also because the high-density layer near $z = 0$ is thicker due to stirring by the turbulence, and requires more total mass to reach a given solids/gas ratio. After $\gtrsim 10^4 \text{ yr}$, most of the mass is in bodies $\sim 10^3$ to 10^4 cm in size. Bodies $\sim 10^2 \text{ cm}$ are strongly depleted because of the peak in radial velocity at that size, which causes them to grow rapidly through this size range, or to be swept up by the larger bodies.

From Fig. 9 it is seen that the dust/gas ratio varies only slightly with z through most of the disk's thickness, but it decreases steadily with time as small aggregates diffuse downward and are accreted by the large bodies near the central plane. (Figure 10 shows the evolution of the optical thickness.) The thickness of the densest layer is a few times 10^{-4} AU ($5 \times 10^4 \text{ km}$). The calculation was halted after 10^4 yr because the solids/gas mass ratio reached a peak value $\simeq 0.4$, and then began to *decrease*. This decrease is due to the fact that the settling rate for large bodies (actually, the rate of damping inclinations for Keplerian orbits by gas drag) is proportional to t_e^{-1} (Adachi et al. 1976), while the random velocity induced by turbulence (Eq. 16) varies as $t_e^{-1/2}$. Therefore, sufficiently large bodies ($t_e \gg 1/\Omega$) are stirred more effectively

than they are damped. In this simulation, the solid bodies may continue to grow by collisions to much larger sizes, but will never form a layer that is sufficiently thin and dense to become gravitationally unstable.

Figure 9. Vertical distribution of solids/gas mass ratio with time for $V_t = 10^3$ cm s^{-1} . Contour interval is 1000 yr.

These simulations assumed perfect sticking of particles and thus give only a lower limit to the time scales for growth and settling. If an arbitrary sticking efficiency β (≤ 1) is assumed, then the results are very similar, but with all time scales increased by a factor of $1/\beta$. The outcomes of such simulations may well be different if fragmentation is allowed, as the sticking efficiency would be expected to vary with relative velocity (or size). Also, the long time scale associated with the turbulent case implies that radial transport of solids would be significant. The small grains that are coupled to the gas will diffuse both inward and outward over a distance of order $(V_t H t)^{1/2}$, in this case more than 0.5 AU. In addition, orbital decay of the largest bodies exceeds 1 AU, meaning that they would be lost into the Sun (presumably replaced by others

spiraling inward from larger distances). Thus, the one-dimensional model is incomplete at best, and its results should be interpreted cautiously. Further progress will require a two-dimensional model with both vertical and radial resolution.

B. Fluid-Dynamical Modeling of a Dense Particle-Gas Layer

Simulations of settling with coagulation generally produce a significant concentration of large (meter-sized?) bodies toward the central plane of the disk. Whether the nebula is assumed to be laminar or turbulent, such a layer can attain a solids/gas mass ratio of order unity or greater. At such densities, coupling of the particles and gas, as described in Sec. III, becomes significant. The complex flow patterns that result must be modeled numerically by computational fluid dynamical methods. Current models are limited to a single particle size, without coagulation; in effect, particles interact with each other only by their mutual coupling with the gas (Champney and Cuzzi 1990; Cuzzi et al. 1993). The numerical methods used are described in the chapter Appendix.

This model is sufficiently stable and robust to allow modeling of particle layers with mass density exceeding that of the gas by more than 2 orders of magnitude. Due to the present neglect of particle collisional viscosity, these results are of questionable quantitative validity for particle mass densities much larger than that of the gas; nevertheless, major new qualitative aspects of the entire family of viscous, two-phase solutions may be readily observed in cases with a particle density of 1 to 10 times that of gas, where particle viscosity does not play a dominant role.

For example, Figs. 11 and 12 show the gas and particle velocities relative to their assumed unperturbed values (pressure supported orbital motion, $\Delta V = 5.4 \times 10^3 \text{ cm s}^{-1}$, with zero radial and vertical velocity for the gas, Keplerian orbital motion with zero radial velocity and simple vertical settling for the particles). In this simulation, there is no turbulence in the disk, except that which is generated locally by shear near or within the particle layer. In both figures, initial and final particle density profiles are shown, with mass density along the top axis (the gas density at this location, chosen at 1 AU, is $1.4 \times 10^{-9} \text{ g cm}^{-3}$). The fundamental property is the large vertical gradient in the gas orbital velocity; this leads to turbulence which diffuses the particles into a much thicker layer than that in which they were assumed to lie initially. In cases where a thicker initial layer was assumed, the layer flattens into the identical final state, which thus represents a steady-state balance between gravitational settling and vertical diffusion for these nebula and particle properties.

In model calculations to date, using the Schmidt number model describe in Sec. III (Cuzzi et al. 1993), it appears that particles of unit density must grow to at least 10^5 to 10^6 g (depending on location) before being able to settle out from the nebula into a gravitationally unstable state. If they are more "fractal" or fluffy than solid in nature, they need to become more massive by about

Figure 10. Same as 7, but with $V_t = 10^3 \text{ cm s}^{-1}$. The nebula becomes optically thin at $r = 1 \text{ AU}$ on a time scale of 10^4 yr .

an order of magnitude. Initially flattened particle layers of mass density 10 to 100 times that of the gas are seen to "puff up" to vertical thicknesses of several thousand km, as long as particle diameters are $\lesssim 100 \text{ cm}$. For minimum mass solar nebulae, this keeps the particle layer mass density ρ_p well below the critical value for gravitational instability, confirming the conclusions of Weidenschilling (1980,1988) that collisional coagulation is a fundamental process in the formation of planetesimals.

The mean velocity profiles are seen to relate to the location of the particle layer. Well above the layer, when the particles exert no significant influence on the gas, the solutions of Weidenschilling (1977) and Nakagawa et al. (1986) are appropriate, i.e., particles experience a strong headwind in the pressure supported gas, their orbital velocity falls below Keplerian, and they drift radially inwards. At deeper levels within the layer, the particles are increasingly shielded from the headwind as the surrounding gas is speeded up more closely to the Keplerian velocity (several thousand cm s^{-1} faster

Figure 11. Particle velocities relative to planar Keplerian motion, for a layer of midplane mass density initially 10 times that of the gas at 1 AU. The particle orbital velocity profile is shown by the short-dashed curve, and the particle radial velocity profile is shown by the solid curve. The particles have $d = 100$ cm and $\rho_s = 0.1$ g cm $^{-3}$. The values shown are steady state, and have converged after $\sim 100,000$ Cray YMP timesteps, or ~ 2 yr. The initial and final profiles of mass density in the particle layer are shown by the long-dashed curves; the initial profile is flatter, and the layer “puffs up” over the course of the run due to the diffusive effects of shear-driven gas turbulence. The steady-state density of the center of the layer is ≈ 7 times the gas density, while the critical density for gravitational instability of the particle layer at this location is $\sim 10^{-7}$ g cm $^{-3}$, or ~ 10 times larger.

than its pressure-supported value). The lack of a headwind causes the inward drift of the particles to diminish. Simultaneously, as the particles begin to drive the gas to orbital velocities which exceed its pressure-balanced value, the gas acquires an *outward* radial drift in the boundary layer consistent with Ekman layer analogy (Weidenschilling 1980). Another way to understand this is as the result of transfer of angular momentum between the more rapidly rotating particle layer and the more slowly rotating surrounding gas. The effect is confined to a region of thickness comparable to the boundary layer, because that is where the velocity gradients are sufficiently large to generate a significant viscosity and shear stress. The particle drift rates in the upper

Figure 12. Gas velocities relative to pressure supported motion, for the final profile of mass density in the particle layer. The gas orbital velocity profile is shown by the short-dashed curve, and the gas radial velocity profile is shown by the solid curve. These are mean flow velocities; in addition, there is turbulence with fluctuations of comparable magnitude within the layer.

reaches of the layer are in fairly good agreement with the "Ekman" estimates discussed earlier, but deeper within the layer the solid material is less affected. Naturally, this assumes there is no source of turbulence other than the local shear, and that the gas viscosity at this stage and in this region is considerably less than the "alpha model" values of 10^{13} to 10^{15} cm² s⁻¹. Within the particle layer, the gas drifts inward along with the particles. In some cases, the vertical shear in the *radial* velocities can compete with the vertical shear in the *orbital* velocities in contributing to the viscosity, which emphasizes that this is a highly coupled problem.

In detail, the drift rates of gas and particles will probably change once viscosity due to particle collisions is included. For example, one simple estimate of the particle viscosity may be obtained from the expression widely used in studies of planetary rings (Goldreich and Tremaine 1978), using the expressions relating \bar{v}_p^2 to \bar{v}^2 from Eq. (16) (Dobrovolskis 1991, personal

communication);

$$v_p \sim \frac{v_p^2}{2\Omega} \left[\frac{\tau_0}{1 + \tau_0^2} \right] \sim \frac{v_t}{2Sc} \left[\frac{\tau_0}{1 + \tau_0^2} \right] \quad (23)$$

where τ_0 is the dynamical optical depth of the layer (i.e., that due to particles of sizes comparable to the mean mass). Substituting, we obtain

$$\tau_0 \sim \frac{\sigma_s}{\rho_s d} \sim \frac{\rho_p h}{\rho_s d} \sim 10^{-1} \quad (24)$$

where $\rho_p \sim 10^{-8} \text{ g cm}^{-3}$ is the volume mass density in the particle layer, $d \sim 60$ to 100 cm is the typical particle diameter, and $\rho_s \sim 1 \text{ g cm}^{-3}$ is the density of an individual particle. The particle viscosity is comparable to the gas viscosity for the models presented above. When included, this effect will probably increase the inward radial drift of the densest part of the layer, causing a simultaneous increase in the outward flow of the surrounding gas.

VII. CONCLUSIONS

The preceding sections sketch out parts of the possible course of growth of particles from μm to km sizes in the context of current ideas about the solar nebula. It seems likely that planetesimal formation involved at least an early stage of collisional sticking and coagulation of particles. This process depended on poorly constrained properties of the nebula (e.g., temperature, pressure gradients, turbulence) and of the particles themselves (stickiness, mechanical strength, fractal dimension). Many variables need to be examined in more detail, especially collisional behavior of particle aggregates, for which relevant experimental data are sorely lacking.

It is apparent that if grains have a reasonable probability of sticking in collisions, then their size distribution and the vertical distribution of solids in the disk evolve rapidly compared with the expected astrophysical lifetime of the disk ($\sim 10^6 \text{ yr}$). The assumption used by some observers, that size distribution is similar to that of interstellar grains, is not likely to be valid. Moreover, the actual size distribution may not resemble a simple power law, and may vary with location (radial and vertical) in the disk.

In the later stages of accumulation, collective effects (a dense particle layer dragging the gas) could have important consequences. Within the particle layer, ΔV is decreased, which may promote accretion of fragile aggregates; however, there is increased turbulence generated by the shear associated with this layer's motion, which can have the opposite effect. Complex flow patterns can occur, with radial gas motion inward at the central plane, and outward in the boundary layer. In addition to vertical sorting (larger bodies nearer the center of the layer), there may be radial segregation as well, if smaller particles are entrained in the boundary layer. If this stage

is long-lived, there could be significant mixing of solids formed at different distances from the Sun. It is not clear that any such effects would leave visible traces in the meteoritic record, but the possibility should be considered. The computational fluid dynamical model described here is still in the early stages of development; the obvious next step will be to include a spectrum of particle sizes and coagulation within the particle layer.

The later stage (\sim m to km) of planetesimal formation has not yet been examined in detail. Two (at least) possible outcomes can be inferred. If the bodies in the turbulent, shearing layer near the central plane can grow large enough by mutual collisions, they may decouple from the gas sufficiently to allow further settling. In that case, there might be gravitational instability in a layer of $>$ meter-sized bodies, rather than one made of dust grains. On the other hand, a plausible amount of global turbulence, e.g., due to convection in the disk, could prevent gravitational instability no matter how large the solid bodies grow. In that case, collisional coagulation will be the only mechanism of growth at all sizes. These outcomes are model dependent; indeed, both could have occurred in different parts of the disk, or at different times.

Regardless of the actual mechanism by which planetesimals formed, that process was not so efficient as to deplete the dust in the solar nebula and render the disk optically thin. Detection of dust in a circumstellar disk does not rule out the presence of planetesimals, or even planets, within it.

The parts of this chapter do not make a seamless and self-consistent scenario for the origin of planetesimals. One should remember that the accretion of planets from planetesimals involves growth in size by a factor 10^4 , while the formation of km-sized bodies from μ m-sized grains covers 9 orders of magnitude. There is still room for plenty of work within that range.

APPENDIX: MODELING OF A PARTICLE-GAS LAYER

Here we present for reference a self-consistent formulation for computational fluid dynamical simulation of a viscous two-phase (particles plus gas) layer near the central plane of the solar nebula. A more detailed description of this model is given by Champney and Cuzzi (1990) and Cuzzi et al. (1993).

A. Solution of the Mass and Momentum Equations

The full equations of motion in cylindrical coordinates are:

$$\frac{\partial \rho}{\partial t} + w \frac{\partial \rho}{\partial z} + \rho \frac{\partial w}{\partial z} + u \frac{\partial \rho}{\partial r} + \frac{\rho \partial u}{\partial r} + \frac{\rho u}{r} = 0 \quad (\text{A.1})$$

$$\begin{aligned} \frac{\partial w}{\partial t} + w \frac{\partial w}{\partial z} + v \frac{\partial w}{\partial r} + \frac{1}{\rho} \frac{\partial P}{\partial z} = \\ - \frac{GM}{R^3} z - A \rho_p (w - w_p) + \frac{1}{\rho} \frac{\partial \tau_{zz}}{\partial z} + \frac{1}{\rho r} \frac{\partial (r \tau_{zr})}{\partial r} \end{aligned} \quad (\text{A.2})$$

$$\frac{\partial u}{\partial t} + w \frac{\partial u}{\partial z} + u \frac{\partial u}{\partial r} + \frac{1}{\rho} \frac{\partial \rho}{\partial r} =$$

$$\frac{v^2}{r} - \frac{GM}{R^3} r - A \rho_p (u - u_p) + \frac{1}{\rho} \frac{\partial \tau_{zr}}{\partial z} + \frac{1}{\rho r} \frac{\partial (r \tau_{rr})}{\partial r} - \frac{\tau_{\theta\theta}}{\rho r} \quad (\text{A.3})$$

$$\frac{\partial v}{\partial t} + w \frac{\partial v}{\partial z} + u \frac{\partial v}{\partial r} =$$

$$\frac{-uv}{r} - A \rho_p (v - v_p) + \frac{1}{\rho} \frac{\partial \tau_{z\theta}}{\partial z} + \frac{1}{\rho r} \frac{\partial (r \tau_{r\theta})}{\partial r} + \frac{\tau_{r\theta}}{\rho r} \quad (\text{A.4})$$

$$\frac{\partial \rho_p}{\partial t} + w_p \frac{\partial \rho_p}{\partial z} + \rho_p \frac{\partial w_p}{\partial z} + u_p \frac{\partial \rho_p}{\partial r} + \rho_p \frac{\partial u_p}{\partial r} + \frac{\rho_p u_p}{r} =$$

$$\frac{\partial}{\partial z} \left[\frac{v_t}{Sc} \frac{\partial \rho_p}{\partial z} \right] + \frac{\partial}{\partial r} \left[\frac{v_t}{Sc} \frac{\partial \rho_p}{\partial r} \right] \quad (\text{A.5})$$

$$\frac{\partial w_p}{\partial t} + w_p \frac{\partial w_p}{\partial z} + u_p \frac{\partial w_p}{\partial r} = \frac{-GM}{R^3} z - A \rho (w_p - w) \quad (\text{A.6})$$

$$\frac{\partial u_p}{\partial t} + w_p \frac{\partial u_p}{\partial z} + u_p \frac{\partial u_p}{\partial r} = \frac{v_p^2}{r} - \frac{GM}{R^3} r - A \rho (u_p - u) \quad (\text{A.7})$$

$$\frac{\partial v_p}{\partial t} + w_p \frac{\partial v_p}{\partial z} + u_p \frac{\partial v_p}{\partial r} = -\frac{u_p v_p}{r} - A \rho (v_p - v) \quad (\text{A.8})$$

where u , v , w are the mean velocity components in the radial (r), transverse (θ), and vertical z directions, and ρ is the spatial density. Quantities without subscripts refer to the gas, and the subscript p refers to the particles. A is a drag coefficient (equal to $1/\rho t_e$), $R^2 = r^2 + z^2$, v_t is the turbulent kinematic viscosity of the gas phase, and Sc is a dimensionless parameter known as the Schmidt number, which is discussed in Sec. III. The terms τ_{ij} are the components of the viscous stress tensor for the gas phase. In the above equations, no similar terms are included for particle viscosity. Initially in the nebula, the particle volume density is sufficiently low that this is an acceptable approximation. However, as increasingly dense layers are studied, this does become a concern.

Champney and Cuzzi (1990) and Cuzzi et al. (1993) present a numerical model which includes all of the viscous and nonlinear terms, and overcomes the significant numerical challenges by using a perturbation technique in which an analytical solution is first subtracted from the problem. The analytical, or unperturbed, solution consists of Keplerian orbital motion for the particles, pressure supported orbital motion for the gas, and hydrostatic equilibrium in the vertical direction for the gas. In the unperturbed solution, the vertical particle velocity is merely the terminal settling velocity. These solutions are subtracted from the exact equations, and the remaining terms are solved numerically.

In Secs. III and IV we discussed solutions for the mean gas and particle velocities, and for the gas turbulent (eddy) viscosity. The effects of the turbulent boundary layer on dispersion of the particles is modeled as a diffusion term in the particle mass conservation equation (Eq. A.5) where the term ν_t/Sc is the particle diffusion coefficient D . Certain subtleties are associated with derivation of the diffusion term from averaged versions of the exact equations (see Champney and Cuzzi 1990), but models of this form are extensively used in two-phase fluid engineering applications.

GROWTH OF PLANETS FROM PLANETESIMALS

JACK J. LISSAUER

State University of New York at Stony Brook

and

GLEN R. STEWART

University of Colorado

The formation of terrestrial planets and the cores of Jovian planets is reviewed in the framework of the planetesimal hypothesis, wherein planets are assumed to grow via the pairwise accumulation of small solid bodies. The rate of (proto)planetary growth is determined by the size and mass of the protoplanet, the surface density of planetesimals, and the distribution of planetesimal velocities relative to the protoplanet. Planetesimal velocities are modified by mutual gravitational interactions and collisions, which convert energy present in the ordered relative motions of orbiting particles (Keplerian shear) into random motions and tend to reduce the velocities of the largest bodies in the swarm relative to those of smaller bodies, as well as by gas drag, which damps eccentricities and inclinations. The evolution of the planetesimal size distribution is determined by the gravitationally enhanced collision cross-section, which favors collisions between planetesimals with smaller velocities. Deviations from the 2-body approximation for the collision cross-section are caused by the central star's tidal influence; this limits the growth rates of protoplanets. Runaway growth of the largest planetesimal in each accretion zone appears to be a likely outcome. The subsequent accumulation of the resulting protoplanets leads to a large degree of radial mixing in the terrestrial planet region, and giant impacts are probable. Gravitational perturbations by Jupiter probably were responsible for preventing runaway accretion in the asteroid belt, but detailed models of this process need to be developed. In particular, the method of removal of most of the condensed matter (expected in a nebula of slowly varying surface density) from the asteroid region and the resulting degree of radial mixing in the asteroid belt have yet to be adequately modeled. Accumulation of Jupiter's core before the dispersal of the solar nebula may require more condensable material at 5 AU than predicted by standard minimum-mass solar-nebula models.

I. INTRODUCTION

The nearly circular and coplanar orbits of the planets argue for planetary formation in a flattened disk orbiting the Sun (Kant 1755; Laplace 1796). Astrophysical evidence suggests that such disks are the natural byproducts of the collapse of molecular cloud cores leading to star formation (Chapters by Beckwith and Sargent and by Basri and Bertout). The most highly developed theory for explaining planetary growth within such a circumstellar disk is

accretion (aggregation) of solid planetesimals via binary collisions, followed in the case of Jovian type planets by accretion of gas onto solid cores (Safronov 1972; Hayashi et al. 1985).

In this chapter, we review the dynamics of the accretion process from kilometer sized planetesimals to terrestrial planets and the cores of giant planets. The formulas presented herein are valid for single stars of any mass; however, the complexities of planetary accretion in multiple star systems are not treated. We assume as our initial conditions the presence of a disk of stellar composition in orbit about the star. Moreover, our calculations begin when the bulk of the condensed material in the nebula has settled out and agglomerated into bodies at least ~ 1 km in size. The microphysics of the growth of the sub-centimeter grains is very different than the dynamical processes important to later stages of planetary accretion, and growth in the intermediate-size range is believed to be very rapid (Chapter by Weidenschilling and Cuzzi). Our review also neglects the accretion of the gaseous envelopes of the giant planets, except insofar as an atmosphere may enhance the planetesimal accretion cross-section of a protoplanet. This final stage of giant planet growth is reviewed in the Chapter by Podolak et al.

Strictly speaking, the planet formation process is unlikely to be as purely sequential as we have laid out. Grain growth and even the accretion of large planetesimals described in detail herein may well begin during the epoch when a protoplanetary disk is still accreting and redistributing matter (cf. Chapters by Shu and by Adams and Lin). Given that the theories of each of these epochs are still rather primitive, a sequential study of each stage is probably adequate. However, to the extent that planetary growth depends on, e.g., the initial size distribution of planetesimals, we must recognize that various processes currently being treated as separate events occur simultaneously and affect each other.

The star's gravity is the dominant force upon planetesimals, and other forces are generally included as perturbations on the planetesimal's Keplerian orbit. The dominant perturbations to a planetesimal's heliocentric trajectory are usually due to gravitational attraction of other planetesimals and protoplanets. (We use the term protoplanets to refer to exceptionally large planetesimals, not the giant gaseous protoplanets once popularized by Cameron [1962].) When a single protoplanet is the dominant perturber in a given region of the protoplanetary disk, it is convenient to treat its perturbations separately. The dominant nongravitational forces upon planetesimals are mutual inelastic collisions (which may lead to accretion and/or fragmentation), and gas drag. Whole body magnetic forces are believed to be negligible for the dynamics of bodies of kilometer size and larger. However, if electromagnetic induction heating (Herbert 1989) is sufficient to melt planetesimal interiors, then the outcome of physical collisions could be altered.

The distribution of planetesimal velocities is one of the key factors which control the rate of planetary growth. In Sec. II, we review the physical factors important to determining the equilibrium velocity distribution of a swarm

of planetesimals of various sizes when accretion is neglected. The growth rate of a protoplanet in a uniform surface density disk of planetesimals with known velocity dispersion is discussed in Sec. III. In Sec. IV, we follow the simultaneous evolution of planetesimal masses and velocities and show that under a wide variety of initial conditions the largest body in any given accretion zone grows very rapidly and “runs away” from the mass distribution of other accreting bodies in its region of the solar system. The limits to such runaway accretion are quantified in Sec. V. In Sec. VI, we review models of the final stages of planetary accretion, with emphasis on the growth times of planets and the possibility of giant impacts. We conclude with a summary of the major results of planetesimal dynamics and a list of outstanding questions in Sec. VII.

II. PLANETESIMAL VELOCITIES FOR A STATIC MASS DISTRIBUTION

The simplest analytic approach for calculating the evolution of planetesimal velocities uses a “particle-in-a-box” approximation in which the evolution of the mean square planetesimal velocities are calculated via the methods of the kinetic theory of gases. Originally, the particle-in-a-box calculations were developed by Safronov (1972) using relaxation time arguments similar to those used by Chandrasekhar (1942) in stellar dynamics. More recently, these calculations have been refined by employing modern kinetic theory methods (Hornung et al. 1985; Stewart and Wetherill 1988; Barge and Pellat 1990; Ida 1990). A kinetic theory approach appears to be the only viable method for treating the initial stages of planetesimal accumulation because the number of initial planetesimals is extremely large. During the final stages of planetesimal accumulation, the number of planetesimals eventually becomes small enough that a more direct treatment of individual planetesimal orbits is feasible. With a modest number of planetesimals, the most straightforward approach would be a numerical n -body integration of the planetesimal orbits, but the exceedingly long time scales required for the final stages of planetary accumulation (e.g., between 10 and 100 Myr in the inner solar system) severely limit the usefulness of this method. An alternative approach that has enjoyed considerable success is to assume that the planetesimals follow slowly precessing elliptic orbits that are occasionally altered by rare close encounters with other planetesimals. A Monte Carlo procedure is then used to choose successive pairs of planetesimals that interact according to the two-body gravitational scattering formula. This Monte Carlo approach has been extensively developed by Wetherill (1980*b*, 1985, 1986, 1988, 1990*b*).

A. Random Velocity Distribution

In the particle-in-a-box approximation, one ignores the details of individual planetesimal orbits and uses a probability density to describe the distribution of orbital elements in the planetesimal population. Specifically, the orbital

perihelia and longitudes of the ascending node are assumed to be random and the orbital eccentricities e and inclinations i are assumed to be Rayleigh distributed,

$$f(e, i) = 4 \frac{\sigma}{m} \frac{ei}{\langle e^2 \rangle \langle i^2 \rangle} \exp \left[-\frac{e^2}{\langle e^2 \rangle} - \frac{i^2}{\langle i^2 \rangle} \right] \quad (1)$$

where m is the mass of the individual planetesimals and σ is the surface mass density of planetesimals with a particular semimajor axis; $\langle e^2 \rangle$ and $\langle i^2 \rangle$ are the mean square eccentricity and inclination. Although the form of Eq. (1) is difficult to justify rigorously, the randomization of orbits caused by planetesimal interactions in n -body simulations has been found to yield orbital distributions similar to Rayleigh distributions (Wetherill 1980*b*; Ida and Makino 1992*a*).

Another important property of planetesimal orbits is the fact that planetesimals with different semimajor axes orbit the star with different mean velocities. This Keplerian shear is usually introduced into a local velocity distribution by postulating a local mean velocity that reproduces the differential rotation between coplanar circular orbits. Because the orbital phase angles are averaged out in this approximation, the deviations from coplanar circular orbits are reduced to a distribution of random velocities relative to the local mean velocity of a circular orbit. The distribution of random velocities that is locally equivalent to Eq. (1) is a triaxial Gaussian distribution in cylindrical coordinates,

$$f_o(z, \mathbf{v}) = \frac{\Omega \sigma}{2\pi^2 c_r^2 c_z^2 m} \exp \left[-\frac{v_r^2 + 4v_\theta^2}{2c_r^2} - \frac{v_z^2 + \Omega^2 z^2}{2c_z^2} \right] \quad (2)$$

where $2c_r^2 = \langle e^2 \rangle v_K^2$, $2c_z^2 = \langle i^2 \rangle v_K^2$, v_θ is the azimuthal component of velocity relative to the local circular Keplerian velocity, $v_K = (GM_\star/r)^{1/2}$, and $\Omega = v_K/r$ is the orbit frequency. The integral of f_o over velocity space yields the local number density,

$$n = \int d^3\mathbf{v} f_o = \frac{\Omega \sigma}{\sqrt{2\pi} c_z m} \exp \frac{-\Omega^2 z^2}{2c_z^2}. \quad (3)$$

B. Velocity Evolution

Given the local random velocity distribution in Eq. (2), one can write down a kinetic equation for the time evolution of the random velocity distribution caused by mutual planetesimal interactions:

$$\frac{\partial f}{\partial t} + \mathbf{v} \cdot \nabla_{\mathbf{r}} f - \left[\frac{GM_\star \mathbf{r}}{r^3} + (\mathbf{v} + \mathbf{v}_K) \cdot \nabla_{\mathbf{r}} \mathbf{v}_K \right] \cdot \nabla_{\mathbf{v}} f = \frac{\delta f}{\delta t} \Big|_{\text{coll}} + \frac{\delta f}{\delta t} \Big|_{\text{grav}}. \quad (4)$$

The two terms on the right-hand side of the kinetic equation denote the two kinds of planetesimal interactions: (1) physical collisions which dissipate

some or all of the relative kinetic energy of the colliding bodies; and (2) gravitational scattering which conserves the relative kinetic energy but results in a rotation of the relative velocity vector. Physical collisions are usually modeled with a Boltzmann collision operator for hard spheres that has been modified to allow for inelastic collisions (see Trulsen 1971; Hornung et al. 1985). Most published calculations of planetesimal accumulation assume collisions are completely inelastic because physically plausible rebound velocities rarely exceed the mutual escape velocity except for the very smallest planetesimals in the distribution (cf. Sec. III). Violent collisions that produce a size distribution of collision fragments are more likely to occur once sizeable protoplanets are formed. In order to account for the gravitational enhancement of the collision cross-section, a correction factor must be applied to the hard sphere collision operator. An accurate determination of this enhancement factor is rather difficult in general, owing to the tidal influence of the star; a detailed discussion of its calculation is presented in Sec. III.

Gravitational scattering between planetesimals can be modeled with a Fokker-Planck operator similar to that used in stellar dynamics (cf. Binney and Tremaine 1987). The use of a Fokker-Planck operator requires two assumptions. First, the result of a close encounter must be well approximated by the 2-body Rutherford scattering formula, which ignores the gravitational influence of the star for the duration of the encounter. Between successive encounters, the star's gravitational influence is properly taken into account by the left-hand side of Eq. (4). Numerical integrations of the 3-body problem indicate that the average perturbations given by the 2-body approximation are valid within a factor of 2, so long as the random velocities are greater than 0.07 times the surface escape velocity of the two bodies at contact (Wetherill and Cox 1984). More extensive numerical investigations of the 3-body problem support the accuracy of the Fokker-Planck relaxation and energy exchange rates provided that the encounter velocities do not become too small (Ida 1990). Second, the relative velocity between planetesimals must be primarily determined by their random velocities, rather than by Keplerian shear. This assumption is valid for the early stages of planetesimal accumulation, when a very large number of planetesimals can be found within a spherical volume of radius equal to the scale height c_z/Ω of the planetesimal disk.

The essential reason why the Fokker-Planck operator cannot correctly model a gravitational encounter more distant than a scale height is that the Fokker-Planck operator implicitly assumes that gravitational encounters are local events. In particular, it assumes that the two interacting planetesimals have the same local mean velocity, so that their relative velocity is entirely determined by the random velocity distribution (Eq. 2). This assumption is violated for distant encounters, where the relative velocity between planetesimals is largely determined by the difference in their semimajor axes (i.e., by Keplerian shear). Although it is possible to write down formal expressions for the velocity evolution due to distant encounters (see Chapter by Ohtsuki

et al.), an explicit analytic formula is generally not available to replace the Rutherford scattering law, except in a few limiting cases.

One such limiting case occurs when the separation in semimajor axes is large compared to both the orbital eccentricities and the Hill sphere radius h (see Sec. III.C), and is also small compared to both semimajor axes (Hénon and Petit 1986; Hasegawa and Nakazawa 1990). Weidenschilling (1989) evaluated the contribution of distant gravitational encounters in this limit and concluded that they may safely be neglected compared to close gravitational encounters except when a few protoplanets are so large that their surface escape velocities exceed the local random velocity by a factor of ≥ 100 . For these reasons, the maximum encounter distance is set equal to the disk scale height in the Fokker-Planck operator.

Once the interaction terms have been specified, an approximate solution to Eq. (4) can be obtained by linearizing the kinetic equation about the Gaussian velocity distribution f_o stated in Eq. (2):

$$\left[\frac{\partial}{\partial t} + 2\Omega v_\theta \frac{\partial}{\partial v_r} - \left(\frac{\Omega v_r}{2} \right) \frac{\partial}{\partial v_\theta} \right] f_1 = \frac{\delta f_o}{\delta t}|_{\text{coll}} + \frac{\delta f_o}{\delta t}|_{\text{grav}} \quad (5)$$

where $|f_1| \ll |f_o|$. Note that f_o does not appear on the left-hand side of Eq. (5) because it is an integral of the free orbital motion. Linearization is an excellent approximation because the orbit frequency greatly exceeds both the collision rate and relaxation rate due to gravitational scattering. Evolution equations for the mean square random velocities are obtained by taking second-order velocity moments of the linearized kinetic equation. The rate of change of the mean square random velocity is given by

$$\frac{\partial \langle n v^2 \rangle}{\partial t} = \int d^3 v \left(\frac{\partial f_1}{\partial t} \right) v^2. \quad (6)$$

In general, one obtains two coupled equations for the two components of the random velocity associated with the orbital eccentricity and inclination (Hornung et al. 1985). However, during the early stages of planetesimal accumulation the ratio of rms inclination to rms eccentricity is likely to be nearly constant due to an approximate equipartition of energy between the planar and vertical orbital motions. Barge and Pellat (1990) have derived a value of this ratio of approximately 0.6 by simultaneously solving coupled equations for the "thermal" motions in the vertical and horizontal directions. This value may be compared with values close to 0.5 that were obtained by Wetherill (1980*b*) using a Monte Carlo simulation, and by Ida and Makino (1992*a*) using direct n -body calculations. Calculations of steady-state planetesimal velocities indicate that the difference between 0.5 and 0.6 is unimportant compared to the other approximations described above.

Thus, setting $c_z/c_r = 0.5$ in Eq. (2), a single equation is derived for the velocity evolution of a test body of mass m_i interacting with a swarm of field

bodies of mass m_k . Following Stewart and Wetherill (1988), we split the equation into four separate contributions and add a fifth term that models the velocity evolution caused by gas drag in the solar nebula. The rate of change in v_i , the rms velocity of bodies of mass m_i , is given by:

$$\frac{dv_i}{dt} = A + B + C + D + E \quad (7)$$

where the five terms on the right-hand side are:

1. "Viscous stirring" resulting from gravitational scattering:

$$A = \frac{3}{4} \frac{\sqrt{\pi} G^2}{v_i V_{ik}^3} \rho_k \ln \Lambda [(9L - 12\sqrt{3})(m_i + m_k)v_i^2 + (5L - 4\sqrt{3})(m_k v_k^2 - m_i v_i^2)] \quad (8)$$

where ρ_k is the density (specific gravity) of the planetesimals of mass m_k , $V_{ik}^2 \equiv v_i^2 + v_k^2$, $L \equiv \ln[(2 + \sqrt{3})/(2 - \sqrt{3})] \approx 2.634$, and $\Lambda \equiv \sin(\Psi_{\max}/2)/\sin(\Psi_{\min}/2)$. The angle Ψ is related to the impact parameter b according to the Rutherford scattering formula,

$$\sin\left(\frac{\Psi}{2}\right) = \left(1 + \frac{b^2}{b_o^2}\right)^{-1/2} \quad (9)$$

where $b_o = G(m_i + m_k)V_{ik}^{-2}$. The minimum deflection angle, Ψ_{\min} , is calculated with an impact parameter $b = b_{\max} = \max(v_i/\Omega, v_k/\Omega)$. The maximum deflection angle, Ψ_{\max} , is calculated using the impact parameter corresponding to the 2-body gravitational capture cross section,

$$b = b_{\min} = R_g = (R_i + R_k) \left[1 + \frac{2b_o}{(R_i + R_k)}\right]^{1/2}. \quad (10)$$

2. Viscous stirring caused by inelastic collisions:

$$B = \frac{\sqrt{\pi}}{8} \left(\sqrt{3} - \frac{5L}{12}\right) \frac{V_{ik}}{v_i} \rho_k R_g^2 \frac{m_k(v_i^2 - v_k^2) + 2m_i v_i^2}{(m_i + m_k)^2}. \quad (11)$$

3. Velocity damping due to energy dissipated by inelastic collisions:

$$C = -\sqrt{\pi} \left(\frac{11\sqrt{3}}{18} + \frac{L}{24}\right) \frac{V_{ik}}{v_i} \rho_k R_g^2 \frac{m_k(v_i^2 - v_k^2) + 2m_i v_i^2}{(m_i + m_k)^2}. \quad (12)$$

4. Energy transfer from large bodies to small ones via dynamical friction:

$$D = \frac{4\sqrt{\pi} L G^2}{v_i V_{ik}^3} \rho_k \ln \Lambda (m_k v_k^2 - m_i v_i^2). \quad (13)$$

5. *Energy damping caused by gas drag:*

$$E = -\pi \left(\frac{C_D}{2m_i} \right) \rho_g R_i^2 v_i (v_i + \eta) \quad (14)$$

where C_D is the drag coefficient, ρ_g is the gas density, and η is the velocity of a body moving in a circular Keplerian orbit relative to the that of the nebular gas, which orbits at a slower velocity because it is partially supported by thermal pressure (cf. Adachi et al. 1976; Weidenschilling 1977a).

The viscous stirring terms are so denoted because their sum is proportional to the product of the shear stress and the rate of strain generated by the differential rotation of the local mean velocity. The physical source of the energy for the viscous stirring terms is the kinetic energy contained in the sheared mean flow. Mutual planetesimal interactions transform this energy into the random motion associated with orbital eccentricities and inclinations. In a uniformly rotating disk, these two terms would vanish. The dynamical friction term tends to drive the system toward an equipartition of random kinetic energy. In a broad distribution of planetesimal sizes, energy equipartition is never actually achieved because the viscous stirring terms tend to drive the system away from the equipartitioned state towards a state in which velocities are independent of mass. For the special case of $m_i = m_k$ and $v_i = v_k$, these expressions are similar to those found by Safronov (1972) and Kaula (1979a) using relaxation time estimates. The equation for gas drag is adapted from the theory of Adachi et al. (1976). In this formula, the drag coefficient C_D appropriate for the large Reynolds number flows occurring around planetesimals in the circumstellar nebulae is ~ 0.5 (Whipple 1972).

The steady-state velocities predicted by Eqs. (7–14) are displayed in Fig. 1 for several different mass distributions. The mass distributions are labeled by the exponent q in the differential power law $dn/dm \propto m^{-q}$; the planetesimal masses range from 10^{18} to 9.766×10^{24} g in each case. In all the cases plotted, the largest planetesimals have the smallest velocities as a result of the transfer of energy from large bodies to small bodies via dynamical friction. This result is distinctly different from what one obtains from Safronov's relaxation time theory, which omitted dynamical friction. The power law with exponent $q = 2$ is a transitional case because equal amounts of mass are distributed in each logarithmic mass interval in that case. Mass distributions with $q > 2$ have most of their mass in the smaller bodies and are therefore more efficient at draining away the energy from the larger bodies. For large values of q , the velocity distribution achieves its maximum value at an intermediate mass planetesimal where the viscous stirring by gravitational scattering is strong relative to both inelastic collisions, which dominate for small planetesimals, and dynamical friction, which slows the largest bodies. Somewhat surprisingly, omitting the gas drag term from Eq. (14) would hardly change the velocity curves in Fig. 1 at all. Apparently, the absence of gas drag is mostly compensated by a larger energy loss due to inelastic collisions if the steady-state velocities

Figure 1. Steady-state random velocities calculated from Eqs. (7–14) for five different power law mass distributions. The curves are labeled by the exponent q in the differential power law $n(m)dm \propto m^{-q}dm$. The horizontal dotted line gives the escape velocity of the largest body. In all cases, the surface mass density of solids was 20 g/cm^2 , the masses ranged from 10^{18} to $9.766 \times 10^{24} \text{ g}$ and the gas density was $1.18 \times 10^9 \text{ g/cm}^3$.

increase by only a few percent. We suspect that gas drag would have a more significant affect if planetesimals less massive than 10^{18} g were included in the simulations.

C. Relationship Between Random Velocities and Planetesimal Orbital Elements

Planetary accretion occurs within disks of planetesimals on nearly Keplerian orbits about a central star. The particle trajectories can be described using Keplerian orbital elements. Particle-in-a-box calculations approximate the relative orbital motions of planetesimals with a random (or relative) velocity. The relationship between random velocity and orbital elements is by no means straightforward; several different relationships have been used by various authors, causing a great deal of confusion in the field (especially because all of these different quantities are denoted by the symbol v). We attempt to clarify the situation below.

The appropriate conversion between orbital elements and random velocities depends on the specific aspect of the accretion problem being examined. Four different conversions have been used, each of which assumes the epicyclic approximation ($e, i < 1$):

1. The velocity of a planetesimal relative to the mean circular orbit in the disk midplane with the same semimajor axis as that of the planetesimal,

i.e., its epicyclic velocity plus a contribution due to inclination:

$$v_{ep} = (e^2 + i^2)^{1/2} v_K. \quad (15)$$

2. The velocity of a planetesimal relative to the *local* mean circular orbit, averaged over an epicycle:

$$v_{lc} = \left(\frac{5e^2}{8} + \frac{i^2}{2} \right)^{1/2} v_K. \quad (16)$$

This is the local rms velocity one would calculate from the velocity distribution equations (cf. to transform between Eqs. [1] and [2]) and is also the velocity which appears in Eqs. (7–14).

3. The velocity of a planetesimal relative to other planetesimals in the swarm, averaged over an epicycle *and* over a vertical oscillation:

$$v_{sw} = \left(\frac{5e^2}{4} + i^2 \right)^{1/2} v_K. \quad (17).$$

This is the local rms relative velocity that one would calculate from the product of two velocity distributions:

$$v_{sw}^2 = \int d^3v_1 d^3v_2 f_1(\mathbf{v}_1) f_2(\mathbf{v}_2) (\mathbf{v}_1 - \mathbf{v}_2)^2 / n^2.$$

4. The weighted averaged approach velocity of a planetesimal to a proto-planet on a circular orbit averaged over an epicycle. The averaging is weighted by a factor of $1/v^2$ in order to produce the appropriate 2-body approximation to the gravitational enhancement in cross sections for the calculation of accretion rates (cf. Greenzweig and Lissauer 1990):

$$v_{cs} = (e^2 + i^2)^{1/2} \left(\frac{\mathbf{E}(k)}{\mathbf{K}(k)} \right)^{1/2} v_K \quad (18)$$

where $k \equiv (4(I^2 + 1)/3)^{-1/2}$, $I \equiv \sin i/e$, and where $\mathbf{K}(k) \equiv \int_0^{\pi/2} (1 - k^2 \sin^2 \theta)^{-1/2} d\theta$ and $\mathbf{E}(k) \equiv \int_0^{\pi/2} (1 - k^2 \sin^2 \theta)^{1/2} d\theta$ are complete elliptic integrals of the first and second kinds.

III. COLLISION CROSS-SECTIONS AND GROWTH RATES

The size distribution of planetesimals evolves principally due to physical collisions among its members. Stresses caused by tidal forces during close encounters between planetesimals may also fragment very weak bodies, but such disruptive encounters require special circumstances (Boss et al. 1991), and thus can be neglected or folded into the formalism of fragmentation via

physical collisions. The evolution of the size distribution of planetesimals can be studied using coagulation theory (cf. Sec. IV). The inputs required in the coagulation calculations are the collision frequency and physical assumptions regarding the outcome of collisions.

The velocity at which two bodies of radii R_1 and R_2 and masses m_1 and m_2 collide is given by:

$$v_c = (v^2 + v_e^2)^{1/2} \quad (19)$$

where v is the relative velocity of the two bodies far from encounter and v_e is the escape velocity from the point of contact:

$$v_e = \left(2G \frac{m_1 + m_2}{R_1 + R_2} \right)^{1/2}. \quad (20)$$

The rebound velocity is equal to ϵv_c , where $\epsilon \leq 1$ is the coefficient of restitution. If $\epsilon v_c \leq v_e$, then the two bodies remain bound gravitationally and soon re-collide and accrete. Net disruption requires both fragmentation, which depends on the internal strength of the bodies, and post-rebound velocities greater than the escape speed. As we saw in Sec. II, relative velocities of planetesimals are generally less than the escape velocity from the largest typical bodies in the swarm. Thus, unless ϵ is very close to unity, the largest members of the swarm are likely to accrete the overwhelming bulk of material with which they collide. Fragmentation is likely to be most important for very small planetesimals.

In this section, we shall give formulas for the calculation of the collision rates between planetesimals. For the case of the largest bodies in the swarms, which eventually are to grow to planetary size, the rate of collision with material is essentially identical to the accretion rate.

A. The Particle-in-a-Box Approximation

We wish to compute the accretion rate of a given body, which we shall refer to as the protoplanet, embedded within a uniform surface density and velocity dispersion disk of bodies which we shall call planetesimals. The simplest model for computing the collision rate of planetesimals ignores their motion about the central star entirely. This problem can be treated using methods of the kinetic theory of gases (Safronov 1972; Wetherill 1980a). Collisions occur when the separation between the centers of two particles becomes less than the sum of their radii, R_s . The accretion rate of a body in a swarm of planetesimals of density ρ_{sw} (not to be confused with the density or specific gravity of the individual bodies, ρ) at relative velocity v ($= v_{cs}$) is given by:

$$\dot{M}_{PIB} = \rho_{sw} v \pi R_s^2 \left[1 + \left(\frac{v_e}{v} \right)^2 \right] = \rho_{sw} v \pi R_s^2 (1 + 2\theta) \quad (21)$$

where the second term in the parentheses represents the gravitational enhancement of the accretion cross section. The Safronov number, $\theta \equiv (v_e/v)^2/2$, is frequently used to quantify the effects of gravitational focusing.

Note that in a disk of given surface mass density σ , the volume density of the planetesimal swarm is inversely proportional to v , assuming the mean ratio of horizontal to vertical motions (eccentricities to inclinations) remains fixed:

$$\rho_{sw} \approx \frac{\sigma}{2H} = \frac{\sigma}{2a \sin i} \approx \frac{\sigma \Omega}{2v_z} \approx \frac{\sqrt{3}}{2} \frac{\sigma \Omega}{v} \quad (22)$$

where $H = a \sin i$ is the half-thickness (\approx scale height) of the disk and the factor of $\sqrt{3}$ assumes the velocity dispersion is isotropic. Substituting Eq. (22) into Eq. (21), we find that the mass accretion rate of a protoplanet depends on v only through the gravitational focusing factor:

$$\dot{M}_{PIB} = \frac{\sqrt{3}}{2} \sigma \Omega \pi R_s^2 \left[1 + \left(\frac{v_e}{v} \right)^2 \right]. \quad (23)$$

The exact value of the constant in front of the right-hand side of Eq. (23) depends on the velocity distribution; thus, various values have been quoted in the literature and used in estimating growth times for planets.

B. Formulas for the 2-Body Approximation Including Kepler Shear

The particle-in-a-box approximation discussed above works well *locally* as long as encounters are rapid compared to an orbital period, i.e., that relative velocities are high. Actual planetary encounters can be much more complicated than the simple particle-in-a-box model. In addition to the gravitational forces between the colliding bodies, the gravity of the star needs to be taken into account and the 3-body problem must be solved in order to calculate accretion rates. For sufficiently rapid relative velocities, the encounter is brief enough that the tidal effect of stellar gravity can be neglected during the interval in which the gravitational forces between the secondaries is important. Stellar gravity must, however, still be incorporated to determine the flux and velocities of approaching bodies. As the problem is broken into a set of 2-body calculations (which, unlike the 3-body problem, may be solved analytically), this method is known as the 2-body approximation.

The dynamics of planetesimal-protoplanet encounters are the same in the 2-body approximation as in the particle-in-a-box case. The additional problem is finding the average density of planetesimals which a protoplanet encounters and the appropriately weighted encounter velocities “at infinity” in terms of the orbital elements of the bodies. Intermediate steps in the derivation of the accretion rate are omitted in the discussion below, but may be found in Greenzweig and Lissauer (1990, henceforth GL90).

Several simplifying assumptions are required in order to produce a simple analytic expression for the 2-body accretion rate analogous to Eq. (23). First, we assume that orbital eccentricities and inclinations are sufficiently small that terms quadratic in e and $\sin i$ may be neglected (i.e., we make the epicyclic approximation); this assumption is valid for all but possibly the very final stages of accretion. On the other hand, the radial and vertical oscillations of

the planetesimals during one orbital period, ae and $a \sin i$, are assumed to be large compared to the particle-in-a-box accretion radius of the protoplanet, $R_s(1 + v_e^2/v^2)^{1/2}$; accretion rates for the planar case (i.e., where $i = 0$) for both zero and nonzero eccentricities are given by GL90. We also assume that the pre-encounter inclinations and eccentricities of the planetesimal orbits relative to that of the protoplanet are the same for all planetesimals. (If the protoplanet is on a circular orbit, as is often the case [cf. Sec. II], then the relative eccentricity is identical to the eccentricity of the planetesimals; see Eq. [10] of GL90 for the general definition of relative eccentricity.) Distributions in e , i and R_s may be accounted for by integrating the results presented below over these distributions (cf. Sec. III.D).

Under the assumptions stated above, the accretion rate of a protoplanet is given by (cf. Eqs. 30–32 of GL90):

$$\dot{M}_{2B} = P_{2B}(e, i) \sigma h^2 \frac{2\pi}{T} = \frac{\sigma R_s^2}{T} F(I) F_{2B} \quad (24)$$

where $P_{2B}(e, i)$ is the normalized 2-body collision probability as defined by Nakazawa et al. (1989), T is the protoplanet's orbital period, and

$$F(I) \equiv 4 \frac{\sqrt{(1+I^2)}}{I} \mathbf{E}(k) \quad (25)$$

where I is defined by Eq. (18) above. The 2-body gravitational enhancement factor, F_{2B} , is the ratio of a protoplanet's 2-body collision rate to that of a nongravitating protoplanet of identical size:

$$F_{2B} = 1 + \frac{v_e^2}{v^2} = 1 + 2\theta \quad (26)$$

where $v \equiv v_{cs}$.

C. The 3-Body Gravitational Enhancement Factor

The 3-body problem can be solved analytically only for a few special equilibrium cases; thus, numerical integrations are necessary to calculate the 3-body gravitational enhancement factor F_g . The general problem of computing F_g for a variety of planetesimal velocity dispersions over the entire range of different protoplanet masses, radii and orbital locations plausible during the planetary accretion epoch would be intractable were it not for a very useful set of scaling laws based on Hill's (1878) equations. A desirable feature of Hill's equations is their lack of dependence on the ratio of the protoplanet's mass to that of the star as long as $m_1/M_\star < 1$. The radius of a protoplanet's Hill sphere is

$$h = \left(\frac{m_1}{3M_\star} \right)^{1/3} a. \quad (27).$$

An encounter with a planetesimal whose mass is not negligible compared to that of the protoplanet is best described by replacing m_1 in Eq. (27) by $m_1 + m_2$. It is also useful to define the Hill eccentricity e_H , Hill inclination i_H , and relative Hill semimajor axis b_H as:

$$e_H \equiv \frac{ea}{h}, \quad i_H \equiv \frac{ia}{h}, \quad b_H \equiv \frac{a_2 - a_1}{h}. \quad (28)$$

and the scaled accretion radius of a protoplanet as:

$$r_H \equiv \frac{R_s}{h}. \quad (29)$$

Three-body integrations of planetesimal-protoplanet encounters can be scaled to protoplanets of different masses, sizes and separations from stars of any mass if e_H , i_H and r_H remain fixed (Nishida 1983; GL90). Note that r_H is the same for all protoplanets of a given density at a fixed distance from any particular star. A detailed analytic development of the Hill scaling of the accretion problem is presented by GL90.

Following Ida and Nakazawa (1989), we define the collision probability, $P(e_H, i_H, r_H)$, as the ratio of the rate at which bodies hit a protoplanet in a uniform surface density disk to the flux of bodies with semimajor axes in the range $-1 < b_H < 1$ which would pass the planets if their orbits about the star were unperturbed. The value of $P(e_H, i_H, r_H)$ may be calculated from numerical experiments (Ida and Nakazawa 1989; GL90). The mass accretion rate may be obtained from P using the relationship:

$$\dot{M}_{3B} = P(e_H, i_H, r_H) \sigma h^2 \frac{2\pi}{T} \quad (30)$$

and F_g may be determined by dividing \dot{M}_{3B} by the accretion rate for a non-gravitating planet of the same size.

Numerical results for $P(e_H, i_H, 0.005)$, which represents, e.g., a protoplanet of density $\rho = 3.4 \text{ g cm}^{-3}$ orbiting 1 AU from a $1 M_\odot$ star, are presented for a variety of different values of e_H and i_H by Ida and Nakazawa (1989) and GL90. Figure 2 shows the dependence of F_g on random velocities for $r_H = 0.005$ and $e_H = 2i_H$. Similar plots for other values of r_H are presented in GL90. Note that the 2-body approximation is valid for $v/v_e \gtrsim 0.1$, 3-body accretion rates exceed those given by the 2-body formula by up to a factor of 2 when $0.02 \lesssim v/v_e \lesssim 0.1$, and F_g rises less steeply than the 2-body formula at smaller v/v_e , approaching the value of $\sim 1.7 \times 10^4$ as $v \rightarrow 0$.

D. Cross Sections for a Gaussian Velocity Distribution

The formulas quoted above are valid for uniform surface density disks in which all planetesimals either approach the protoplanet at the same speed (particle-in-a-box case) or have the same unperturbed values of e and i (2-body and 3-body cases). While these homogeneous cases provide insight

Figure 2. The 3-body gravitational enhancement of the accretion cross-section of a protoplanet on a circular orbit plotted as a function of planetesimal random velocities (v_{ex}). The radius of the protoplanet is $r_H = 0.005$, which represents, e.g., a protoplanet of density $\rho = 3.40 \text{ g cm}^{-3}$ orbiting 1 AU from a star of mass $1 M_\odot$. The ratio of the mass of the protoplanet to that of the star used in the numerical calculations is $\mu = 10^{-6}$; however, the results should be valid for any $\mu < 1$. Individual points correspond to results for separate runs; in each run all of the planetesimals have identical eccentricities and inclinations with $e_H = 2i_H$, and are distributed in semimajor axis as a uniform surface density swarm. Error bars represent statistical (\sqrt{n}) uncertainties in the numerical experiments. The dotted line represents the limiting case of planar circular orbits. The dashed curve is the 2-body approximation given by Eq. (24). Figure from GL90.

into the dynamics of the orbits leading to collisions, they do not represent a realistic disk of planetesimals. Planetesimal motions are much better approximated by a Rayleigh distribution in e and i (Eq. 1) or, equivalently, a triaxial Gaussian distribution in local velocities (Eq. 2). Using the particle-in-a-box approximation, Vityazev and Pechernikova (1981) found that when $v < v_e$, the average eccentricity of *colliding* planetesimals is $\sim 3^{-1/2} \langle e^2 \rangle^{1/2}$; this implies a factor of ~ 3 enhancement in accretion rates. Greenzweig and Lissauer (1992) compute formulas for the accretion rate of a protoplanet embedded in a uniform surface density disk of planetesimals with such a velocity distribution. They find that in the 2-body approximation, accretion rates when $v < v_e$ are enhanced compared to the case where all planetesimals have e and i equal to the rms of the Rayleigh distribution by a factor which depends weakly on $I (\equiv \sin i / e)$ and always exceeds 2.6. Numerical 3-body integrations show comparable enhancements, except when $\langle e_H^2 \rangle^{1/2} < 1$ (Greenzweig and Lissauer 1992); at very low eccentricities, the enhancement disappears due to the flattening of the accretion rate as $e \rightarrow 0$ (cf. Fig. 2). Qualitatively similar

results have been reported by Ida and Nakazawa (1988) and Ohtsuki and Ida (1990).

IV. EARLY STAGES OF PLANETESIMAL ACCUMULATION

The velocity dependence of the collision cross section described above leads to a strong coupling between the evolution of the velocity and size distributions of planetesimals. The study of planetary accumulation therefore requires a simultaneous calculation of the velocity evolution and size evolution of the planetesimal swarm. The early stages of planetesimal evolution has been modeled by several authors (Greenberg et al. 1978,1984; Nakagawa et al. 1983; Ohtsuki et al. 1988; Wetherill and Stewart 1989). All of these papers use some variant of the particle-in-a-box approximation, but they differ in their treatment of the velocity evolution and their method of simulating the planetesimal size evolution. The most important result that has emerged from this work is that the evolving planetesimal size distribution can follow two qualitatively distinct paths that are characterized by very different time scales. The slower evolutionary path exhibits an orderly growth of the entire size distribution so that all the planetesimals remain tied to the continuous size distribution throughout the early stages of planetesimal accumulation. The term *runaway accretion* refers to a different evolutionary path where the largest planetesimal in the local region grows much more rapidly than the remainder of the population and therefore becomes detached from the continuous size distribution. Recent modeling efforts have focused on the task of delineating the circumstances under which *runaway accretion* may or may not occur (Ohtsuki et al. 1990; Ohtsuki and Ida 1990; Wetherill 1989,1990a). In this section we review the causes of runaway accretion and discuss the relevance of this process to planet formation.

A. Solutions of the Coagulation Equation

The origin of runaway accretion can be best understood in the context of various solutions to the discrete form of the coagulation equation,

$$\frac{dn_k}{dt} = \frac{1}{2} \sum_{i+j=k} A_{ij} n_i n_j - n_k \sum_i A_{ik} n_i \quad (31)$$

which describes the time evolution of the number of bodies n_k with mass m_k . The merger of smaller bodies increases n_k , whereas the incorporation of bodies of mass m_k into larger bodies causes n_k to decrease. Analytical solutions to Eq. (31) are known for a few simple forms of the collision probability A_{ik} (Safronov 1972; Trubnikov 1971; Wetherill 1990a). Although none of these special cases accurately represent the velocity-dependent collision probabilities described in Sec. III, the few analytical solutions to the coagulation equation provide a rigorous test for the accuracy of any numerical algorithm used to solve the coagulation equation. Two such solutions which exhibit

orderly growth rather than runaway accretion are the cases when A_{ij} equals a constant and when A_{ij} is proportional to the sum of the masses, $m_i + m_j$. Ohtsuki et al. (1990) used these two solutions to show how numerical algorithms that employ fixed mass-coordinate divisions to represent the mass distribution can produce erroneous results. They conclude that numerical calculations of planetesimal accumulation which use a mass ratio between neighboring mass coordinates that exceeds $\sqrt{2}$ can substantially overestimate the rate of planetary growth.

In contrast to the fixed mass-coordinate algorithms used by most previous workers, Wetherill and Stewart (1989) represented the size distribution with a number of moving "batches," each containing a large number of bodies of the same mass. In this Lagrangian-type scheme, the mass value characterizing each batch is allowed to grow by the sweep-up of smaller bodies as well as by merger with other bodies in the same batch. Wetherill (1990a) has presented test calculations using this method which show better agreement with the two analytical solutions described above than was obtained by Ohtsuki et al.

A more stringent test of any numerical procedure for solving the coagulation equation is the ability to reproduce the solution when A_{ij} is proportional to the product of the masses $m_i m_j$ because this is a case known to exhibit runaway growth of the largest body. As pointed out by Wetherill (1990a), the analytical solution for this case is best understood by replacing Eq. (31) with a set of equations which explicitly separate out the evolution of the largest body in the distribution:

$$\frac{dn_k}{dt} = \frac{\gamma}{2} \sum_{i+j=k} ij n_i n_j - \gamma k n_k \sum_i i n_i - \gamma k_R k n_k \quad (32)$$

$$\frac{dk_R}{dt} = \gamma k_R \sum_k k^2 n_k \quad (33)$$

where the masses have been normalized such that $A_{ij} = \gamma ij$ and k_R is the normalized mass of the largest body. The last term on the right-hand side of Eq. (32) represents the mass lost from bin "k" as a result of collisions with the largest body. These equations are consistent with a time independent total mass n_o where

$$n_o = k_R + \sum_k k n_k. \quad (34)$$

The solution of Eq. (32) was found by Trubnikov (1971) to be

$$n_k(\eta) = \frac{n_o(k\eta)^{k-1} e^{-k\eta}}{k! k} \quad (35)$$

where $\eta = n_o \gamma t$ is a dimensionless time variable. The time evolution of the runaway body is obtained by substituting the solution (35) into Eq. (34) and solving for k_R .

Wetherill (1990a) has utilized the above solution to verify the accuracy of the numerical procedure used by Wetherill and Stewart (1989) in their calculation of planetesimal evolution. A crucial attribute of Wetherill and Stewart's calculation is the probabilistic procedure used to simulate abrupt changes in the mass of the largest body. During a time step of length Δt , the number of merging collisions between bodies in batch "*i*" and bodies in batch "*j*," ν_{ij} , is given by the formula

$$\nu_{ij} = n_i n_j A_{ij} \Delta t. \quad (36)$$

When "*i*" and "*j*" represent very large bodies, ν_{ij} often falls between 0 and 1. It is physically reasonable to interpret a fractional value of ν_{ij} as a collision probability per time step because collisions between very large bodies do not really occur during every time step. The procedure used by Wetherill and Stewart is therefore to create a new batch containing one body only when $m_i + m_j$ exceeds the mass of the largest body by a factor δ (where $1.07 < \delta < 1.15$) and ν_{ij} exceeds a random number between 0 and 1. Numerical calculations using this procedure are able to reproduce the runaway growth predicted by Eqs. (34) and (35) quite accurately, aside from a small time lag that depends on the value chosen for δ (Wetherill 1990a). Alternative numerical procedures which fail to simulate the abrupt changes in the size of the largest body can artificially suppress runaway growth. Taken together, these studies of the coagulation equation provide an important lesson: it is always advisable to test one's numerical procedures against known solutions of the coagulation equation before drawing any conclusions about the physical causes of runaway accretion of the planets.

B. The Causes of Runaway Accretion

The three analytic solutions of the coagulation equation described above indicate a bifurcation between solutions which display orderly growth and solutions which display runaway growth of the largest body. The decisive factor that determines which branch the solution will take during planetesimal accumulation is the velocity dependence of the collision rate described in Sec. III. In general, a velocity distribution which exhibits smaller velocities for the larger bodies (as is shown in Fig. 1) will increase the effective mass dependence of the collision rate and will therefore increase the likelihood of runaway accretion. Wetherill and Stewart (1989) presented a series of calculations which serve to delineate the conditions required for runaway accretion to occur. In those calculations which omitted the energy equipartition terms proportional to $(m_k v_k^2 - m_i v_i^2)$ in Eqs. (7–14), orderly growth of the planetesimal size distribution was found. These results show qualitative agreement with the earlier results of Safronov (1972) and Nakagawa et al. (1983), who also neglected the energy equipartitioning caused by gravitational scattering.

When Wetherill and Stewart (1989) included the energy equipartition terms in their velocity evolution equations, they found runaway growth of the

largest planetesimal to occur. Complementary calculations by Ohtsuki and Ida (1990) confirm the result that runaway accretion occurs when the random velocities decrease with increasing planetesimal mass. Another mechanism which may decrease the velocities of the largest bodies is the enhanced gas drag that would result from gravitational concentration of nebular gas around massive planetesimals (Takeda et al. 1985). Ohtsuki et al. (1988) present calculations including this enhancement of gas drag which also display runaway accretion. These recent investigations were motivated to large degree by the pioneering work of Greenberg et al. (1978) that first reported runaway accretion. However, Wetherill and Stewart were unable to reproduce runaway growth when using the same physical assumptions that were stated by Greenberg et al., and the validity of those early results remains controversial (cf. Spaute et al. 1991; Kolvoord and Greenberg 1992).

As energy equipartition via gravitational scattering plays a pivotal role in the bifurcation between orderly and runaway growth, is important to establish the limits of validity of the velocity evolution equations discussed in Sec. II. Ida (1990) has presented an extensive series of 3-body orbit integrations in order to determine directly the ability of a protoplanet on a circular orbit to alter the velocity distribution of the surrounding planetesimal swarm as well as the ability of a planetesimal swarm to damp the eccentricity and inclination of a protoplanet via dynamical friction. Ida finds that the energy equipartition rate agrees well with the 2-body results at high velocities. However, when e_H of the smaller planetesimals drops below 2, the rate of equipartition stops increasing with decreasing velocity (unlike the 2-body case, where the rate increases indefinitely). Ida's work therefore implies that dynamical friction continues to operate at low velocities, but the energy equipartition rate attains a maximum asymptotic value that is given by setting $e_H = 2$ in the 2-body formula. When the velocity evolution Eqs. (7-14) are modified to include the limiting equipartition rate, one finds that the steady-state velocities of the largest planetesimals are somewhat greater than shown in Fig. 1. Nevertheless, the velocities of the largest bodies are still found to be substantially smaller than $e_H = 2$ in size distributions where most of the mass is contained in the smaller planetesimals. In light of this result, it appears likely that runaway growth of the largest planetesimals will occur in spite of the limiting equipartition rate found by Ida.

Although the causes of runaway accretion are fairly well established, the precise rate of runaway growth remains somewhat uncertain because the statistical arguments used to derive the velocity evolution equations begin to break down once runaway growth has begun. The Fokker-Planck operator used to derive Eqs. (7-14) implicitly assumes that successive gravitational encounters are uncorrelated, so that random velocities evolve in a random-walk fashion. However, once a protoplanet grows much more massive than any other body in the local accretion zone, each successive gravitational encounter with this protoplanet tends to be correlated with the preceding encounter. In the limit that one can neglect mutual interactions among the

smaller planetesimals, the smaller planetesimals will always approach the protoplanet with the same velocity owing to the conservation of their Jacobi constant with respect to the protoplanet. Wetherill and Stewart (1989) placed limits on the importance of this effect by presenting an accretion calculation which omitted perturbations by the largest body in the zone. The rate of runaway accretion was accelerated in that case, due to the reduced random velocities.

When a single protoplanet is the dominant perturber in a zone, the velocity dispersion ceases to be isotropic. Because of the coupling between azimuthal and radial motions, the protoplanet is able to excite eccentricities in planetesimals initially on circular orbits, but due to the symmetry of the equations of motion about the plane of the protoplanet's orbit, the protoplanet cannot excite inclinations in coplanar planetesimals. Numerical studies of planetesimals with initially small e_H and i_H imply much more rapid growth of eccentricity than inclination (Ida 1990; GL90). The rate of planetary growth can be greatly accelerated in such hot, flat disks. (For details, see the discussion surrounding Eq. [50] in GL90.)

Realistically, the precise rate of runaway growth is determined by the relative frequency of encounters with the protoplanet compared to the rate of velocity evolution due to gas drag and mutual interactions among the smaller planetesimals. Hayashi et al. (1977) have stressed the importance of calculating the evolution of both semimajor axes and eccentricities in order to determine the long-term evolution of the Jacobi "constant" when all of these processes are active. More detailed simulations of this problem are needed to better constrain the maximum accretion rate during runaway growth.

C. The Problem of the Asteroid Belt

The absence of a large terrestrial planet in the region between the orbits of Mars and Jupiter provides a strong constraint for models of solar system formation. Numerical simulations of planetesimal accumulation in the primordial asteroid belt yield runaway growth of a protoplanet more massive than 10^{27} g on a time scale of several times 10^5 yr if the influence of Jupiter is neglected (Wetherill 1989). Gravitational perturbations by Jupiter could have curtailed runaway in the asteroid belt only if Jupiter's core had also formed on a time scale of several times 10^5 yr. The early runaway growth of Jupiter's core has therefore emerged as a desirable feature in scenarios of planet formation.

The accumulation of Jupiter's core on a time scale of <1 Myr appears to be possible if the surface density of condensable materials at Jupiter's orbit was ≥ 20 g cm $^{-2}$ (Lissauer 1987; Wetherill 1989). This large a surface density is not predicted by standard minimum-mass solar-nebula models. (A minimum-mass solar nebula is a model circumsolar disk which contains only the amount of condensable material currently present in the planets, augmented with volatiles to solar composition and spread out to give a smooth density distribution in radius. The total mass of the protoplanetary disk in such models is 0.01 to 0.02 M_\odot .) One possibility is that the surface density of solids

may have been enhanced at Jupiter's orbit due to water ice condensation and by diffusive transport of condensable water vapor from the inner solar system (Stevenson and Lunine 1988). However, we believe that the more likely explanation is that the surface mass density of the protoplanetary disk in the region where the giant planets accreted was a factor of several greater than that predicted by minimum-mass models. This "excess" mass not only could account for the rapid formation of the cores of the giant planets (Sec. V; cf. Lissauer 1987), but also offers a source of condensable material large enough to have produced the $\sim 50 M_{\oplus}$ of comets believed to exist in the Oort cloud at the present epoch, even after losses over the age of the solar system have been accounted for (Fernandez and Ip 1984; Duncan et al. 1987; Weissman 1990). Moreover, disk stability analysis, which suggests a preferred mass of protoplanetary disks equal to $\sim 1/3$ that of the central star (Chapter by Adams and Lin; cf. Shu et al. 1990), and observations of relatively massive disks around many young stars (Chapter by Beckwith and Sargent), reinforce our opinion that minimum-mass models of the solar nebula are headed towards the dustbin of history.

Although Jovian perturbations are widely invoked to explain the asteroid belt, the precise mechanism that halted planet formation is still a subject of some dispute. The only way to stop planet growth is to increase the planetesimal velocities to a value substantially greater than the surface escape velocity of the largest bodies in a local region. The difficulty with invoking gravitational perturbations by Jupiter for this purpose is that the resultant eccentricity pumping is only appreciable at narrow resonance locations. Several authors have discussed how the dissipation of the nebular gas could have shifted the resonance locations, thereby causing Jupiter's resonances to sweep through the entire asteroid belt (Heppenheimer 1980; Torbett and Smoluchowski 1980; Ward 1981). Detailed models which predict the time scale for removal of the gas are required to evaluate this suggestion properly. Changes in Jupiter's semimajor axis due to accretion of gas and/or ejection of planetesimals from the solar system could also have caused Jovian resonances to have swept across the asteroid belt (Safronov and Gusseinov 1989).

Another possible way to pump up velocities in the asteroid belt is to postulate a population of Jupiter-zone planetesimals that are scattered into the asteroid belt once Jupiter becomes sufficiently massive. Recent Monte Carlo calculations of this scenario show that the necessary large velocities are produced in the asteroid belt if the Jupiter zone planetesimals are as massive as the Earth and if one of these bodies becomes trapped in the asteroid belt for an extended period of time (Ip 1987; Wetherill 1989). This result is somewhat unsatisfying, because one must then require this Earth-size body to end up near a strong Jupiter resonance in order to provide a mechanism for its removal. It is also not clear that such a population of Jupiter-zone planetesimals would be created during the rapid runaway growth of Jupiter's core.

One variant of the previous model is that a planet-sized body did form at ~ 3 AU from the Sun. This body could then have excited the eccentricities of

the current asteroids prior to being ejected from the solar system by resonant perturbations from Jupiter. In this case, asteroid belts might not be a common feature among planetary systems otherwise much like our own. More detailed simulations of planetesimal accumulation which accurately model Jupiter perturbations should help narrow the possibilities (cf. Wetherill 1991c).

V. LIMITS TO RUNAWAY GROWTH

Runaway accretion with high F_g requires low random velocities, and thus small radial excursions, $2ae$, of planetesimals. This implies that a protoplanet's feeding zone is limited to the annulus of planetesimals which it can gravitationally perturb into intersecting orbits. Thus, rapid runaway growth must cease when a protoplanet has consumed most of the planetesimals within its gravitational reach (Lissauer 1987).

For the case of a protoplanet on a circular orbit, the standard theory of the restricted 3-body problem places an upper bound on the initial semimajor axis, b_H , that may lead to collision. Neglecting gas drag and interactions with other planetesimals, a planetesimal whose orbital elements satisfy the inequality:

$$\frac{3}{4}b_H^2 - e_H^2 - i_H^2 \geq 9 \quad (37)$$

cannot enter the protoplanet's Hill sphere (see, e.g., Artymowicz 1987). For example, a particle which initially has $e_H = i_H = 0$ and $b_H > 2\sqrt{3} \approx 3.5$ remains in superior orbit to the protoplanet, although its path may be perturbed (this perturbation preserves the left-hand side of Eq. (37), which is a version of the Jacobi constant). For a single encounter (one synodic period), GL90 find that planetesimals with initial $e_H = i_H = 0$ and $b_H > 2.6$ do not approach closer than $0.1 h$ from the protoplanet; however, Kary et al. (1993) show that most planetesimals with initial $e_H = i_H = 0$ and $1.3 < b_H < 3.2$ come within $0.1 h$ of the protoplanet during 20 synodic periods. For nonzero "initial" eccentricity and/or inclination, the accretion zone expands slightly, but for e and i low enough for F_g to be large, planetesimals with $|b_H| > 4$ cannot be accreted. Thus, the accretion zone of a protoplanet embedded in a disk of low random-velocity planetesimals extends over the region:

$$|b_H| < B \quad (38)$$

where B depends on the magnitude of other perturbations on the planetesimals, and typically is ~ 3.5 to 4 in a quiescent disk.

The size of a protoplanet's Hill sphere expands as it accretes matter. The mass of a protoplanet which has accreted all of the planetesimals within an annulus of width $2\Delta r$ is:

$$m = \int_{r-\Delta r}^{r+\Delta r} 2\pi r' \sigma(r') dr' \approx 4\pi r \Delta r \sigma(r). \quad (39)$$

Setting $\Delta r = Bh = Br(m/3M_\star)^{1/3}$, we obtain the isolation mass to which a protoplanet orbiting at a distance r from a star of mass M_\star may grow:

$$m = \frac{(4\pi Br^2\sigma)^{3/2}}{(3M_\star)^{1/2}} = 2.10 \times 10^{-3} \left(\frac{Br^2\sigma}{2\sqrt{3}} \right)^{3/2} \left(\frac{M_\odot}{M_\star} \right)^{1/2} M_\oplus \quad (40)$$

where the mass of the Earth $M_\oplus = 5.98 \times 10^{27}$ g, r is expressed in AU and σ in g cm^{-2} (Lissauer 1987). For example, assuming $B = 2\sqrt{3}$, a minimum-mass solar nebula with $\sigma = 10 \text{ g cm}^{-2}$ at 1 AU implies protoplanet isolation at $0.066 M_\oplus$; whereas $\sigma = 3 \text{ g cm}^{-2}$ at 5 AU implies protoplanet isolation at $1.36 M_\oplus$.

Runaway growth can persist beyond the isolation mass given by Eq. (40) only if additional mass can diffuse into the protoplanet's accretion zone. Three plausible mechanisms for such diffusion are scattering between planetesimals, perturbations by protoplanets in neighboring accretion zones and gas drag. The process of radial drift due to scattering within the vicinity of a protoplanet has not yet been analyzed quantitatively and remains a major open question.

Drift due to gas drag has been modeled in more detail. Weidenschilling and Davis (1985) suggested that a protoplanet can enhance the effects of gas drag on material orbiting just outside its accretion zone in the following manner: As planetesimals drift slowly inwards due to gas drag, they eventually encounter and are trapped into small integer commensurabilities (resonances) with the protoplanet. The eccentricities induced at such resonances lead to high-velocity collisions which grind planetesimals into small debris. Small planetesimals are very strongly affected by gas drag; they cannot be stopped by protoplanet resonances, and thus rapidly drift into the protoplanet's accretion zone.

Alternatively, radial motion of the protoplanet may bring it into zones not depleted of planetesimals. Gravitational torques due to excitation of spiral density waves in the gaseous component of the protoplanetary disk have the potential of inducing rapid radial migration of protoplanets; however, as the migration rate depends on the difference between comparable positive and negative torques (due to excitation of waves at resonances interior and exterior to the protoplanet's orbit, respectively), the magnitude of this effect is extremely difficult to quantify (Goldreich and Tremaine 1980; Ward 1986). Recently it has been suggested that gravitational focusing of gas could vastly increase the rate of inward drift of protoplanets due to gas drag (Takeda et al. 1985; Ohtsuki et al. 1988). This result would have profound implications for models of planetary accretion. However, the fluid calculations assumed low Reynolds number, which may be appropriate for a turbulent protoplanetary disk, but not for a laminar one. The effects of the stellar gravitational field upon the flow pattern also must be examined.

Radial drift of planetesimals relative to a protoplanet increases the protoplanet's isolation mass only if the protoplanet is able to efficiently accrete those planetesimals which approach its orbit. The case of planetesimals decaying inwards (due to gas drag) towards a planet on a circular orbit has been

studied by Kary et al. (1993). They find that unless the planet's accretion radius is $\gtrsim 0.01 h$ (which would imply a distended thick atmosphere), a majority of the planetesimals miss the planet, and continue to drift inwards towards the star. Thus, radial drift is not as promising a mechanism to increase a planet's isolation mass as was previously believed.

VI. FINAL STAGES OF PLANETESIMAL ACCUMULATION

The self-limiting nature of runaway growth strongly implies that massive protoplanets form at regular intervals in semimajor axis throughout the inner solar system. The mutual accumulation of these protoplanets into a small number of widely spaced planets necessarily requires a stage characterized by large orbital eccentricities, significant radial mixing, and giant impacts. Mutual gravitational scattering can pump up the relative velocities of the protoplanets to values comparable to the surface escape velocity of the largest protoplanet, which is sufficient to ensure their mutual accumulation into planets. The large velocities imply small collision cross sections and hence long accretion times. In the outer solar system, the limits of runaway growth are less severe; it is feasible that runaway growth of Jupiter's core continued until it attained the necessary mass to rapidly capture its massive gas envelope (Lissauer 1987).

A. Simulations of Terrestrial Planet Formation

The transition from runaway growth in isolated accretion zones to the mutual accumulation of protoplanets in large eccentricity orbits has so far only been studied qualitatively. The limiting runaway mass given by Eq. (40) suggests that runaway growth in the inner solar system will yield protoplanets of mass $\sim 10^{26}$ g, with their semimajor axes spaced 0.01 to 0.02 AU apart. At this stage, most of the original mass will be contained in the large protoplanets, so their random velocities will no longer be strongly damped by energy equipartition with the smaller planetesimals. Even if the protoplanets form in circular orbits, mutual gravitational perturbations among several bodies can eventually induce eccentricities of order 0.01 ($e_H \approx 5$), which is sufficient to enable their orbits to cross so the protoplanets can suffer close gravitational encounters. Stagnation of protoplanets in isolated orbits is unlikely because the width of the accretion zone at the end of runaway growth roughly coincides with the maximum orbit separation from which neighboring pairs of protoplanets can significantly perturb each other.

Once the protoplanets have perturbed one another into crossing orbits, their subsequent orbital evolution is governed by close gravitational encounters and violent, highly inelastic collisions. Wetherill (1980*a*, 1985, 1986, 1988, 1990*b*) has described numerous simulations of this final stage of accretion, exploring a wide range of initial conditions. Surprisingly, the results of these simulations are not strongly affected by the earlier runaway growth stage. Regardless of whether the simulations start from a swarm of 500 bodies of mass 10^{25} g or just 30 protoplanets of mass several times 10^{26} g, the end result is

the formation of 2 to 5 terrestrial planets on a time scale of about 100 Myr. An important feature of Wetherill's simulations is that planetesimal orbits execute a random walk in semimajor axis due to successive gravitational encounters. The resulting widespread mixing of material throughout the terrestrial planet region greatly diminishes any chemical gradients that may have existed during the early stages of planetesimal formation. Although, some correlations between the final heliocentric distance of a planet and the region where most of its constituents originated are preserved in the simulations (Wetherill 1988). Nevertheless, Mercury's high iron abundance is therefore less likely to arise from chemical fractionation in the solar nebula and more likely to be caused by a catastrophic giant impact during the final stages of accretion (see Sec. VI.B below).

Although radial mixing does occur, the total mass and orbital angular momentum of the swarm is nearly conserved during its accumulation into planets. The energy lost as heat in collisions, however, amounts to a few percent of the total orbital energy, resulting in a significant spreading of the disk. Thus, in order to end up with the same angular momentum distribution as is observed for Mercury, Venus, Earth and Mars, one must confine the initial swarm of protoplanets to a narrow annulus with most of the mass between 0.7 and 1.1 AU (Wetherill 1988). More plausible initial mass distributions which vary smoothly with heliocentric distance are incapable of reproducing the observed angular momentum distribution of the inner planets unless the planetesimal swarm can be supplied with extra "free" energy from an external source, e.g., Jupiter. By free energy, we mean energy in excess of that required for a circular orbit at a given semimajor axis:

$$E_f \equiv E - \Omega L \quad (41)$$

where E is orbital energy and L is the magnitude of the orbital angular momentum. Thus, the free energy may be increased by the removal of energy and angular momentum, provided $\Delta E/\Delta L < \Omega$.

The problem of removing excess angular momentum from the terrestrial planets is intimately tied to the larger problem of explaining the extreme depletion of mass between the orbits of Mars and Jupiter. A large radial redistribution of mass is apparently required, but the candidate mechanisms proposed to accomplish this redistribution are poorly constrained at present. Whatever process pumped up the velocities of the asteroids must have yielded a vast quantity of small collision fragments that would have been susceptible to gas drag. These collision fragments would tend to spiral in toward the Sun, thereby enhancing the density of solids in the terrestrial planet zone. Large protoplanets may also experience significant orbital decay by exciting spiral density waves in the gaseous disk (Ward 1986, 1988, 1989b). Ward calculates that protoplanets more massive than 10^{27} g suffer significant orbital evolution inwards towards the protostar on a 1 to 10 Myr time scale via this process. Numerical simulations of planetesimal accumulation which

include orbital migration due to density wave torques also show significant redistribution of mass and angular momentum in the terrestrial planet zone (Wetherill 1990*b*, 1991*b*). More detailed studies are needed to determine if density wave torques can fully resolve the angular momentum problem in the inner solar system.

B. Giant Impacts

The mutual accumulation of numerous protoplanets into a small number of planets must have entailed many collisions between protoplanets of comparable size. As, in the post-runaway era, the random velocities keep pace with the escape velocity of the larger protoplanets, collisions between smaller bodies result in disruption instead of aggregation. The largest bodies are resistant to collisional disruption because their gravitational binding energy exceeds the kinetic energy of the collision. When the largest protoplanet reached a mass comparable to the Earth's mass, bodies near the size of Mercury became marginal cases, with collisions just as likely to strip off material as to add to the final mass of the planet. This result led Wetherill (1988) and Vityazev et al. (1988) to suggest that Mercury's silicate mantle was stripped off in a giant impact, leaving behind an iron-rich core (cf. Benz et al. 1988). Wetherill's simulations also lend support to the giant impact hypothesis for the origin of the Earth's Moon (e.g., Stevenson 1987); during the final stage of accumulation, an Earth-size planet is typically found to collide with several objects as large as the Moon and frequently one body as massive as Mars. The obliquities of the rotation axes of the planets provide independent evidence of the occurrence of giant impacts during the accretionary epoch (Safronov 1966, Lissauer and Safronov 1991).

C. Accretion Time Scales

Growth of planet-sized bodies from kilometer-sized planetesimals involves an increase in radius of 4 to 5 orders of magnitude. The planetary accretion rates given by Eqs. (19–26) all vary as the surface area of the planet R_s^2 . Thus, for all other parameters constant, a planet's radius grows at a (statistically) uniform rate, and most of the growth time is spent in the last decade of radial expansion. The late phases of planetary growth are therefore crucial to determining the overall length of the accretionary epoch. Thus, a stage of runaway growth which ends in isolated protoplanets which must pump up velocities in order to collide and continue their agglomeration to planetary size, leads to accretion time scales similar to those models in which runaway never occurs.

Of course, protoplanet radius is not the only parameter in the equations which varies with time. Runaway accretion starts slowly (small F_g) and accelerates with time; thus it is possible that the "initial" size distribution of planetesimals significantly influenced the growth times of the planets. For example, a "protoplanet" initially of radius 10 km, at 5.2 AU from a $1 M_\odot$ star, in a disk of surface mass density $\sigma = 15 \text{ g cm}^{-2}$ whose velocity dispersion

is controlled by planetesimals 5 km in radius, would require $\sim 2 \times 10^5$ yr to grow large enough that $F_g = 3000$ (at which point $e_H = 2$ and protoplanet perturbations become an important factor in exciting noncircular motions of planetesimals; cf. GL90). This protoplanet would take a subsequent $\sim 6 \times 10^5$ yr to attain a mass of $15 M_\oplus$ (Lissauer 1987). A protoplanet in an equivalently skewed initial distribution of larger planetesimals would take much longer to reach $F_g = 3000$, whereas the runaway would proceed much faster in a swarm of smaller planetesimals, because the radius doubling time for the protoplanet would be shorter.

VII. CONCLUSIONS

The planetesimal hypothesis provides a viable theory of the growth of the terrestrial planets, the cores of the giant planets and the smaller bodies present in the solar system. The formation of solid bodies of planetary size should be a common event, at least around stars which do not have binary companions orbiting at planetary distances. The formation of giant planets, which contain significant fractions of H_2 and He, requires rapid growth of planetary cores, so that gravitational trapping of gas can occur prior to the dispersal of the gas from the protoplanetary disk. According to the scenario which we have outlined, the largest bodies in any given zone are the most efficient accreters, in the sense that they double in mass the fastest. Such runaway accretion of a few large solid protoplanets can lead to core formation in ~ 1 Myr, provided disk masses are a few times as large as those given by minimum-mass models of the solar nebula. Thus, it appears possible that giant planets may also be common, although this conclusion must be regarded as much more tentative.

The ultimate sizes and spacings of solid planets are determined by their ability to gravitationally perturb each other into crossing orbits. Such perturbations often are due to weak resonant forcing, and occur on time scales much longer than the bulk of planetesimal interactions discussed herein. These interactions are not yet fully understood, although a great deal of progress has been made in recent years (Wisdom 1983; Chapter by Duncan and Quinn). Although quantitative formulas for scaling planetary sizes and spacings will require a better grasp of these processes, a few qualitative remarks can be made. First, a more massive protoplanetary disk will probably produce larger but fewer planets. Second, stochastic processes are important in planetary accretion, so nearly identical initial conditions could produce quite different outcomes, e.g., the fact that there are 4 terrestrial planets in our solar system as opposed to 3 or 5 or 6 is probably just the luck of the draw (cf. Wetherill 1988). Third, migration of some planetesimals over significant distances within the protoplanetary disk probably occurred, leading to a radial mixing of material which condensed in differing regions of the solar nebula. Fourth, although the spacing of giant planets is probably determined by similar processes to that of solid planets, their ultimate sizes may depend more on such factors as how fast they grew relative to the dispersal of the nebula and their potential

ability to halt their own growth by gravitationally truncating the gaseous disk (Lin and Papaloizou 1979a).

Many aspects of planetary growth remain poorly understood. The asteroid belt currently contains much less than a planetary mass of material, and that material is spread over countless bodies which move at high velocities relative to each other. Models of the protoplanetary disk suggest this is unlikely to be due to an initial absence of condensed material. Perturbations by Jupiter and/or Jupiter-scattered protoplanets have been invoked for preventing planetary growth in the asteroid zone by increasing relative velocities of planetesimals, and for clearing material from that region; however, many problems remain with these scenarios (cf. Sec. IV.C). Planetesimal dynamics in the Uranus-Neptune region are complicated by the fact that bodies in this region are not tightly bound to the solar system: The difference between circular orbit velocity and escape speed from the solar system at 30 AU is less than the escape speed from the Moon. Using a planetary accumulation model analogous to those which Wetherill has successfully applied to the late stages of growth of the terrestrial planets (cf. Ipatov 1987), Ipatov (1989) finds that the mass of material ejected into hyperbolic orbits from the Uranus-Neptune region during the accretionary epoch exceeds the amount of solid matter incorporated into these planets by approximately an order of magnitude. Moreover, much of the material remaining in heliocentric orbit has spread to tens of AU beyond the original outer boundary of the disk. However, Ipatov's calculations start with planetesimals of identical size and neglect dynamical friction; these assumptions suppress runaway growth and thus lengthen the accretion time scales to unreasonably large values. Further studies of planetesimal accumulation in the outer regions of protoplanetary disks are needed to answer the many interesting questions raised by this study (Lissauer et al., in press).

PLANETARY ACCRETION IN THE SOLAR GRAVITATIONAL FIELD

KEIJI OHTSUKI, SHIGERU IDA, YOSHITSUGU NAKAGAWA

University of Tokyo

and

KIYOSHI NAKAZAWA

Tokyo Institute of Technology

We describe accumulation of planetesimals based on current studies on collisions and gravitational scattering of planetesimals in the solar gravitational field. First we examine the condition of runaway growth of protoplanets based on the collision rate between planetesimals and express it in terms of relative velocity between protoplanet and planetesimals. We find that random velocity (i.e., eccentricity and inclination of Kepler orbit) sensitively controls runaway growth of protoplanets. Next we describe the evolution of random velocity due to gravitational scattering and inelastic collisions, both in the solar gravitational field, and show that these processes drive the planetesimals toward equipartition of energy of random motion. Using these results, we estimate planetesimal velocities in each stage of accumulation, and examine the sequence of planet formation from planetesimals. Runaway growth of protoplanets is expected in an intermediate stage of accumulation, when the growth time scale is considerably shorter, while in the subsequent stage with high relative velocity, their growth will be decelerated. Finally, we discuss an appropriate treatment in numerical simulation of planetesimal accumulation.

Among the unsolved questions in the origin of the solar system, the most serious one is that no theory or numerical simulation has so far succeeded in explaining the formation of Uranus or Neptune within the age of the solar system without any *ad hoc* assumptions. The formation of Jupiter and Saturn before the dispersal of the solar nebula also remains to be explained. Although runaway growth of protoplanets has been recently discussed as a possible mechanism to considerably shorten the time scale of planetary formation (Wetherill and Stewart 1989), it has not yet been clarified how runaway growth proceeds in the late stage of accretion which determines the whole growth time of planets. In order to understand the whole planetary accretion process, various approaches have so far been taken to clarify individual fundamental processes. Safronov (1969) first studied them quantitatively by analytical methods. Subsequently, they have been studied in more detail mainly through computer simulation incorporating various effects such as gas drag of the solar nebula, gravitational interaction between planetesimals, or collisional

disruption (see, e.g., Greenberg et al. 1978; Nakagawa et al. 1983; Ohtsuki et al. 1988; Wetherill and Stewart 1989; see Chapter by Lissauer and Stewart). However, as yet the effects of the solar gravitational field on the velocity change caused by gravitational scattering and collisions have not been taken into account in these studies. We cannot obtain a reliable time scale of planetary formation until we clarify all these fundamental processes in the solar gravitational field.

In recent years, the kinetic behavior of planetesimals (i.e., collisions and gravitational scattering) in the solar gravitational field has been extensively studied through orbital calculations in the three-body problem or direct N -body simulations. In this chapter, we review recent studies of fundamental processes and, using these results, we examine the sequence of planetary growth from planetesimals. First, we briefly describe the Hill's approximations, which provide us with useful tools to study the interaction between planetesimals (Sec. I). In Sec. II, we examine the condition of runaway growth of a protoplanet, using the collision rate in the solar gravitational field. We express the condition in terms of relative velocity between protoplanet and planetesimals. Subsequently, we discuss the velocity evolution caused by gravitational scattering (Sec. III) and by collisional accretion (Sec. IV), and find that both processes drive planetesimals toward energy equipartition for random motion. The fundamental processes determining the random velocity in each stage of planetesimal accumulation are summarized in Sec. V, where we find that runaway growth of protoplanets is expected in an intermediate stage of planetary growth. Finally, in Sec. VI, we discuss an appropriate numerical treatment of planetesimal accumulation.

I. HILL'S APPROXIMATIONS IN THE THREE-BODY PROBLEM

A planetesimal moves along an elliptic orbit around the Sun. When it occasionally comes very close to another planetesimal, the orbit is disturbed through gravitational scattering or collisions. Thus, we may focus on a small region when we describe such interactions between planetesimals. The coordinates of planetesimals in this region are referred to a reference point that moves on a circular orbit with semimajor axis a_{ref} at the Keplerian angular velocity $\Omega = (GM_{\odot}/a_{\text{ref}}^3)^{1/2}$. In this case, equations for the motion of the planetesimal relative to the point of reference may be linearized. These linearized equations are called Hill's equations (Hill 1878; Hénon and Petit 1986; Nakazawa and Ida 1988).

In general, if particles move under a potential force linear to their position vectors and the interaction term is a function of the relative distance between the particles alone, the motion of particles can be separated into the relative motion and the center of mass motion. Such separation is impossible in the general three-body problem, because the potential force $GM_{\odot}r_i/r^3$ in this case is nonlinear to the position vectors. In Hill's equations, on the other

hand, the solar gravity is expressed in a linear form, and the motions are separable. This is a striking advantage of the use of Hill's equations.

Hénon and Petit (1986) and Nakazawa and Ida (1988) introduced orbital elements defined by

$$\begin{cases} \mathbf{e}_i \equiv (e_i \cos \tau_i, e_i \sin \tau_i) \\ \mathbf{i}_i \equiv (i_i \cos \omega_i, i_i \sin \omega_i) \end{cases} \quad (1)$$

where τ_i and ω_i are the longitudes of the perihelion and the ascending nodes. We can confirm that the solutions to Hill's equations are expressed by linear combinations of the components of \mathbf{e}_i and \mathbf{i}_i (Nakazawa and Ida 1988). This means that the orbital elements \mathbf{e}_i and \mathbf{i}_i are also separated into those for the relative motion and for the center of mass motion: the orbital elements for the center of mass motion are given by

$$\begin{cases} \mathbf{e}_R \equiv (e_R \cos \tau_R, e_R \sin \tau_R) = m'_1 \mathbf{e}_1 + m'_2 \mathbf{e}_2 \\ \mathbf{i}_R \equiv (i_R \cos \omega_R, i_R \sin \omega_R) = m'_1 \mathbf{i}_1 + m'_2 \mathbf{i}_2 \end{cases} \quad (2)$$

with

$$m'_i = \frac{m_i}{m_1 + m_2} \quad (3)$$

and those for the relative motion are

$$\begin{cases} \mathbf{e}_{21} \equiv (e_{21} \cos \tau, e_{21} \sin \tau) = \mathbf{e}_2 - \mathbf{e}_1 \\ \mathbf{i}_{21} \equiv (i_{21} \cos \omega, i_{21} \sin \omega) = \mathbf{i}_2 - \mathbf{i}_1 \end{cases} \quad (4)$$

Because the center of mass motion is unaffected by gravitational scattering or collisions, the orbital elements \mathbf{e}_R and \mathbf{i}_R of the center of mass motions before and after encounter are the same, while those of the relative motion are affected by these interactions.

The above characteristics of Hill's approximations enable us to study the behavior of planetesimals directly in terms of the orbital elements, without any ambiguity which might be caused when we define "random velocity of planetesimals" in several different ways (Chapter by Lissauer and Stewart). Kinetic behavior of planetesimals discussed in this chapter is essentially described in terms of their eccentricity and inclination, which are more fundamental quantities than "random velocity." However, we need to define "relative random velocity v_{21} " when we compare some quantities (e.g., collision rate) of planetesimals in the solar gravitational field with those in free space. In this case, we use a simple form defined by

$$v_{21} = (e_{21}^2 + i_{21}^2)^{1/2} v_K \quad (5)$$

with $v_K (= a_{\text{ref}} \Omega)$ being circular Keplerian velocity.

Another remarkable advantage in Hill's approximations is that we can rewrite the equations of relative motion into a nondimensional form in which

the planetesimal masses m_1 and m_2 or heliocentric distance a_{ref} never appear explicitly. We scale time by Ω^{-1} and length by ha_{ref} , where

$$h = \left(\frac{m_1 + m_2}{3M_{\odot}} \right)^{1/3}. \quad (6)$$

The size of radial excursion $e_{21}a_{\text{ref}}$ and the amplitude of vertical oscillation $i_{21}a_{\text{ref}}$ for the relative motion are then scaled respectively as

$$\begin{cases} \tilde{e}_{21} = e_{21}/h \\ \tilde{i}_{21} = i_{21}/h \end{cases} \quad (7)$$

(\tilde{e}_{21} and \tilde{i}_{21} correspond to “Hill eccentricity e_H ” and “Hill inclination i_H ” defined by Eq. (28) of the Chapter by Lissauer and Stewart). Thus once we obtain the solutions to the nondimensional equations, we may apply them to planetesimals with arbitrary masses and arbitrary a_{ref} by use of the relations (6) and (7).

II. COLLISION RATE AND RUNAWAY GROWTH

A. Condition of Runaway Growth

Here we examine the condition of runaway growth of a protoplanet. We consider a simple situation wherein test protoplanets are embedded in a swarm of small field planetesimals with mass m_2 and the protoplanets grow through the collision with these planetesimals. The growth rate of the test protoplanet with mass m_1 ($> m_2$) is

$$\frac{dm_1}{dt} = m_2 n_s < P > \quad (8)$$

where n_s is the number of field planetesimals in a unit surface of $(ha_{\text{ref}})^2$ [$h \simeq (m_1/3M_{\odot})^{1/3}$; see Eq. (6)], and $<P>$ is the collision rate per unit surface number density averaged over the velocity distribution of the planetesimals.

Let the right-hand side of Eq. (8) be proportional to m_1^{α} . The growth time scale of the protoplanet defined by

$$T_{\text{grow}} = \left(\frac{1}{m_1} \frac{dm_1}{dt} \right)^{-1} \quad (9)$$

is then proportional to $m_1^{1-\alpha}$. It means that for $\alpha > 1$ larger protoplanets grow more rapidly than smaller protoplanets (or planetesimals) and runaway growth occurs, while for $\alpha < 1$ larger ones grow more slowly and the growth should be orderly (Wetherill and Cox 1985). From its definition, α is given by

$$\begin{aligned} \alpha &= \frac{d \ln(n_s < P >)}{d \ln m_1} \\ &= \frac{2}{3} + \frac{d \ln \tilde{v}_{21}}{d \ln m_1} \frac{d \ln < P >}{d \ln \tilde{v}_{21}} \end{aligned} \quad (10)$$

where we used the relation $n_s \propto (ha_{\text{ref}})^2 \propto m_1^{2/3}$, and \tilde{v}_{21} is the “relative random velocity” in a nondimensional form, defined by $\tilde{v}_{21} = v_{21}/hv_K = (\tilde{e}_{21}^2 + \tilde{i}_{21}^2)^{1/2}$ [see Eqs. (5) and (7)]. Equation (10) shows whether runaway growth occurs or not depends on the \tilde{v}_{21} -dependence of $\langle P \rangle$ and the m_1 -dependence of \tilde{v}_{21} (Ohtsuki and Ida 1990). We examine the above dependence in the followings, and describe the condition of runaway growth in terms of m_1 -dependence of \tilde{v}_{21} .

B. \tilde{v}_{21} -Dependence of P

First, we examine \tilde{v}_{21} -dependence of the collision rate. The collision rate in the solar gravitational field has been numerically obtained by calculating the orbits in the three-body problem with various initial conditions and counting the collision orbits (Nishida 1983; Wetherill and Cox 1985; Ida and Nakazawa 1989; Greenzweig and Lissauer 1990). These results are described in detail in the Chapter by Lissauer and Stewart.

In Fig. 1, we plot collision rate P (without velocity distribution of planetesimals) as a function of \tilde{v}_{21} . We assume $\tilde{e}_{21}:\tilde{i}_{21} = 2:1$ because this ratio is expected for relatively large random velocities as a result of gravitational scatterings (Ida 1990; Ida and Makino 1992a). In this figure, P_{2B} is the collision rate with the two-body approximation and P is numerically obtained by orbital calculation; P for $\tilde{v}_{21} < 20$ is drawn using the numerical results for 12 discrete sets of $(\tilde{e}_{21}, \tilde{i}_{21})$ with $\tilde{e}_{21} = 2\tilde{i}_{21}$ (data points obtained by numerical calculation are shown by triangles), while that for $\tilde{v}_{21} > 20$ is drawn by extrapolation of P_{2B} (for detailed definitions of P and P_{2B} , see Chapter by Lissauer and Stewart). As first noted by Wetherill and Cox (1985), a discrepancy between P and P_{2B} exists in the low-velocity region, where P takes constant value for $\tilde{v}_{21} < 0.1$. In such a low-velocity case, the approach velocity is almost determined by the Keplerian shear velocity rather than random velocity due to \tilde{e}_{21} and \tilde{i}_{21} (see, e.g., Binney and Tremaine 1987; Greenberg et al. 1988; Ida 1990), thus P is independent of \tilde{e}_{21} or \tilde{i}_{21} . In the two-body approximation, on the other hand, such systematic relative motion as the Keplerian shear is not taken into account, which gives rise to the above discrepancy. Collision rate in this shear-dominated regime is discussed in detail by Greenberg et al. (1991). On the other hand, P is well approximated by P_{2B} for $\tilde{v}_{21} > 5$. This is because the random motion is large enough to dominate the relative velocity in such cases, and the two-body approximation in gravitational encounters is valid. We will call this velocity regime the dispersion-dominated regime.

We also need take into account the velocity distribution of planetesimals in evaluating collision rate. Ida and Makino (1992a) confirmed by N -body simulation (three-dimensional, 400 nonaccreting equal-mass planetesimals) that the distributions of \tilde{e}_2 and \tilde{i}_2 become Gaussian through mutual gravitational scatterings. The collision rates $\langle P \rangle$ averaged with the Gaussian velocity distribution is presented by Ida and Nakazawa (1988), Ohtsuki and Ida (1990), and Greenzweig and Lissauer (1992). They find that the velocity dependence of the averaged collision rates is almost the same as P , and $\langle P \rangle$

Figure 1. Collision rate P (in the solar gravitational field) and P_{2B} (in free space) per unit surface number density as a function of \tilde{v}_{21} in the case of $\tilde{e}_{21}:\tilde{i}_{21} = 2:1$. The value of the escape velocity ($\tilde{v} \simeq 35$ at 1 AU) is also indicated. The data points obtained by our calculations are shown by triangles and these values are consistent with Greenzweig and Lissauer (1990). The original values obtained by Ida and Nakazawa (1989), which were also used in Ohtsuki and Ida (1990), are slightly smaller than these values for $\tilde{v}_{21} > 2$, as pointed out by Greenberg et al. (1991).

is enhanced by a few times compared to P ; the velocity dependence of $\langle P \rangle$ is given by

$$\frac{d \ln \langle P \rangle}{d \ln \tilde{v}_{21}} \simeq \begin{cases} 0 & \text{for } \tilde{v}_{21} < 0.1 \\ -1 & \text{for } 0.1 < \tilde{v}_{21} < 1 \\ -2 & \text{for } 1 < \tilde{v}_{21} < 10 \\ -1.5 & \text{for } \tilde{v}_{21} \simeq 20 \\ -1 & \text{for } \tilde{v}_{21} \simeq 40 \end{cases} \quad (11)$$

and, for $\tilde{v}_{21} > 40$, $d \ln \langle P \rangle / d \ln \tilde{v}_{21}$ gradually increases to zero with increasing \tilde{v}_{21} . Hence, the condition of runaway growth, $\alpha > 1$, is equivalent to the condition

$$\frac{d \ln \tilde{v}_{21}}{d \ln m_1} < \begin{cases} -\infty & \text{for } \tilde{v}_{21} < 0.1 \\ -1/3 & \text{for } 0.1 < \tilde{v}_{21} < 1 \\ -1/6 & \text{for } 1 < \tilde{v}_{21} < 10 \\ -2/9 & \text{for } \tilde{v}_{21} \simeq 20 \\ -1/3 & \text{for } \tilde{v}_{21} \simeq 40. \end{cases} \quad (12)$$

C. m_1 -Dependence of \tilde{v}_{21}

Next, we reduce the condition of runaway growth to the condition of mass-dependence of random velocity. We introduce the following assumptions: (i) each field planetesimal has the equal mass m_2 ; (ii) the mass m_2 and velocity $v_2 = [(e_2^2 + i_2^2)^{1/2} v_K]$ of field planetesimals are constant; (iii) the random velocity is proportional to m^q . In this case, the velocity of a test protoplanet, $v_1 = (e_1^2 + i_1^2)^{1/2} v_K$, is given by

$$v_1(m_1) = \left(\frac{m_1}{m_2} \right)^q v_2. \quad (13)$$

Because $h \propto m_1^{1/3}$ for $m_1 \gg m_2$, the scaled velocity of the protoplanet, $\tilde{v}_1 (= v_1/hv_K)$, and that of the field planetesimal, \tilde{v}_2 , have the relations $\tilde{v}_1 \propto m_1^{q-1/3}$ and $\tilde{v}_2 \propto m_1^{-1/3}$, respectively. From Eqs. (4) and (5), we then have

$$\tilde{v}_{21}^2 \simeq \tilde{v}_1^2 + \tilde{v}_2^2 \simeq \begin{cases} \tilde{v}_1^2 & \text{for } q > 0 \ (\tilde{v}_1^2 \gg \tilde{v}_2^2) \\ \tilde{v}_2^2 & \text{for } q < 0 \ (\tilde{v}_1^2 \ll \tilde{v}_2^2). \end{cases} \quad (14)$$

Using Eqs. (13) and (14), we obtain

$$\frac{d \ln \tilde{v}_{21}}{d \ln m_1} = \begin{cases} q - 1/3 & \text{for } q > 0 \\ -1/3 & \text{for } q < 0. \end{cases} \quad (15)$$

We find that $d \ln \tilde{v}_{21}/d \ln m_1$ cannot be smaller than $-1/3$. From Eqs. (12) and (15), we find that runaway growth is possible only for $1 < \tilde{v}_{21} < 40$. In an intermediate stage of planetary accretion, \tilde{v}_{21} takes the values nearly equal to or smaller than 20 (Sec. V). Thus, for $\tilde{v}_{21} < 20$, we can write the condition of runaway growth as

$$\frac{d \ln \tilde{v}_{21}}{d \ln m_1} < -\frac{2}{9} \quad (16)$$

which is equivalent to the condition

$$q < \frac{1}{9}. \quad (17)$$

Assuming that the steady state in random velocity is achieved through the balance between the enhancement due to gravitational scattering and damping due to inelastic collisions, Safronov (1969) obtained $q = 1/3$. Nakagawa et al. (1983) considered that the damping is due to gas drag of the solar nebula and obtained $q = 1/9$. These authors did not find runaway growth. On the other hand, Stewart and Wetherill (1988) and Wetherill and Stewart (1989) considered the effects of dynamical friction caused by gravitational scattering, which lead to energy equipartition between planetesimals with different masses. They show that the random velocity of large planetesimals is effectively suppressed to lead to negative q (if energy equipartition is completely

realized, we have $q = -1/2$) and runaway growth of a small number of protoplanets was found in their simulation. Greenberg et al. (1978) also obtained negative q and found runaway growth, although the accuracy of their numerical code has been questioned in several respects (Wetherill and Stewart 1989; Ohtsuki et al. 1990; Spaute et al. 1991; see also Kolvoord and Greenberg [1992] for refutations). Thus, whether runaway growth occurs or not is determined by q , the mass dependence of the random velocity. The random velocity is governed by mutual gravitational scattering, inelastic collisions, and gas drag. In all the above studies, gravitational encounters are treated by the two-body approximation. Wetherill and Cox (1984) demonstrated that the two-body approximation for gravitational scattering is valid for $\tilde{v}_{21} > 2$, but it is not valid for $\tilde{v}_{21} < 2$. We need to determine the velocity of planetesimals including the effects of solar gravitational field for such low velocity cases. In the next two sections, we review the recent studies of gravitational scattering and inelastic collisions in the solar gravitational field.

III. GRAVITATIONAL SCATTERING

Ida (1990) considered a bimodal population of planetesimals with arbitrary mass ratio and examined the change in the mean random velocity of the Population 1 with mass m_1 caused by gravitational encounters with the Population 2 with mass m_2 . He derived the equations for the change rates of eccentricity as

$$\frac{d \langle \tilde{e}_1^2 \rangle}{dt} \simeq m'_2 < \frac{m'_2 \tilde{e}_{21}^2}{T_{VSe}} + \frac{m'_2 \tilde{e}_2^2 - m'_1 \tilde{e}_1^2}{T_{DFe}} > \quad (18)$$

with

$$\begin{cases} T_{VSe}(\tilde{e}_{21}, \tilde{i}_{21}) = \tilde{e}_{21}^2 / n_s(m_2) [\Delta \tilde{e}_{21}^2] \\ T_{DFe}(\tilde{e}_{21}, \tilde{i}_{21}) = -\tilde{e}_{21} / 2n_s(m_2) [\Delta \tilde{e}_{21\parallel}] \end{cases} \quad (19)$$

where $\Delta \tilde{e}_{21}^2$ and $\Delta \tilde{e}_{21}$ are the changes in \tilde{e}_{21}^2 and \tilde{e}_{21} during an encounter, and $\Delta \tilde{e}_{21\parallel}$ is the component of $\Delta \tilde{e}_{21}$ parallel to $\tilde{\mathbf{e}}_{21}$. “ $\langle \rangle$ ” in Eq. (18) denotes average over the Gaussian velocity distributions of Populations 1 and 2, and “[]” in Eq. (19) denotes ensemble average taking into account the synodic period of interacting planetesimals (for detail, see Ida 1990). The first term of the right-hand side of Eq. (18) represents the transformation of the solar gravitational potential energy to energy of random motion, and is called “viscous stirring” term. The second term represents the energy exchange toward energy equipartition (i.e., $m_1 \tilde{e}_1^2 = m_2 \tilde{e}_2^2$) between the planetesimals with different masses and is called “dynamical friction” term. T_{VSe} and T_{DFe} are the time scales of viscous stirring and dynamical friction. Similar equations for inclination are also obtained, and the time scales of viscous stirring and dynamical friction for inclination are denoted by T_{VSi} and T_{DFi} , respectively.

Although the orbital changes in general cases cannot be obtained analytically, those for distant encounters, where the minimum distance during encounter is so large that the changes are quite small, can be obtained by a perturbation method. In such cases, Goldreich and Tremaine (1982) derived $\Delta \tilde{e}_{21}$ for coplanar and initially circular ($\tilde{e}_{21}, \tilde{i}_{21} = 0$) orbits, and Hasegawa and Nakazawa (1990) derived $\Delta \tilde{e}_{21}$ and $\Delta \tilde{i}_{21}$ for general cases with $\tilde{e}_{21}, \tilde{i}_{21} \neq 0$. Weidenschilling (1989) extended the result of Goldreich and Tremaine to general cases in an approximate manner and calculated the viscous stirring rate due to distant encounters. He found that the stirring rate does not include the logarithmically divergent term which appears in the two-body relaxation rate in free space [cf. Eq. (22) below].

Ida (1990), on the other hand, evaluated the above time scales through orbital calculations. He evaluated the contribution from close encounters by numerical integration of about 10^8 orbits and that from distant encounters by using the results of Hasegawa and Nakazawa (1990). He found that distant encounters in the solar gravitational field hardly contribute to the viscous stirring and dynamical friction. He also found that T_{DFe} and T_{DFi} take nearly equal positive values, so we simply denote T_{DFe} and T_{DFi} by T_{DF} ; these positive values ensure that mutual gravitational scattering works in the direction of energy equipartition in both planar and vertical motions. We define the time scales of total viscous stirring T_{VS} by

$$\frac{1}{T_{VS}} = \frac{1}{T_{VSe}} + \frac{1}{T_{VSi}}. \quad (20)$$

In the dispersion-dominated regime, $T_{VSi} \simeq T_{VSe} (\simeq T_{VS})$. On the other hand, in the shear-dominated regime where relative motion is almost horizontal, viscous stirring in the horizontal direction is much more effective than that in the vertical direction, and we have $T_{VSi} > T_{VSe} (\simeq T_{VS})$.

We plot T_{VS} and T_{DF} in Fig. 2. Using T_{VS} and T_{DF} , the evolution of $\langle \tilde{v}_1^2 \rangle$ is written as [cf. Eq. (18) above]

$$\frac{d \langle \tilde{v}_1^2 \rangle}{dt} \simeq m'_2 < \frac{m'_2 \tilde{v}_{21}^2}{T_{VS}} + \frac{m'_2 \tilde{v}_2^2 - m'_1 \tilde{v}_1'^2}{T_{DF}} >. \quad (21)$$

In most previous studies of planetesimal accumulation, dynamical friction was neglected and the time scale of viscous stirring was simply assumed to be equal to the two-body relaxation time T_{2B} in free space obtained by Chandrasekhar (1942); T_{2B} is given by

$$T_{2B} \simeq \frac{1}{\pi \tilde{r}_G^2 n \tilde{v}_{21} \ln \Lambda} \simeq \frac{\tilde{v}_{21}^4}{10^2 n_s \ln \Lambda} \quad (22)$$

where $n = n_s / 2\tilde{i}_{21}$ is the spatial number density, $\ln \Lambda$ comes from the contribution of distant encounters ($\Lambda = v_{21}^2 / G(m_1 + m_2)n^{1/3}$ and $\ln \Lambda \sim 10$), and \tilde{r}_G is the scaled gravitational radius given by

$$\tilde{r}_G = \frac{G(m_1 + m_2)}{v_{21}^2 h a_{\text{ref}}} = \frac{3}{\tilde{v}_{21}^2}. \quad (23)$$

Figure 2. Normalized time scales in units of Ω_K^{-1} , as a function of \tilde{v}_{21} ($n_s = 1$). In the dispersion-dominated regime ($\tilde{v}_{21} > 5$), T_{VS} and T_{DF} are well approximated by ordinary two-body relaxation time T_{2B} . On the other hand, they deviate from T_{2B} in the shear-dominated regime ($\tilde{v}_{21} < 2$) where the effects of the solar gravity are important.

We also plot T_{2B} in Fig. 2. Stewart and Wetherill (1988) pointed out the importance of the dynamical friction and calculated its rate as well as viscous stirring rate by solving the Boltzmann equation following the formalism of Hornung et al. (1985) (Chapter by Lissauer and Stewart). In their study, they treated gravitational encounters with the two-body approximation neglecting the solar gravitational field and, hence, the time scales of the viscous stirring and the dynamical friction are given by T_{2B} . It can be seen in Fig. 2 that T_{VS} and T_{DF} obtained by the three-body calculation are in good agreement with T_{2B} in the dispersion-dominated regime, which means that previous treatment with the two-body approximation is valid in these cases. However, shear-dominated encounters become important in the runaway accretion stage (Barge and Pellat 1991; see also Sec. V). In this case, T_{VS} and T_{DF} are much greater than T_{2B} and, hence, the two-body approximation breaks down.

With the time scales T_{VS} and T_{DF} given in Fig. 2, we examine the relative importance of dynamical friction to viscous stirring. We assume $m_1 \gg m_2$ ($m'_1 \sim 1$, $m'_2 \ll 1$). First, we consider the random velocity change in the dispersion-dominated regime. If $\tilde{v}_1^2 \geq \tilde{v}_2^2$ (i.e., $\tilde{v}_{21}^2 \simeq \tilde{v}_1^2$), Eq. (21) reduces to

$$\frac{d \langle \tilde{v}_1^2 \rangle}{dt} \simeq m'_2 \tilde{v}_1^2 < \frac{m'_2}{T_{VS}} - \frac{1}{T_{DF}} \rangle \simeq -m'_2 \tilde{v}_1^2 < \frac{1}{T_{DF}} \rangle. \quad (24)$$

Hence, dynamical friction is dominant and \tilde{v}_1 will decrease rapidly. Ida and Makino (1992b) examine the effects of dynamical friction on a protoplanet embedded in a swarm of small planetesimals by N -body simulation. They confirm that eccentricity and inclination of the protoplanet decay in a time

scale of T_{DF} , as shown in Eq. (24). Thus, we may consider that \tilde{v}_1 is reduced so that $m_2 \tilde{v}_2^2$ and $m_1 \tilde{v}_1^2$ are of the same order. In this case, $\tilde{v}_{21}^2 \simeq \tilde{v}_2^2$, and Eq. (21) reduces to

$$\frac{d < \tilde{v}_1^2 >}{dt} \sim m_2'^2 \tilde{v}_2^2 < \frac{1}{T_{VS}} - \frac{1}{T_{DF}} > \quad (25)$$

where we find that both viscous stirring and dynamical friction contribute to velocity evolution. We conclude that the high random velocity of large protoplanets is effectively suppressed through dynamical friction. It gives negative q in Eq. (13), which should lead to runaway growth and, consequently, the growth time of planets is substantially shortened (see Sec. V). However, if the runaway continues, \tilde{v}_{21} should be reduced to the low velocity regime where $T_{VS} < T_{DF}$, and viscous stirring becomes more effective than dynamical friction. The protoplanet would then have a larger velocity than is expected from energy equipartition (Ida and Makino 1992*b*; Barge and Pellat 1991).

IV. INELASTIC COLLISIONS AND ACCRETION

Colliding planetesimals accrete or rebound from one another depending on the relative impact velocity and restitution coefficient. The magnitude of relative impact velocity v_{imp} is approximately given by $v_{\text{imp}}^2 \simeq v_e^2 + v_{21}^2$, where v_e is the escape velocity and v_{21} is relative random velocity. If the collision is sufficiently dissipative that the relative velocity just after the impact is smaller than the escape velocity, then the colliding planetesimal should ultimately accrete. In some previous numerical simulations of planetesimal accumulation, the velocity damping caused by collisions was taken into account according to the data of laboratory impact experiments (see, e.g., Hartmann 1978; Greenberg et al. 1978; Wetherill and Stewart 1989). However, these authors evaluated the random velocity with the two-body approximation in free space.

Recently, Ohtsuki (1992*a*) examined the probability of gravitational sticking for inelastic collisions between planetesimals in heliocentric orbits, using three-body trajectory integrations. He found that most collisions lead to accretion if $v_{21} \leq v_e$ and the restitution coefficient is less than 0.7. It can be shown that the random velocity of planetesimals does not considerably exceed the escape velocity, because gas drag of the solar nebula is effective (Sec. V). Thus, as long as the restitution coefficient is small enough, it can be considered that most collisions between planetesimals may lead to accretion. (In the final stage of accumulation where random velocity of small planetesimals is enhanced by gravitational scattering by protoplanets, collisions between small planetesimals may result in fragmentation.) From this point of view, Ohtsuki (1992*b*) derived the equation for the random velocity evolution due to accretion by coupling the evolutions of both the random velocity and the

mass distribution. The evolution of mean eccentricity of Population 1 with mass m_1 is written as

$$n_s(m_1) \frac{d}{dt} \langle \tilde{e}_1^2 \rangle = -n_s(m_1) \int_0^\infty n_s(m) \langle P(m_1, m) \rangle \{ \langle \tilde{e}_1^2 \rangle_{\text{col}} - \langle \tilde{e}_1^2 \rangle \} dm + \frac{1}{2} \int_0^{m_1} n_s(m_2) n_s(m_3) \langle P(m_2, m_3) \rangle [\langle m_2'^2 \tilde{e}_2^2 + m_3'^2 \tilde{e}_3^2 \rangle_{\text{col}} - \langle \tilde{e}_1^2 \rangle] dm_2 \quad (26)$$

with

$$m_3 = m_1 - m_2 \text{ and } m_i' = m_i/m_1 \quad (27)$$

where $P(m_i, m_j)$ is the collision rate between m_i and m_j , $\langle \rangle$ denotes the average over the velocity distributions, and $\langle \rangle_{\text{col}}$ denotes the average over the velocity distributions of colliding pairs weighted with their collision rate. In the above, eccentricities are scaled by $h = (m_2 + m_3/3M_\odot)^{1/3} = (m_1/3M_\odot)^{1/3}$. The first term on the right-hand side of Eq. (26) represents the collision between planetesimals with mass m_1 and those with other masses, and the second term expresses the merger of m_2 and m_3 to form a planetesimal with mass m_1 . We obtain a similar equation for the evolution of inclination.

The first term of Eq. (26) has the following consequences: if the average energy $\langle \tilde{e}_1^2 \rangle_{\text{col}}$ leaving from the original assemblage 1 as a result of a collision with other planetesimals is larger than the average energy $\langle \tilde{e}_1^2 \rangle$ of the original assemblage, this term works so as to decrease $\langle \tilde{e}_1^2 \rangle$, and vice versa. The contribution of the first term depends on the form of the velocity distribution function and the collision rate. Because the collision rate of planetesimals with lower velocity is larger (Fig. 1), planetesimals with lower velocity leave from the assemblage more frequently than those with high velocity. We then expect that this term should work so as to increase the average random velocity as long as we consider the velocity change caused by accretion alone.

The terms in the braces of the second term on the right-hand side of Eq. (26) are written as

$$\langle m_2'^2 \tilde{e}_2^2 + m_3'^2 \tilde{e}_3^2 \rangle_{\text{col}} - \langle \tilde{e}_1^2 \rangle = (\langle \bar{E}_c \rangle_{\text{col}} - \langle E_1 \rangle) / m_1 \quad (28)$$

where $E_i = m_i \tilde{e}_i^2$, and $\bar{E}_c = m_2' E_2 + m_3' E_3$ is the weighted mean of random energy of colliding planetesimals. The right-hand side of Eq. (28) may be interpreted as follows; if $\langle \bar{E}_c \rangle_{\text{col}}$ is larger than $\langle E_1 \rangle$, a newly formed planetesimal with mass m_1 contributes to the increase in the average random energy of Population 1. If $\langle \bar{E}_c \rangle_{\text{col}}$ is smaller than $\langle E_1 \rangle$, on the other hand, it contributes to the decrease in the average random energy. As a result, accretion proceeds so that a planetesimal should keep the same random energy on average, although its mass continues to increase due to accretion. We then expect that accretion should drive the system toward energy equipartition

between planetesimals with different masses. If the energy equipartition $E_i = E_{eq}$ ($= \text{const.}$) is already achieved through the above accretion or gravitational scattering described in Sec. III, it is not violated by the subsequent accretion, as in Eq. (28) we have

$$m_2'^2 \tilde{e}_2^2 + m_3'^2 \tilde{e}_3^2 = (m_2' + m_3') E_{eq} / m_1 = E_{eq} / m_1 \quad (29)$$

which shows that the weighted mean of random energy of colliding planetesimals is the same as that before collision.

V. SUMMARY

We have described the velocity evolution caused by gravitational scattering and accretion in the last two sections. Another important process, which we have not discussed in this chapter and still remains to be solved, is the gas drag force on a planetesimal moving in the solar nebula. The gas drag force on a Keplerian particle with small size ($m < 10^{24}$ g) was studied by Adachi et al. (1976) and Weidenschilling (1977a), and that on a massive planetesimal ($m \geq 10^{25}$ g) with its gravitational effect in uniform flow with relatively low Reynolds number ($\simeq 20$) was numerically studied by Takeda et al. (1985). Applying the drag law of Takeda et al. to planetesimals, Ohtsuki et al. (1988) simulated accumulation of planetesimals to the full-size Earth. They found that the drag force on a protoplanet at the final stage becomes so large that its orbit should greatly decay toward the Sun during accumulation. Ohtsuki et al. then concluded that the drag force obtained by Takeda et al. in uniform flow with low Reynolds number must be overestimated for planetesimals in Keplerian motion which move in shear flow of the solar nebula.

In Table I we summarize fundamental processes which determine the random velocity in each stage of planetesimal accumulation.

A. Early Stage

First, we consider an early stage where the typical mass of planetesimal m is about $10^{18} \sim 10^{20}$ g. We define collision time T_{coll} by

$$T_{\text{coll}} = \frac{1}{n_s P}. \quad (30)$$

Using the gas drag law obtained by Adachi et al. (1976), we define the time scale of velocity damping due to gas drag by

$$T_{\text{gas}} = \frac{mv_m}{\frac{1}{2} C_D \pi r_m^2 \rho_{\text{gas}} v_m^2} \sim 5 \times 10^6 \left(\frac{a}{1 \text{ AU}} \right)^{13/4} \tilde{v}_m^{-1} \text{ yr} \quad (31)$$

where m , r_m , and v_m are the mass, radius, and random velocity of a planetesimal, C_D is drag coefficient (we put $C_D = 1$), and ρ_{gas} is the mass density of the

TABLE I
Fundamental Processes Determining the Random Velocities of Planetesimals in Each Accretion Stage^a

Accretion Stage	Typical Mass at 1 AU	Processes Determining Random Velocity
Early stage	$m = 10^{18-20} \text{ g}$	VS Inelastic collisions and accretion Gas drag
Intermediate stage	$M \leq 10^{25} \text{ g}$	v_m $\left\{ \begin{array}{l} \text{VS by small planetesimals} \\ \text{Gas drag} \end{array} \right.$
Runaway era: Protoplanet formation	$(M < M_t)$	v_M : DF by small planetesimals ($M v_M^2 \sim m v_m^2$)
Final stage	$M \geq 10^{25} \text{ g}$	v_m $\left\{ \begin{array}{l} \text{Gravitational scattering by protoplanets} \\ \text{Gas drag, if nebular gas exists} \end{array} \right.$ v_M $\left\{ \begin{array}{l} \text{DF by small planetesimals or VS by protoplanets} \\ \text{Gas drag, if nebular gas exists} \end{array} \right.$

^a M and m are the typical masses of a protoplanet and a small planetesimal, and v_M and v_m are their typical random velocities. Total mass of planetesimals in a feeding zone of the protoplanet is denoted by M_t . VS and DF represent viscous stirring and dynamical friction due to gravitational scattering, respectively.

Figure 3. Time scales T_{VS} , T_{gas} , and T_{coll} (in units of year) at 1 AU with $\Sigma = 7 \text{ g cm}^{-2}$: (a) in an early stage for $m = 10^{20} \text{ g}$, and (b) in an intermediate stage for $m = 10^{24} \text{ g}$.

nebular gas [we adopted $\rho_{gas} = 1.4 \times 10^{-9} (a/1\text{AU})^{-11/4} \text{ g cm}^{-3}$, following Hayashi (1981)]. Scaled velocity \tilde{v}_m is given by

$$\tilde{v}_m = v_m / h_m v_K \text{ with } h_m = \left(\frac{2m}{3M_\odot} \right)^{1/3}. \quad (32)$$

Because the difference in sizes of planetesimals is not appreciable in this stage, the relative velocity \tilde{v}_{mm} for planetesimal-planetesimal encounter is approximately given by $\tilde{v}_{mm} \simeq \sqrt{2}\tilde{v}_m$. In Fig. 3a, T_{coll} and T_{gas} , together with T_{VS} defined by Eq. (20) in this stage ($m = 10^{20} \text{ g}$) at 1 AU are plotted as a function of \tilde{v}_m . In evaluating T_{coll} and T_{VS} , we adopted $\Sigma = 7 \text{ g cm}^{-2}$ for the surface mass density of planetesimals, following Hayashi (1981). If we consider that the random velocity of the planetesimal is determined by the balance between the enhancement by gravitational scattering and damping by gas drag, the crossing point of the two lines for T_{VS} and T_{gas} gives the value of

the equilibrium velocity. It can be seen in Fig. 3a that an equilibrium state is expected at $\tilde{v}_m \simeq 40$. We also find that in the neighborhood of this equilibrium velocity, T_{coll} is also comparable to T_{gas} and T_{VS} , thus inelastic collision and accretion discussed in Sec. IV are also important in this stage. That is, in addition to gravitational scattering, accretion may make a large contribution to the velocity evolution toward energy equipartition as discussed in Secs. III and IV.

We find in Fig. 3a that the equilibrium velocity is slightly larger than the escape velocity \tilde{v}_e ($\tilde{v}_e \simeq 35$ at 1 AU), which lies quite close to the upper boundary of the runaway growth condition given in Sec. II. Thus, it is not clear whether runaway growth occurs in this stage or not.

B. Intermediate Stage

Next, we consider an intermediate stage, where the typical mass of planetesimals is 10^{22-24} g. The time scales T_{coll} , T_{gas} , and T_{VS} for $m = 10^{24}$ g at $a = 1$ AU are plotted in Fig. 3b as a function of \tilde{v}_m . From the value of \tilde{v}_m at the crossing point of T_{VS} and T_{gas} , we expect that an equilibrium state is achieved at

$$\tilde{v}_m \simeq 20 \left(\frac{m}{10^{24} \text{g}} \right)^{-1/15} \quad (33)$$

where we again used Eq. (31) and adopted $\Sigma = 7 \text{ g cm}^{-2}$, and also used a relation $T_{VS} \propto \tilde{v}_m^4$, which is valid for $\tilde{v}_m > 5$ (Fig. 2). This equilibrium velocity is slightly smaller than the escape velocity. In this stage, T_{coll} is much larger than T_{gas} or T_{VS} at the above equilibrium velocity. It shows that an equilibrium state between viscous stirring by gravitational scattering and damping by gas drag is achieved and inelastic collision is not important in determining the velocity. In such a high-velocity regime as is given by Eq. (33), $T_{DF} \simeq T_{VS}$ and dynamical friction is also effective in reducing the random velocity of the large planetesimal and we have negative q , as mentioned in Sec. III. The condition (16) is then satisfied and several planetesimals start runaway growth in this stage. Let the mass of the largest planetesimal formed in this stage be M ($> m$) and its random velocity be v_M . The scaled relative velocity in an encounter between planetesimals with masses M and m is given by

$$\tilde{v}_{Mm} \simeq \frac{(v_M^2 + v_m^2)^{1/2}}{h_M v_K} \simeq 20 \left(\frac{m}{10^{24} \text{g}} \right)^{-1/15} \left(\frac{2m}{M} \right)^{1/3} \quad (34)$$

where

$$h_M = \left(\frac{M + m}{3M_\odot} \right)^{1/3} \simeq \left(\frac{M}{3M_\odot} \right)^{1/3}. \quad (35)$$

From Eqs. (34) and (35) we find that once a large planetesimal is formed, \tilde{v}_{Mm} decreases as M grows and the condition of runaway growth continues to be satisfied. As a result, the large planetesimal should grow much more rapidly than its neighbors. We will call it a protoplanet. When M increases

to be larger than $10^3 m$, we have $\tilde{v}_{Mm} \leq 2$, where we cannot use the two-body approximation for collision rate or gravitational scattering: runaway growth would lead to the situation where the three-body effects are important. It should be noted that runaway growth should terminate if \tilde{v}_{21} becomes so small that the condition (12) is violated.

If we do not take into account the effects of dynamical friction on a protoplanet, the planetary growth should be orderly as demonstrated by Wetherill and Stewart (1989). In this case, the encounter velocity between largest planetesimals is given by

$$\tilde{v}_{MM} \simeq \frac{(v_M^2 + v_K^2)^{1/2}}{h_M v_K} \simeq \sqrt{2} \times 20 \left(\frac{M}{10^{24} \text{g}} \right)^{-1/15} \quad (36)$$

which is larger than \tilde{v}_{Mm} given by Eqs. (34) and (35) at least by a factor of $(M/m)^{1/3}$. As shown in Eq. (11), the collision rate is almost inversely proportional to the square of the scaled encounter velocity for $1 < \tilde{v}_{21} < 20$. Hence, we expect that the growth time of a protoplanet in the runaway accretion stage is substantially shorter than that in the orderly accretion case: we have a relation

$$T_{\text{grow}}^{\text{runaway}} \simeq \left(\frac{m}{M} \right)^{2/3} T_{\text{grow}}^{\text{orderly}}. \quad (37)$$

C. Final Stage

In a final accretion stage, runaway protoplanets become so large that their masses cannot be neglected compared to the total mass of small planetesimals. In this case, the aspects of gravitational scatterings change drastically from those in the intermediate stage. This would have the following two consequences: first, the process which determines the random velocity v_m of small planetesimals would change. In the final stage, the velocity v_m would be largely influenced by gravitational scattering caused by protoplanets, while in the preceding stages v_m is determined by mutual scattering between small planetesimals. Consequently, \tilde{v}_{Mm} would become much larger than the value given by Eq. (34). Second, the process which determines the random velocity v_M of protoplanets would also change. As Lissauer and Stewart state in their chapter, mutual scattering between protoplanets would become more important in determining v_M , rather than dynamical friction caused by the small planetesimals. In this case, \tilde{v}_M would be much larger than the value in the case where dynamical friction is effective.

If the first aspect is dominant, even planetesimals in relatively distant orbits will be able to come close to protoplanets and feeding zones of the protoplanets would gradually expand. As a result, runaway growth of a protoplanet will occur from several protoplanets in the expanded feeding zone, which will lead to rather calm final accretion. If the second aspect is dominant, on the other hand, orbits of the protoplanets will be largely perturbed and may cross one another, which will lead to the final accretion

with giant impacts as Lissauer and Stewart state. However, we do not yet know which aspect is dominant.

It should be noted that the growth time of protoplanets in this high velocity stage becomes much larger than that in the preceding runaway stage with low relative velocity; it should be of the same order of $T_{\text{grow}}^{\text{orderly}}$ rather than $T_{\text{grow}}^{\text{runaway}}$ given by Eq. (37). In view of the giant planet formation scenario through gravitational instability of its surrounding atmosphere, the protoplanet in the Jovian region should grow large enough (say, ten times the Earth's mass; see Mizuno 1980) before the dispersal of the solar nebula gas to cause the instability. Hence, it is not so easy to solve the problem of the formation time scale of the Jovian planets even in the runaway growth scenario.

VI. DISCUSSION

In recent years, collisions and gravitational scattering between planetesimals in the solar gravitational field have been appreciably clarified through both analytic studies and numerical integration of a large number of orbits. Through these studies we have made considerable progress in understanding the elementary processes governing the planetary growth.

After the fundamental physical processes determining the random velocity of planetesimals have been clarified, we can study the planetary accretion in detail by numerically solving the so-called coagulation equation which, of course, includes the effects of the spatial change of the mass distribution caused by radial diffusion due to gravitational scattering and inward drift due to gas drag force (Nakagawa et al. 1983; Ohtsuki et al. 1988; Spaute et al. 1991). When we use a numerical code to solve the coagulation equation, accuracy of the code must be tested by, for example, comparing numerical and analytic solutions (Ohtsuki et al. 1990; Wetherill 1990a). However, a more serious problem in using the coagulation equation is that if a small number of protoplanets start runaway growth, it becomes difficult to describe the growth of both a small number of runaway protoplanets and many small planetesimals by the coagulation equation alone (Wetherill 1990a). Recently, Tanaka and Nakazawa (1992) derived a new coagulation equation for a stochastic distribution function, which can exactly describe the accretion even at the final stage of formation of a single body. They also showed that the ordinary coagulation equation, which has been used in the previous studies of planetesimal accumulation (see, e.g., Safronov 1969; Greenberg et al. 1978; Nakagawa et al. 1983; Ohtsuki et al. 1988), cannot describe the coagulation process when an appreciable number of particles with mass greater than $(M_t m_0)^{1/2}$ are formed (M_t is the total mass of the system and m_0 is the mass of a smallest particle). For example, if we consider a system of planetesimals with $M_t = 10^{28}$ g and $m_0 = 10^{18}$ g, we cannot correctly simulate the evolution of the number of planetesimals with mass greater than 10^{24} g by the use of the ordinary coagulation equation. The stochastic coagulation equation derived by Tanaka and Nakazawa (1992) is, however, difficult to solve for general

forms of coalescence rate, even numerically. Thus, we have to combine the statistical treatment with a mass-distribution function for small planetesimals and direct N -body simulation for large protoplanets to simulate the final stage of accretion. Wetherill and Stewart (1989) and Spaute et al. (1991) introduced a stochastic component into their simulation and developed a numerical code which can follow the evolution of both the size distribution of a planetesimal swarm and the size of a small number of the largest bodies treated as discrete objects. These codes need to be further extended to include the radial motion of planetesimals caused by gas drag or gravitational scattering.

With the elucidation of these elemental processes and an appropriate treatment in numerical simulation of the planetary growth, we will be able to simulate the planetary accretion in a more realistic manner for a given initial distribution of planetesimals.

Acknowledgments. We thank E. H. Levy for encouraging us to write this chapter. We are also grateful to S. Watanabe, D. R. Davis, S. J. Weiden-schilling, J. J. Lissauer, and G. R. Stewart for fruitful discussions and helpful comments, and to K. Kudo for cooperation in preparing the manuscript.

GASEOUS ACCRETION AND THE FORMATION OF GIANT PLANETS

NASA Ames Research Center

This chapter presents a review of the structure and composition of the giant planets and the theory of their formation and growth. All of the giant planets have heavy-element cores of 5 to 15 M_{\oplus} , and have envelopes which contain large amounts of high-Z material in addition to hydrogen and helium. The planets most probably formed through the core instability mechanism. This is a much more complex mechanism than was previously thought, depending, as it does, on several time-dependent parameters. We present the results of new, more detailed, simulations. Towards the end of accretion, the transfer of angular momentum to the outer layers of the contracting protoplanet should lead to the formation of a disk. This disk may be the site of satellite formation. Some recent simulation results are shown.

I. INTRODUCTION

The events that formed our solar system are not, in themselves, accessible to observation, but the various members of the solar system do provide us with a number of clues to their origin. The outer planets are a particularly promising area to search for such clues. In the first place, if we neglect the Sun itself, almost all of the remaining mass of the solar system resides in the outer planets (the precise fraction depends on the mass of the Oort cloud comets). In addition, unless the Oort cloud mass is very large indeed, almost all of the angular momentum of the system (including the Sun) resides in these planets.

A second way in which the outer planets can provide us with clues to the origin of the solar system is through their compositions. In their present state, mass loss from these planets is very low. Using the standard Jeans escape formula (Chamberlain and Hunten 1987) and taking the Jovian exospheric temperature to be 1000 K, we find that even for H^+ , which has an effective

mass of only 8.3×10^{-25} g, only several thousand ions are lost in the lifetime of the solar system. For Uranus, with an exospheric temperature of 700 K, and a much lower gravitational acceleration, the escape rate for H^+ is much higher, $\sim 2 \times 10^{17}$ g in the lifetime of the solar system, but this too is only a small fraction of the hydrogen reservoir of that planet. In other words, the outer planets are expected to have maintained their primordial composition.

A third way in which the outer planets provide clues to the origin of the solar system is through their satellite systems. The present state of these satellites, both dynamical and compositional, is the direct result of the evolutionary history of their parent planets. We should therefore expect them to contain clues to that history.

In Sec. II, we review the procedure for computing model planetary interiors, and present the results of such models. Section III summarizes the current view of how the outer planets formed, through the core instability mechanism. Section IV presents the results of evolutionary models for the outer planets. We present the main conclusions in Sec. V.

II. GIANT PLANETS TODAY

A. Modeling Procedure

The procedure for constructing model interiors is straightforward in principle, and has been reviewed in the past (see, e.g., Podolak and Reynolds 1985; Podolak et al. 1991). For the sake of completeness, we briefly review the relevant equations here. Planetary rotation causes a noticeable departure from sphericity. Most modeling efforts deal with the problem by defining a "level surface" as the surface on which the sum of the gravitational and rotational forces is constant. A particular level surface is denoted by:

$$s(r, \theta) = r \left[1 + \sum_{n=0}^{\infty} \epsilon_{2n}(r) P_{2n}(\cos \theta) \right]. \quad (1)$$

Here θ is the colatitude, the P_{2n} are Legendre polynomials, the ϵ_{2n} define the shape of the surface, and r is the radius of a sphere with a volume equal to the volume contained within the level surface. With this definition of r , conservation of mass is given by

$$\frac{dM(r)}{dr} = 4\pi r^2 \rho(r) \quad (2)$$

where $M(r)$ is the mass contained within a sphere of radius r , and $\rho(r)$ is the density at r . The assumption of hydrostatic equilibrium for a rotating fluid, including a latitude-averaged centrifugal force gives

$$\frac{dP}{dr} = - \left[\frac{GM(r)}{r^2} - \frac{2\omega^2 r}{3} \right] \rho(r). \quad (3)$$

Here G is Newton's constant of gravitation, P is the pressure, and ω is the angular velocity.

The departure from sphericity induced by the rotation appears in the gravitational field as a departure from a $1/r$ potential field.

$$V(s, \theta) = -\frac{GM}{s} \left[1 - \sum_{n=1}^{\infty} \left(\frac{R_e}{s} \right)^{2n} J_{2n} P_{2n}(\cos \theta) \right] \quad (4)$$

where M is the mass of the planet, R_e is the equatorial radius, and the J_{2n} are the multipole moments of the gravitational field. The measured values of the J_{2n} can be compared to those computed from the internal density distribution via

$$J_n = -\frac{1}{MR_e^n} \int \rho(r) r^n P_n(\cos \theta) d\tau \quad (5)$$

where $d\tau$ is an element of volume. Further details on the level surface approach can be found in the book by Zharkov and Trubitsyn (1978). An alternative approach to evaluating the effects of rotation is discussed by Hubbard et al. (1975).

Perhaps the point of greatest uncertainty in computing interior models is the equation of state

$$P = P(\rho, T) \quad (6)$$

where T is the temperature. Even before one can worry about the problem of computing an equation of state, one must decide which materials the equation of state will be computed for. Jupiter and Saturn have densities so low that hydrogen must be the major constituent. Helium should be present because of its high cosmic abundance. These two species are so volatile that they can only enter the planet in the gas phase. Additional materials can be incorporated into the planet as solids if they are sufficiently refractory, or as either solid or gas (depending on temperature) if they are of intermediate volatility (Podolak and Cameron 1974). Models of the outer planets require, in general, equations of state for three classes of material: gas, ice and rock. It must be understood that these names are generic, and refer to the volatility of the material, not the phase in which it is found in the planet. "Gas" refers to hydrogen and helium in solar proportions, "ice" is generally taken to be a solar mix of H_2O , CH_4 , and NH_3 , and "rock" is usually taken to be a mix of SiO_2 , MgO , FeS , and FeO . In some models Fe and Ni are used in place of FeS and FeO . Hydrogen exists in two forms: a low-pressure molecular phase, and a high-pressure metallic phase. The pressure at which a transition from metallic to molecular hydrogen occurs is not well determined, but is probably in the 3 to 5 Mbar range (Marley and Hubbard 1988). This is the phase transition that is most important for the determination of the density profile. There are other transitions that could be of importance for modeling planetary interiors. In shock experiments water becomes an ionic melt, $H_3O^+OH^-$ (Mitchell and Nellis 1982), and Smoluchowski (1975) has suggested that molecular hydrogen undergoes a

transition to a more conducting (but still molecular) phase before it becomes a metal. These transitions and others do not substantially affect the computed density profile, but will be important for determining the conductivity of the material, and hence for the computation of magnetic fields. There are various techniques used for computing the equations of state of the relevant materials. Details of these techniques, their relative merits and accuracies have been summarized by Podolak and Reynolds (1985) and Podolak et al. (1991).

One other piece of information that is needed for computing the equation of state is the temperature profile in the planet. For the case of Jupiter, the profile can be computed in a straightforward manner. Jupiter's intrinsic luminosity is considerably higher than the value expected in equilibrium with the Sun (Hanel et al. 1981). It is possible to estimate the thermal conductivity of metallic hydrogen, and compute the temperature gradient required to provide the observed thermal flux. The result is that over most of the planet the thermal gradient must be much higher than the adiabatic gradient, and that most of the interior must therefore be convecting (Hubbard 1968; Bishop and DeMarcus 1970). This implies that the temperature gradient throughout most of the interior is very close to adiabatic, provided that there are no major phase transitions (Stevenson and Salpeter 1976). Saturn, with a luminosity about one third that of Jupiter's and a greater fraction of its hydrogen in the low-conductivity molecular state, must also have an adiabatic gradient throughout a large fraction of its interior. A similar argument can be given for Neptune, and has been applied to models of Uranus as well. Thus all current model of the outer planets assume that the temperature gradient is given by

$$\frac{dT}{dr} = \frac{dP}{dr} \left(\frac{dT}{dP} \right)_{\text{adiabatic}}. \quad (7)$$

It is not completely clear that the adiabatic approximation applies to Uranus, however. Unlike the other planets, Uranus has a very small internal heat source, so the argument regarding the efficiency of heat transport fails. It is true that the cooling time for both Uranus and Neptune is extremely long, so that almost any reasonable initial temperature profile (due to the release of accretional energy, for example) would result in a planet that is convecting today. The problem is that such profiles result in planets that are much hotter than Uranus and Neptune are today, indicating that the cooling of these planets is not yet sufficiently well understood. This problem will be discussed in more detail in Sec. IV. Finally, Uranus does have a magnetic field (Connerney et al. 1987) and this indicates that at least part of the interior is convecting, although there may be large regions of the planet where other mechanisms are sufficient to transport the small flux (see Podolak et al. [1991] for a more complete discussion of the relation between the low heat flux and the magnetic field). For our purposes it is sufficient to be aware that the arguments for an adiabatic temperature profile in the outer planets are not as compelling for Uranus.

TABLE I
Observational Data

Property	Jupiter	Saturn	Uranus	Neptune
Mass (10^{29} g)	18.99	5.68	0.8682	1.0243

^a The observed value is consistent with 1 to the precision of the measurements.

1. Jupiter. The flybys of Jupiter by Pioneers 10 and 11, and by Voyagers 1 and 2 have allowed rather precise determinations of the parameters required for interior models. Although refinements are continually being made in these parameters, their values have been well determined since about 1975, and all models published after that date can, in some sense, be considered "current." As for the best modern values for the radius, mass, and gravitational field parameters, they are shown in Table I. The equatorial radius of Jupiter is that determined by Lindal et al. (1981) at the 0.1 bar level, and recomputed at the 1 bar level (Hubbard and Horedt 1983). The most recent analysis of the gravity field as determined by all four of the spacecraft flybys is given by Campbell and Synnott (1985). The values for the multipole moments are all normalized to a radius of 7.1398×10^9 cm. J_3 $[= (1.4 \pm 5) \times 10^{-6}]$ and the sectorial harmonics are small, $[C_{22} = (-3 \pm 15) \times 10^{-8}, S_{22} = (-0.7 \pm 15) \times 10^{-8}]$ and consistent with zero, as expected for a body in hydrostatic equilibrium. The rotation period of the main body of the planet is taken to be equal to that of the magnetic field (Seidelmann and Divine 1977). The atmospheric properties are also shown in Table I. Particular attention should be paid to the helium mass fraction, $Y = 0.18 \pm 0.04$. Many of the earlier models used a value considerably larger than this, so while they give a density distribution that matches the gravitational moments, the composition represented by that distribution may need to be reinterpreted.

Shortly after the Pioneer flybys of Jupiter, a meeting was held in Tucson to review the latest results, and how they affected our view of the planet. At this meeting three new sets of models were presented. Each of these sets was representative of a different approach to the problem of planetary modeling. The work of Stevenson and Salpeter (1976) concentrated mostly on improving the physics that went into the models. Thus they examined the miscibility of the hydrogen-helium mixture, the strength of the assumption that the volume of a mixture of species is simply the sum of the volumes occupied by the individual species (the "additive volume law"), and the extent of superadiabaticity in the models. Of necessity, they limited their investigation to envelopes composed of only hydrogen and helium. They found that the observed parameters could be fit by models in which this hydrogen-helium envelope surrounded a dense core (rock) of some 9–11 M_{\oplus} . It should be noted, that they chose $Y = 0.25$ – 0.32 , values that were then consistent with the expected abundance on Jupiter. Since we now know that Y is considerably smaller, those models may now be reinterpreted to indicate that the envelope is enriched in some high- Z material above the usual solar composition.

A second set of models was presented by Zharkov and Trubitsyn (1976). Their approach was to allow for a variable composition envelope, and to attempt to assess the abundance of high- Z material in the envelope. This, of course, could only be done at the expense of a less rigorous treatment of the equations of state. Thus, the densities of materials other than hydrogen were simply taken to be proportional to the density of hydrogen. They found that if they took the envelope to be in solar composition, then a rock core of 10–13

M_{\oplus} was needed to match the gravitational moments, quite similar to the result of Stevenson and Salpeter (1976). This is especially so, since Zharkov and Trubitsyn chose a similar value of the helium abundance ($Y = 0.26$). Here too, these models must be reinterpreted to show that the envelope is indeed enriched in high- Z material. A second set of models was computed that had 30–40 M_{\oplus} of high- Z material in the envelope, and no rock core. It is interesting that the observational data do not allow us to decide whether the high- Z material is in the envelope or in the core. This is due to the fact that, as can be seen from Eq. (5), J_n is proportional to the integral of the density weighted by the radius to the n th power. Because the core is confined to small radii, it does not contribute significantly to J_n . Instead, the J_n determine the run of density in the outer part of the envelope, and this density distribution accounts for most of the mass of the planet. The core provides any additional mass that is required. The core is thus a second-order effect, and can be present or absent, depending on the details of the envelope density. This is true for models of all the outer planets.

The third modeling paper (Hubbard and Slattery 1976) suggested still another approach: concentrate on finding the class of density profiles that fit the observed mass, radius and gravitational moments. The composition represented by such a profile can be determined afterwards. For Jupiter, Hubbard and Slattery pointed out that the polytrope $P = 1.9545\rho^{2.05263}$ provides an excellent fit to the mass, radius and J_2 of Jupiter (although J_4 is a bit high). Models of this type are important for defining the limits placed on the allowed density distributions by the observed gravitational field. This particular density distribution corresponds to a planet-wide enhancement of high- Z material of some 30 M_{\oplus} . Once again, since Hubbard and Slattery used a helium abundance corresponding to $Y \simeq 0.25$, this enhancement must be revised upwards, but this will be offset by the fact that J_4 was too high (in absolute value) indicating that the density in the outer envelope must be reduced. This model has no dense core. These three approaches have formed the basis for all later modeling attempts.

In the intervening years a number of other Jupiter models have been computed (Podolak 1977; Slattery 1977; Hubbard et al. 1980; Grossman et al. 1980; Hubbard and Horedt 1983) and these were summarized in the last *Protostars and Planets* volume (Podolak and Reynolds 1985). Since that book, there have been two new sets of Jupiter models. The first (Gudkova et al. 1989) follows the second approach outlined above, and assumes $Y = 0.18$, in agreement with observation. The model consists of four layers: an outer layer of molecular hydrogen, helium, and "ice," with the ice comprising 2% by mass, a second layer with both rock and ice mixed in with the gas, a third layer which is identical to the second, except that the hydrogen here is metallic, and has a rock-ice core of 4.99 M_{\oplus} . The ratio of ice to rock in the planet is 3, in agreement with solar abundances. The total mass of ice in the planet is 50.08 M_{\oplus} , while the total mass of rock is 16.55 M_{\oplus} . When allowance is made for the lower helium abundance, this is consistent with

earlier models.

The second of the most recent models (Hubbard and Marley 1989) follows the third approach and concentrates on finding the density distribution that optimizes the fit to the observed parameters within the framework of a model that has a dense core surrounded by a hydrogen-helium envelope. They find that if the core is composed of rock, then it has a mass of $8.3 M_{\oplus}$, and the envelope has $Y = 0.25$. Assuming that the ice that complements the rock in solar composition ($\sim 25 M_{\oplus}$) is mixed into the envelope, then the actual helium abundance is reduced to $Y = 0.21$, which is consistent with observation. The mass fraction of ice in the envelope is then about 0.08, which is a bit high, but of the order of what is observed. If the core is taken to consist of a mixture of rock and ice, then because of the lower density of such a mixture, its mass must be increased to $12 M_{\oplus}$. In this case, however, the value of $Y = 0.25$ must be explained as an additional enrichment of high- Z material above solar composition.

In conclusion, Jupiter seems to consist of a high-density core of some 5 to $15 M_{\oplus}$ surrounded by an envelope which is itself substantially enriched in high- Z material over solar composition. The most recent models put the high- Z enrichment at about $50 M_{\oplus}$ of ice and rock, although the models cannot, at present, differentiate between these two materials.

2. *Saturn.* For Saturn, the model input parameters are again shown in Table I. The equatorial radius was determined by Lindal et al. (1985) at the 1-bar level. The mass, determined from satellite orbits and spacecraft tracking is from Null et al. 1981. The gravitational moments are taken from Nicholson and Porco (1988), but are normalized to the 1-bar radius. The rotation period of the main body of the planet is taken to be equal to that inferred from periodicities in kilometer-wavelength radio storms (Desch and Kaiser 1981). The 1-bar temperature is from Tyler et al. 1982 and the internal heat flux is from Hanel et al. 1983. Finally, the helium mass fraction in the atmosphere (Conrath et al. 1984) is well below the solar value assumed by all but the most recent Saturn models. This is the reason that most of these earlier models had difficulties in matching the observed J_4 (Podolak and Reynolds 1985).

Here too there have been two recent sets of Saturn models. That by Gudkova et al. (1989) consists of five layers. The outer layer consists of molecular hydrogen, helium, and ice, with the ice comprising 2% by mass, and $Y = 0.064$. Below it is a second layer with both rock and ice mixed in with the gas. This is followed by a third layer which is identical to the second, except that the hydrogen here is metallic, a fourth layer composed of helium, rock and ice (to allow for the excess helium that has settled out of the outer layers), and a rock-ice core of $5.7 M_{\oplus}$. Once again the ratio of ice to rock in the planet is 3, in agreement with solar abundances. The total mass of ice in the planet is $21.42 M_{\oplus}$, while the total mass of rock is $6.98 M_{\oplus}$. It is interesting that the $20 M_{\oplus}$ cores that were determined by earlier models are here replaced with a helium-rock-ice mixture which also has a mass of about $20 M_{\oplus}$, while the nearly solar composition envelope of the

earlier is replaced by one that is significantly enriched in high- Z material, but depleted in helium. The density profile remains relatively unchanged, but its interpretation in terms of composition is very different.

The models of Hubbard and Marley (1989) are not as detailed in their choice of compositional layers, but because of this they can be used to explore the space of allowable density distributions more widely. They find that the core mass must be between 9 and 20 M_{\oplus} , depending on its composition. This is surrounded by a metallic hydrogen envelope which is heavily enriched in helium or some other dense component. Surrounding this is a molecular hydrogen envelope with $Y = 0.06$, but with an enrichment of some other high- Z material. If this other material is assumed to be H_2O ice, then it comprises some 20 M_{\oplus} . This is quite similar to the Gudkova et al. result.

3. *Uranus*. Uranus' vital statistics are given in Table I. The equatorial radius is from Lindal et al. (1987) at the 1-bar level. The mass is from Anderson et al. 1987, and the gravitational moments, from French et al. (1988), but normalized to the 1-bar radius. The rotation period of the main body is taken to be equal to the magnetospheric rotation rate determined by Warwick et al. (1986). The 1-bar temperature is from Lindal et al. (1987), and the helium mass fraction in the atmosphere is from Conrath et al. (1987). In the case of Uranus, the helium abundance in the upper atmosphere is consistent with solar composition.

The rotation period and gravitational moments are now known with much greater accuracy than before the Voyager flyby, so that only those models computed after 1986 can be said to be adequate representations of the planet. Such models have been computed by Podolak and Reynolds (1987), Gudkova et al. (1988), Hubbard and Marley (1989), and Stevenson (1989). They are reviewed in Podolak et al. (1991). The models all have very similar density distributions, characterized by a small or vanishing core surrounded by a region where the density slowly decreases from about 4.5 g cm^{-3} to about 2 g cm^{-3} at 70% of the planetary radius. At this point there is a rapid decrease to zero density at the edge of the planet. Although the models essentially agree on the form of the density distribution, there is an ambiguity with regard to the composition represented by that distribution. This comes about because many different combinations of materials give very similar densities. For example, a mixture, by mass, of 0.75 rock and 0.25 gas will give a density very similar to ice for a large range of pressure (Podolak et al. 1991), so that an arbitrary mixture consisting of 75% rock and 25% gas as one component and ice as the second component will always have the density of pure ice. For this reason, it is not possible to derive the ratio of ice to rock in Uranus from interior models alone. This same ambiguity applies to models of the other planets as well, but in Jupiter and Saturn these high- Z materials comprise only a small fraction of the mass. Because of this, their contribution to the gravitational field is small, and it is at present impossible to resolve rock from ice in these planets even when they are not mixed. The solar ratio ice to rock is assumed, but it can not be verified. In Uranus and Neptune, where ice and rock make up the

bulk of the planet, such a resolution is possible if the materials are not mixed, and could have interesting cosmogonic consequences (Podolak and Reynolds 1984). The ambiguity introduced by the possibility of mixtures, however, complicates the problem.

4. *Neptune*. The most recent determination of Neptune's parameters was made by the Voyager 2 flyby (see Table I). Tyler et al. (1989) measured the equatorial radius, at the 1-bar level and the mass. The gravitational moments are from Owen et al. (1991) but normalized to the 1-bar radius. The 1-bar temperature and the ratio of absorbed solar power to thermally emitted power are from Conrath et al. (1989). The helium mass fraction in the atmosphere seems to be similar to that for Uranus (Conrath et al. 1991).

Of the above parameters, the rotation period, J_2 , and J_4 have been revised substantially as a result of the recent Voyager flyby. As these parameters are very important for interior models, all of the pre-Voyager models lose their relevance. There are two recent sets of calculations done using the revised parameters, those of Podolak et al. (1990), and those of Hubbard et al. (1991). The models of Podolak et al. consisted of three layers, a rock core, an ice layer, and an envelope consisting of hydrogen, helium, H_2O , NH_3 , and CH_4 . The hydrogen to helium ratio is solar, in agreement with the observations of both Uranus' and Neptune's atmospheres, and the H_2O , NH_3 , and CH_4 are in the solar ratio to each other, but may be enhanced by some factor A over their solar ratio to hydrogen. They find a rock core of $1.2 M_\oplus$, and an envelope of solar composition (i.e., $A = 1$). Their model also gives a ratio of ice to rock for the planet of 13. This is about four times the solar value. Once again, due to the ambiguity described above, we can replace the ice layer in the model by a mixture of rock, gas, and ice, so the ice to rock ratio can be brought down to the solar value, or less. They showed that Uranus and Neptune may have very similar compositions (in the sense of the ice to rock ratio) in spite of their differences in density.

The work of Hubbard et al. (1991) investigated the effects of differential rotation. Although there are strong latitudinal gradients in the atmospheric wind profile, Hubbard et al. showed that these differences do not extend very deeply into the planet. As a result, the density profiles computed for a differentially rotating planet are similar to those computed for a uniformly rotating planet. Their models are very similar to those of Podolak et al. and they too conclude that the compositions of Uranus and Neptune are probably very similar.

B. Atmospheric Composition

The models described above give considerable information about the density distribution in the planetary interior. They cannot, however, set anything more than limits on the compositional details a particular density distribution may represent. Observations of the upper atmosphere of these planets, on the other hand, give precise information on the composition, but are, of necessity, limited to the very outer layers of the planet. Nonetheless, some interesting

conclusions may be drawn. The different H/He ratios in the outer planets have already been mentioned above. Because both H_2 and He are thought to have been accreted directly from the nebula in the gas phase, it is difficult to see how the various planets could have accreted different relative amounts of these two gases. The different ratios observed are believed to be relevant only to the outer layers of these planets. Theoretical studies indicate that at high pressures helium may not be miscible in hydrogen (Stevenson, unpublished; Hubbard and MacFarlane 1985; Hubbard and DeWitt 1985). It is possible that the low helium abundance observed in Saturn is due to this immiscibility, and the subsequent rain-out of helium in the outer layers of the planet. The He/H ratio on Jupiter is larger than that on Saturn, but is lower than that of Uranus, Neptune, and the Sun (Gautier and Owen 1989). It is possible that helium rain-out has begun in Jupiter as well. The total (volume integrated) He/H ratios in all of the outer planets is expected to be solar, however.

The deuterium/hydrogen (D/H) ratio observed in the atmospheres of the giant planets provides important clues to the origin of these bodies. In Jupiter, in which $\sim 90\%$ of the mass consists of H and He, the atmospheric D/H should reflect the average value in the solar nebula at the time of formation. The observed Jovian value deduced from abundances of monodeuterated methane is $D/H = (2.0 \pm 0.6) \times 10^{-5}$ (Lutz et al. 1983), in agreement with the presumed interstellar D/H value at the time of origin of the solar system. It is also consistent with the fact that the lower mass limit for deuterium burning is about 20 Jupiter masses.

About 70% of the mass of Saturn consists of H and He, and again one expects the atmospheric D/H to reflect the primordial value. The observed value from monodeuterated methane, consistent with the Jovian value, is $D/H = (1.6^{+1.6}_{-1.0}) \times 10^{-5}$ (de Bergh et al. 1986, 1988).

The situation is quite different in Uranus and Neptune. In these planets, the H and He component is less than 10% of the total planetary mass, so that exchange of deuterium with an icy reservoir could significantly affect the atmospheric ratio. The error bars on deuterium enhancement are still quite large. For Uranus, $D/H = (7.2^{+7.2}_{-3.6}) \times 10^{-5}$, and for Neptune, $D/H = (12^{+12}_{-8}) \times 10^{-5}$ (de Bergh et al. 1990). If we assume that the initial nebular D/H was 2×10^{-5} and that D/H in the initial icy planetesimals which were accumulated to form Uranus and Neptune was 10 times larger due to isotopic fractionation effects, as indicated in Halley's comet (de Bergh et al. 1990), then a mass balance calculation leads to limits on the ratio of icy material to rocky material in Uranus and Neptune. The lower limits on D/H suggest that the mass of nebular hydrogen and helium was about equal to the mass of icy material (i.e., the enhanced icy D/H was diluted about twofold with nebular D/H), while the upper limits suggest that the atmospheric D/H mainly represents the enhanced value in the icy material, so that the mass of hydrogen brought in with the icy component considerably exceeds the hydrogen captured directly

from the nebula. Quantitatively, this means that

$$M_{\text{H-He}}/M_{\text{ice}} < 0.8 \quad (8)$$

where $M_{\text{H-He}}/M_{\text{ice}}$ is the ratio of the mass of nebular H-He to the mass of ice in Uranus or Neptune. The interior models discussed above suggest that $M_{\text{H-He}}/M_{\text{ice}} \sim 0.1$. Unfortunately, the error bars and our ignorance of the initial deuterium enrichment factor for the icy material preclude more definitive limits for now.

In addition to hydrogen and helium, there are also observations of other elements. Of particular interest is the C/H ratio. Although some of the atmospheric carbon is locked up in such molecules as C_2H_2 , and C_2H_6 , these are nonequilibrium species produced by photolysis and lightning. Most carbon is in the form of CH_4 , and can be readily observed in this form in Jupiter and Saturn. Although CH_4 does condense out in the tropospheres of Uranus and Neptune, it can still be observed in the deeper atmospheres of these planets. There is a definite increase in the C/H ratio as one goes farther out in the solar system. Thus the values of C/H in Jupiter, Saturn, Uranus, and Neptune are 2.3, 2–6, ~ 25 , and ~ 35 times the solar ratio, respectively (Gautier and Owen 1989). This trend can be understood in the context of the core instability model (see Sec. III.B).

The N/H ratios on Jupiter and Saturn are similar to the C/H ratios (Gautier and Owen 1989), but the values for Uranus and Neptune appear to be even lower than the solar ratio (de Pater and Massie 1985). No completely satisfactory explanation has yet been given for this (see de Pater et al. 1989), but these observations must somehow be incorporated into any theory of outer planet formation.

C. Satellites of the Giant Planets

In certain ways, the giant planet systems are miniature solar systems that contain not only the giant planet itself, but an entire retinue of satellites and a magnificent ring system located close to the planet. Here, we summarize the basic characteristics of the satellites, with emphasis on properties that constrain models of their formation. We lump the rings with the satellites, since it is now widely believed that the micron to meter sized particles that constitute the rings of the outer planets are derived by meteoroid impact of larger parent objects, i.e., small satellites in the region of the rings (see Esposito et al. 1991).

All four giant planets have large numbers of satellites surrounding them and all four have ring systems. This abundance of surrounding objects may be contrasted with the comparative paucity of satellites around the terrestrial planets, that collectively possess only three moons and that have no rings. Thus, some aspect of the formation of the giant planets, perhaps connected with their having gaseous envelopes or forming when the solar nebula was still present, promoted the development of a satellite system around them;

whereas, such a situation did not readily occur for the terrestrial planets. Indeed, all three moons of the terrestrial planets are thought to have gone into orbit around their planets either as a result of capture processes (Phobos and Deimos) or as a result of a giant impact event (the Earth's moon), events that did not result in many objects at a variety of distances.

The orbital properties of the satellites of the giant planet permit them to be divided into two major categories: regular and irregular satellites. Regular satellites have prograde orbits of low eccentricity and low obliquity (with respect to the planet's equatorial plane), whereas irregular satellites have high obliquities, often possess high eccentricities (Triton is an exception, probably because of tidal evolution), and travel in both retrograde and prograde directions. All four giant planets contain numerous regular satellites. They are situated from a fraction of the planet's radius above its atmosphere to several tens of planetary radii away. In all four systems, the largest regular satellites, having diameters up to about 5000 km (Titan, Ganymede, and Callisto), are found farthest from the planet, with their sizes tending to more or less systematically decrease to values on the order of tens of kilometers at the closest distances. Their orbital properties and propinquity to their associated planets suggest that the regular satellites formed in the same region of space where they are currently located and that they therefore formed as part of the same process that led to the assembly and/or early evolution of their planet. Possible source materials for them include the primordial solar nebula and the outer envelope of the giant planet.

Irregular satellites are known to be present around all the giant planets, except for Uranus. They are always found at distances greater than that of the regular satellites. Typically, they are found at distances of several hundred planetary radii, although Triton is located at 15 planetary radii (probably due to significant tidal orbital evolution following capture). We note that distances of several hundred planetary radii correspond to positions close (within a factor of several) to the outermost position at which a satellite can be maintained in a stable orbit against solar and other planetary perturbations over the age of the solar system. Thus, the irregular satellites, including Triton, were presumably formed in the outer solar nebula and later captured into loosely bound orbits about their planet. This means that solid objects as large as several thousand km in diameter (Triton's diameter is 2700 km) were formed in the outer solar system. (Pluto is probably another example of such a sized body.) More typically, irregular satellites have sizes that range from several tens to several hundreds of kilometers.

Table II summarizes some of the salient properties of the regular satellites, irregular satellites, and rings of the giant planets. In this table, we have not tried to enumerate the poorly known properties of the ring moons and so have separated the regular satellites outside of the major rings from those inside them. The variables M_{sat}/M_{pl} and J_{sat}/J_{pl} in this table are the ratios of the total mass and orbital angular momenta of the regular satellites to the mass and spin angular momenta of their parent planets, respectively. Both ratios

TABLE II
Comparison of Satellite Systems

Property ^a	Jupiter	Saturn	Uranus	Neptune
Regular Satellites				
Number	8	17	15	6
Location (R_{pl})	1.8 – 27	2.3 – 59	2.0 – 23	1.9 – 4.8
M_{sat}/M_{pl}	2.1×10^{-4}	2.4×10^{-4}	1.1×10^{-4}	2.9×10^{-4}
J_{sat}/J_{pl}	6.5×10^{-3}	6.6×10^{-3}	6.5×10^{-3}	2.1×10^{-2}
Irregular satellites				
Number	8	1	0	1
Location (R_{pl})	156 – 333	216		227
Rings				
Location (R_{pl})	1.3 – 1.8	1.1 – 8 ^b	1.6 – 2	1.7 – 2.5
M_{ring}/M_{pl}		6×10^{-8}	6×10^{-11}	
Max τ	5×10^{-5}	> 1.5	> 1.5	0.1

^a The symbols R, M, and J refer to radius, mass, and angular momentum, respectively; subscripts *sat*, *pl*, and *ring* refer to satellite, planet, and rings, respectively; and max τ is the maximum value of the normal optical depth at visible wavelengths.

^b The major rings of Saturn, the A, B, and C rings, are located between 1.2 and 2.3 R_{pl} .

have very similar values for the Jupiter, Saturn, and Uranus systems. These similarities, in conjunction with the similarity in the architecture of these three systems, suggest that they formed through some common process. The lower values of these ratios for the Neptune system may be a result of a disruption of the outer part of the original regular satellite system that followed the capture and orbital evolution of Triton (Goldreich et al. 1989; McKinnon and Leith 1990).

The ratios of J_{sat}/J_{pl} in Table II show that there is a very important difference between the regular satellite systems of the outer planets and the planetary system itself. More than 99% of the angular momentum of the solar system is contained in the orbital angular momenta of the planets, whereas a very sizeable fraction of the angular momenta of the outer planet systems is contained in the spin angular momenta of the planets. Even augmenting the orbital angular momenta of the regular satellite systems by the gases that may have been present in the disks within which they formed would at best result in orbital angular momenta comparable to that of their associated planets. Put another way, the regular satellites formed much closer to their parent planets (in units of the planet's size) than did the planets with respect to the Sun. Moreover, the occurrence of low obliquity, prograde orbits in both types of systems strongly suggest that the regular satellites formed within flattened disks that contained both gases and solid matter.

The bulk composition of the satellites of the outer solar system provides an important constraint on the composition of the nebular disk within which they formed, and, by implication, on the source of this nebula. Estimates of the bulk composition of the larger satellites can be obtained from the measured mean densities and assumptions about their major constituents (see, e.g., Johnson et al. 1987). The Voyager spacecraft flybys of all four giant planet systems have provided accurate mean densities for the larger satellites in these systems. If one assumes that water ice (ice) and silicates (rock) constitute the two major constituents of their interiors, then the mass fractions of ice and rock may be derived by fitting models of their interior structure to the observed mean density and size of these bodies. Useful limiting cases are provided by alternatively assuming that the ice and rock are homogeneously distributed throughout their interior (homogeneous models) and that the rock and ice are fully segregated from one another, with the heavier rock forming a central core (differentiated models). For objects of the size of the largest satellites (i.e., Titan, and the Galilean satellites), the differentiated model is probably closer to the truth, whereas for bodies having a size on the order of a few hundred kilometers or smaller, the homogeneous model is probably closer to the truth (Johnson et al. 1987).

Figure 1 summarizes the silicate mass fractions inferred for the larger satellites of the giant planet systems (Smith et al. 1989). The horizontal lines labeled "CO-rich" and "CH₄-rich" refer to the silicate mass fractions expected for nebulae having a solar abundance of elements that are cold enough for water to be present almost entirely in the solid phase, rather than the vapor

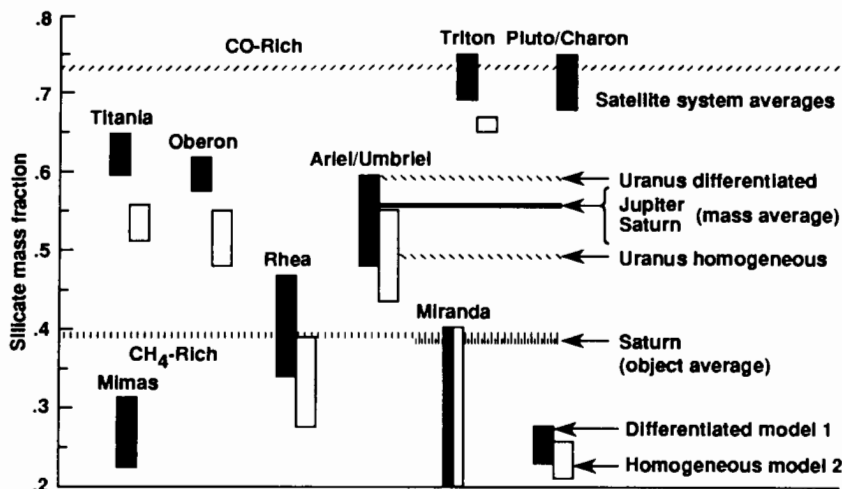

Figure 1. Comparison of model silicate mass fractions for several outer planet satellites and the Pluto/Charon system. Two types of satellite interior structure are given, a fully differentiated body with a silicate core and an ice mantle, and a homogeneous undifferentiated mix of water ice and silicates. Radiogenic heating is taken into account in the current thermal structure of the interiors. Also shown are approximate values for silicate mass fraction for bodies formed in CO-rich and CH₄-rich nebular conditions and the system averages from several satellites.

phase. These lines are displaced by a significant amount from one another because C has an abundance that is about half of that of O. Thus, if CO is the dominant form of C in the nebula, there is a lot less O left to form H₂O. In both of these cases, about 15% of the O is tied up in silicates. When the most current values of the solar abundances of C, O, and Si are used (Anders and Grevesse 1989; Grevesse et al. 1991), we find that the CO-rich line in Fig. 1 shifts considerably down to 0.53, while the CH₄-rich line decreases a bit to 0.33. Results shown for the mass-weighted Jupiter and Saturn system refer to the average silicate mass fraction of the fully icy Galilean satellites Ganymede and Callisto and to a value heavily dominated by Titan, respectively.

There are several important trends to note from Fig. 1. First, the silicate mass fraction inferred for any of the regular satellites shown in this figure is distinctly smaller than the silicate mass fractions characterizing Triton and Pluto/Charon. Since the latter presumably formed in the outer solar nebula (see above), this difference implies that the nebular disks within which the regular satellites formed were compositionally different from that of the outer solar nebula. While the silicate mass fractions of the regular satellites span the full range of values expected for nebulae having oxidation states ranging from fully reduced to fully oxidized, the silicate mass fractions inferred for Triton and Pluto/Charon are distinctly larger than those expected even for a

fully reduced nebula. The latter puzzling circumstance may imply that there are still nontrivial errors in the solar abundances, that the capture of Triton by Neptune and its subsequent orbital evolution and the formation of the Pluto/Charon system, perhaps by a giant impact, resulted in a preferential loss of water, or that our compositional assumptions are in error.

Second, the silicate mass fractions of the larger Uranian satellites (Ariel, Umbriel, Titania, and Oberon) are very similar to those of the largest icy satellites of the Jupiter and Saturn systems. Since the former are sufficiently small that the gravitational energy of their accretion is much less than the latent heat needed to sublimate all their water (these two energies are comparable for the latter), not much water could have been lost in the assembly of the largest satellites, contrary to the suggestion made by Stevenson et al. (1986). One could attempt to rescue this suggestion by Stevenson et al. (1986) by postulating that high velocity impacts by comets resulted in the preferential loss of water from Ganymede, Callisto, Titan, and the Uranian satellites. However, it would then be puzzling that the smaller regular satellites of Saturn that are situated deeper in Saturn's gravitational well (except for Iapetus) are more ice rich than is Titan. Third, the silicate mass fraction of Titan (Saturn mass average) is significantly larger than those for some of the other, smaller Saturnian satellites (Mimas, Rhea, and Miranda). This difference could be attributed alternatively to the vaporization and loss of water accompanying the formation of Titan (Stevenson et al. 1986; but see above) or to a time evolution in the properties of the Saturnian nebula (Pollack et al. 1991).

Figure 1 does not include the two inner Galilean satellites, Io and Europa. These objects have a much higher mean density than do Ganymede and Callisto and hence have silicate mass fractions close to unity. This difference is thought to reflect a trend towards warmer temperatures at closer distances in the Jovian nebula, which limited the amount of water vapor that condensed at the distances where Io and Europa formed (Pollack and Reynolds 1974). One could alternatively attribute the systematic variation of the density of the Galilean satellites deeper in Jupiter's gravitational well by comets. However, the lack of similar trends among the Saturnian and Uranian satellites casts doubt on this latter hypothesis. The dominant presence of water ice in the rings of Saturn and the occurrence of low-albedo material in the rings of Uranus (perhaps derived from C-containing ices) suggest a progressive decrease in temperature from the Jovian to the Saturnian to the Uranian nebula (Pollack et al. 1991).

Information on the composition of the irregular satellites of the giant planets, with the notable exception of Triton, can best be inferred from their spectral reflectivity properties. Strictly speaking, composition inferred in this fashion refers only to the satellites' surface. However, since the objects of interest are sufficiently small that they probably have not differentiated and since their surfaces are excavated to considerable depths by impacts, the inferred composition is likely to apply to the body as a whole. The larger irregular satellites of Jupiter and Saturn's one known irregular satellite, Phoebe,

have low albedos, comparable to those of dark asteroids and carbonaceous chondrites (Degewij et al. 1980). By contrast, the small regular satellites of both systems have much higher albedos. This difference again suggests a difference in the compositions of the satellite-forming nebulae and the outer solar nebula.

III. FORMATION AND GROWTH OF THE GIANT PLANETS

A. Gas Instability Model

There have been two scenarios proposed in the literature for the formation of the giant planets. We will refer to them as the gas instability model and the core instability model. The gas instability model postulates that the primitive solar nebula was sufficiently massive that large portions of it could become unstable against gravitational collapse. The end products of such a collapse, giant gaseous protoplanets (GGP's), are supposed to evolve into the giant planets we see today. This hypothesis has the advantage that it allows naturally for the accretion of large masses of solar composition material on a short (dynamic) time scale. The most detailed studies of this model were those of Cameron and his colleagues (DeCampi and Cameron 1979; Cameron et al. 1982; Cameron 1985).

This hypothesis has a number of disadvantages, however. First, as we have seen above, the outer planets all contain substantial components of high- Z material. GGP scenarios require special mechanisms to supply this additional nonsolar component. Second, as solids are accreted by the GGP, they will be dissolved and mixed with the gas at the high temperatures and pressures in the GGP interior. It is hard to see how a core would form under such conditions (Stevenson 1982*a*). Third, such a scenario is especially difficult to justify for the case of Uranus and Neptune, which are composed mostly of high- Z material, with relatively little hydrogen and helium. Fourth, as Cameron himself pointed out (Cameron 1989), an instability of this type requires a nebular mass of the order of a solar mass or more. This is higher than the value currently suggested for the solar nebula (Strom et al. 1989*a*). A final argument can be brought from the theory of brown dwarfs.

The largest giant planet, Jupiter, has many physical properties in common with the so-called brown dwarfs, which are objects of solar composition having masses less than about $0.08 M_{\odot}$. This similarity (electron-degenerate convective interior, low intrinsic luminosity primarily derived from depletion of thermal energy) suggests that a continuum of such objects exists, extending from objects with mass $M \sim 0.001 M_{\odot}$ (Jupiter) up to the hydrogen-burning limit at $M \sim 0.08 M_{\odot}$ (Burrows et al. 1989). However, Boss (1986*b*) has shown that a minimum mass exists for collapse of a fragment of an interstellar H-He cloud into a condensed object of the brown-dwarf or Jovian type, and this minimum mass is $\sim 0.02 M_{\odot}$, or about 20 Jovian masses. Thus giant planets must apparently form by a two-stage nucleation process, in a solar nebula where solid particle densities are sufficiently high for trigger nuclei to

form before the gas dissipates. The formation of brown dwarfs may be more analogous to the formation of giant gaseous protoplanets. The end products of either formation path are quite similar, differing principally in the existence or nonexistence of a dense rocky core.

B. Core-Instability Model

The core-instability model of the giant planets postulates that they initially grew through the accretion of planetesimals, i.e., in the same fashion that the terrestrial planets formed. However, in contrast to the terrestrial planets, the giant planets grew quickly enough and to large enough masses so as to gravitationally capture progressively larger amounts of gas from the surrounding solar nebula, prior to its dissipation. Eventually, a point was reached in the accretional growth of Jupiter and Saturn that gas accretion became a runaway process and these planets ended up with more gas mass than planetesimal mass. Uranus and Neptune may not have quite reached the point of having runaway gas accretion before the solar nebula dissipated. The term core refers to the planetesimal derived mass, which, at least initially, was concentrated in the central region of the protoplanet. The term instability refers to the eventual occurrence of a gas runaway phase, i.e., a period when gas was added extremely rapidly. A recent suggestion for forming Jupiter's core quickly has been made by Stevenson and Lunine (1988), but it is not clear how this mechanism can be applied to the other giant planets.

C. Critical Core Mass

These authors assumed that the planetesimal mass (high- Z material) was totally segregated in a central core from the gas (low- Z material) and that the gaseous envelope was in convective equilibrium throughout its extent and hence had an adiabatic temperature profile. They constructed a series of hydrostatic models, in which the core mass was varied. Above a core mass of about $100 M_{\oplus}$ for a particular choice of solar nebula conditions, they were unable to construct a static model and suggested that larger-sized cores promoted a hydrodynamical instability in the gas of the surrounding solar nebula. Furthermore, the core mass depended sensitively on the choice of the nebular boundary conditions. Because of this sensitivity and the high core mass required for instability for the nominal choice of parameters, this model did not seem to readily explain the near constancy of the core masses of the giant planets nor the absolute values of these masses.

In the late 1970s, Mizuno and his colleagues revisited the core instability model. Rather than assuming a convective envelope, they calculated the radiative temperature gradient and only in places where it was superadiabatic was it reset to the adiabatic value. In their classic paper, Mizuno et al. (1978) found that large radiatively stable regions existed within the envelopes of their static models. As a result, the critical core mass above which it was no longer possible to construct a static model was found to be about $10 M_{\oplus}$. Furthermore, the value of the critical core mass was shown to be very

insensitive to the temperature/density values in the surrounding solar nebula and to the amount of grains postulated to be present in the envelopes. Such a result appeared to offer a natural explanation for the great similarity (within a factor of several) of the high- Z masses of the giant planets, with these masses ranging from a little more than $10 M_{\oplus}$ for Uranus and Neptune to several tens of M_{\oplus} for Jupiter and Saturn. Some addition of planetesimals following the onset of runaway gas accretion could readily account for the modest differences in the high- Z masses of the giant planets.

At the time Mizuno was performing his calculations, Harris (1978) was also examining this class of models and estimating the factors that controlled the critical core mass. He pointed out that the value of the critical core mass might depend sensitively on the rate of core accretion, an insight that has turned out to be quite important in some subsequent studies of this problem. Stevenson (1982a) was able to derive analytically Mizuno's major results. He found that the critical core mass decreased significantly when the opacity in the envelope decreased, the accretion time scale increased, or the mean molecular weight of the envelope increased. Studies of the core instability in the case of an isothermal atmosphere were done by Sasaki (1989).

Figure 2. Mass of core (solid curve) and envelope (dashed curve) as a function of time. Cases 1, 6, and 7 are for accretion rates of 10^{-6} , 10^{-5} , and $10^{-7} M_{\oplus} \text{ yr}^{-1}$, respectively. The full solar abundance of small grains is assumed. Case 5 is the same as case 1, but the grain abundance has been reduced by a factor of 50.

The first evolutionary calculations of the core instability model were performed by Bodenheimer and Pollack (1986). These workers used a code, similar to ones used to model the pre-main-sequence evolution of stars, to follow the time history of accretion. They did this by constructing a sequence of static models that were connected in time by a prescribed, time-independent accretion rate of planetesimals and a calculated rate of gas addition from the surrounding solar nebula. The latter was based on the amount of contraction that the envelope underwent in a given time step, with the amount of gas added depending on the gas density in the solar nebula and the size of the outer zone temporally opened up by contraction. Figure 2 illustrates the temporal evolution of the core (solid curves) and envelope (dashed curves) masses for several models of Bodenheimer and Pollack (1986). Cases 1, 6, and 7 correspond to planetesimal accretion rates of 10^{-6} , 10^{-5} , and $10^{-7} M_{\oplus} \text{ yr}^{-1}$, respectively, with there being a full solar abundance of small grains in all these models. Case 5 is the same as case 1, except that the grain abundance has been decreased by a factor of 50. According to this figure, during the early growth of the protoplanet, when its core mass is on the order of a few M_{\oplus} , the mass of the envelope represents only a tiny fraction of the total mass. However, as the core mass approaches a critical value of about $15 M_{\oplus}$, the envelope mass rapidly increases and becomes comparable to the core mass. Beyond this point, the planet's mass rapidly increases due almost entirely to the addition of gas to the envelope. Although the gas accretion rate becomes progressively more rapid as the critical core mass is approached and exceeded, the gas accretion is never hydrodynamic as long as the solar nebula can supply gas fast enough. For the purposes of the current discussion, we will define the critical core mass as being the value at which the envelope mass equals the core mass (note that in these evolutionary calculations, the rate of gas accretion varies smoothly with time); and the runaway gas accretion phase as commencing when a critical core mass is reached (while the gas accretion rate varies smoothly with time, it exponentially increases).

Figure 3 illustrates the temporal variation of the luminosity of the protoplanets of Fig. 2. When the core mass lies below the critical value, the luminosity is provided chiefly by part of the gravitational energy released by the accreting planetesimals. The rest of this energy goes into heating the envelope. However, as the critical core mass is approached and exceeded, the luminosity is generated chiefly by part of the gravitational energy released by the envelope's contraction. At this stage, a very strong positive feedback exists between envelope contraction and gas accretion in the sense that the more massive the envelope is the more rapidly it contracts and the more rapidly it contracts the greater the rate of gas addition. Thus, the critical core mass reflects the transition point between when the planetesimal accretion rate is large enough to keep the envelope puffed up and its rate of contraction moderate to when these conditions are no longer met.

Bodenheimer and Pollack (1986) found that the critical core mass depended most sensitively on the rate of planetesimal accretion. As can be

Figure 3. Variation with time of the luminosity of the protoplanets shown in Fig. 2.

anticipated from the above discussion, the critical core mass decreased when the planetesimal accretion rate was lowered. In particular, the critical core mass equalled 11.2, 16.8, and 28.9 M_{\oplus} for models 7, 1, and 6, which had planetesimal accretion rates of 10^{-7} , 10^{-6} and 10^{-5} $M_{\oplus} \text{ yr}^{-1}$, respectively. The critical core mass changed very little when the solar nebula boundary conditions were varied, in accord with Mizuno's results, and when the grain abundance was decreased by a factor of 50. The latter result does not appear to agree with Stevenson's (1982a) results. The reason for this may be that molecular opacity (e.g., water vapor) has a more important influence on the overall structure of the envelope than does grain opacity: the critical core mass did change significantly when both the grain and water abundances were decreased by sizable amounts.

All the calculations discussed so far have been based on a fairly naive specification of the planetesimal accretion rate, namely that it is constant in time. However, significant variations in this rate can be expected. As the planet's mass increases, its gravitational influence extends further out, and the size of its feeding zone increases. In addition, its envelope becomes massive enough to stop planetesimals passing through it, hence increasing the capture cross section. Both of these processes tend to increase the accretion rate. On the other hand, as the feeding zone becomes depleted of planetesimals, the accretion rate will decrease. Pollack et al. (1990,1991) are carrying out the first set of calculations in which both the planetesimal and gas accretion rates are being calculated in a self-consistent fashion. The planetesimal accretion

rate is being determined for situations in which their random velocities are determined by a combination of gravitational interactions with the protoplanet (this yields a velocity comparable to the escape velocity at its tidal radius) and with one another (this yields a velocity comparable to the escape velocity at their surfaces). The three-body calculations (planetesimal, planet, Sun) of Greenzweig and Lissauer (1990, 1992) are being used to evaluate the capture cross section and hence accretion rate, with allowance being made for capture occurring within the envelope. The planetesimal accretion rate calculated in this fashion (it is now time variable) is used in the protoplanet model of Bodenheimer and Pollack (1986) to evaluate the gas accretion rate.

Figure 4. Results of new simulations for a protoplanet at Jupiter's distance from the Sun. Ratio of computed accretion cross section to geometrical cross section as a function of core mass.

Figures 4–8 show typical results from these new simulations, for a model at Jupiter's distance from the Sun that begins with a surface density of planetesimals of about 10 g cm^{-2} , i.e., a factor of several times larger than the so-called minimum-mass solar nebula (just enough mass to make all the planets). All the planetesimals were assumed to be 100 km in radius. Figure 4 shows the ratio of the calculated accretion cross section of the protoplanet to

Figure 5. Results of new simulations for a protoplanet at Jupiter's distance from the Sun. Radius of core (solid curve) and effective radius of capture (dashed curve) as a function of core mass.

its geometrical cross section as a function of core mass. Throughout the entire accretion period shown, this ratio is on the order of 10^4 due to the dominant effect of gravitational focussing: the random velocities of the planetesimals are small compared to the escape velocity at the effective capture radius of the protoplanet. Thus, accretion is fast.

Figure 5 compares the radius of the core (solid curve) to the effective capture radius (dashed curve). When the core mass is less than a few M_{\oplus} , the envelope has too little mass to stop incoming planetesimals and hence they are stopped at the surface of the core. For larger core masses, however, the envelope is massive enough to stop incoming planetesimals well above the core interface due to a slowing down of the planetesimals by gas drag and their fragmentation by gas dynamical pressure. This larger "stopping radius" leads to a larger three-body capture cross section (Greenzweig and Lissauer 1990). As a result, the accretion rate is significantly augmented.

Figure 6 shows the envelope and total masses as a function of core mass. Just as in the older calculations of Bodenheimer and Pollack (1986), a critical core mass is achieved when the core mass equals about $16 M_{\oplus}$. The reasons are, however, very different. As shown in Fig. 7, the surface density of

Figure 6. Results of new simulations for a protoplanet at Jupiter's distance from the Sun. Envelope mass and total mass as a function of core mass.

planetesimals in the planet's feeding zone is severely reduced from its initial value when the core mass exceeds about $12 M_{\oplus}$. This causes a very large drop in the rate of planetesimal accretion (Fig. 8), which results in the onset of a rapid contraction of the envelope and eventually runaway gas accretion. Prior to the depletion of planetesimals in the feeding zone, the rate of planetesimal accretion increases with time due to a combination of the envelope being able to stop planetesimals at increasing distances from the center and a growth in the size of the feeding zone (it varies as the cube root of the planet's total mass). Thus, it is more and more difficult to reach a critical core mass until the feeding zone is severely depleted. These results suggest that the critical core mass is *not* a universal constant, but rather depends sensitively on the surface density of planetesimals. Conversely, it may be possible to constrain the surface density of planetesimals from the joint constraints of the estimated high- Z masses of the giant planets (the surface density cannot be too large) and the lifetime of the solar nebula (the surface density cannot be too small). For the model shown in Figs. 4–8, a critical core mass is reached in about 7 Myr. Since the lifetime of the solar nebula was probably not much longer than this, the surface density at Jupiter's distance was probably not much less than 10 g cm^{-2} . Similarly, the surface density could not have been much more than a factor of several times larger than this number or Jupiter would have accreted too much high- Z mass.

Figure 7. Results of new simulations for a protoplanet at Jupiter's distance from the Sun. Surface density of planetesimals as a function of core mass.

D. End of Accretion

We have followed the accretion of the giant planets to the point at which they have accreted about $15 M_{\oplus}$ of high- Z material, their envelope masses have become comparable to that of the core, and they are approaching or have entered into a runaway gas accretion stage. Here, we consider the factors that may have led to a termination of gas and planetesimal accretion. At this point, we note the important difference between Jupiter and Saturn on the one hand and Uranus and Neptune on the other hand: most of Jupiter's and Saturn's masses are contained in their low- Z components (H and He). Thus, they experienced a runaway gas accretion phase, according to the core instability model. However, the opposite is true for Uranus and Neptune. Therefore, they did not experience such a phase. By considering factors that limited the accretion of both components, we may gain some insight into the reasons for this essential difference.

We first consider the potential amount of gas mass that Jupiter might have accreted. When fully grown, Jupiter's tidal radius equalled about 0.36 AU. Jupiter's gravity severely perturbed the orbits of both solids and gases whose

Figure 8. Results of new simulations for a protoplanet at Jupiter's distance from the Sun. Planetesimal accretion rate as a function of core mass.

orbital radii lay within about 3 tidal radii on either side of its orbit (Greenzweig and Lissauer 1990). Augmenting the planetesimal surface density estimated above by a factor of 100 to allow for the surface mass density of gas, we find that Jupiter could have readily had access to about $2500 M_{\oplus}$ of gas when it was fully grown. This may be compared to its current gas mass of about $270 M_{\oplus}$. At earlier times, when its mass was less than its current value, Jupiter would have access to as much mass as it needed, since the tidal radius scales as the cube root of its mass. Thus, Jupiter (and Saturn too) should not have been limited in the amount of gas mass they accreted by the need to transport gas from zones outside of the neighboring region of the nebula that its gravity strongly affected. Indeed, it might seem puzzling at this point that Jupiter and Saturn did not acquire more gas.

One obvious limitation on the amount of gas mass accreted by the giant planets was set by the dissipation of the solar nebula. If a giant planet took long enough to reach a critical core mass, the amount of gas available in the solar nebula may have been substantially reduced from its earlier values by this dissipation. Since there was probably a fair spread in the time scales over which the four giant planets approached a critical core mass, with Jupiter probably reaching this point first and Saturn second, the dissipation of the

solar nebula probably had its biggest effect on the amounts of gas that Uranus and Neptune accreted.

Another limitation on the amount of gas mass that the giant planets attained may have been set by their gravitational interaction with the gas in the surrounding solar nebula. Just like a small satellite in the region of planetary rings can open up a gap in the rings around them, so too can a protoplanet clear a gap around itself in the solar nebula when it reaches a large enough mass (Lin and Papaloizou 1979a). The condition for just being able to clear a gap is that the tidal gravitational torque that the planet exerts on the surrounding solar nebula equals the viscous torque by which the nebula tries to fill in vacated regions. The former torque is proportional to the planet's mass, while the latter torque depends on the effective (probably turbulent) viscosity coefficient. Tidal truncation could have occurred when Jupiter reached its current mass for plausible values of the turbulent viscosity coefficient (Lin and Papaloizou 1979a, 1985). One might speculate that tidal truncation limited Saturn's gas accretion and perhaps even prematurely shut off gas accretion for Uranus and Neptune before they achieved critical core masses. Alternatively, the gas masses of Uranus and Neptune could have been limited by the solar nebula dissipating before their planetesimal feeding zones were severely depleted.

A planet's gravitational torque that can produce a gap results from a combination of its perturbation of the orbits of individual entities (e.g., gas molecules or small volumes of gas) and the mutual interaction (gravitational, viscous) of these entities. Both processes alter the affected orbits. Thus, gap clearing could have readily occurred for the gas component of the solar nebula, but may have been ineffective for planetesimals (they interact too infrequently). Furthermore, Jupiter at its present mass is quite effective at altering the orbits of planetesimals situated within a few AU of its orbit into ones that cross its orbit (Gladman et al. 1990). A similar statement can be made for virtually the entire region of the outer solar system once all four giant planets had formed (*ibid*). Thus, within a time scale much shorter than the age of the solar system, virtually any planetesimal located in the outer solar system (from a little beyond Neptune's orbit to somewhat inside Jupiter's orbit) would have had its orbit perturbed into one that crossed that of a giant planet. The fate of the planetesimal depended on the size of the planet at the time their orbits crossed. If the giant planet's envelope filled a fair fraction of its Hill sphere, as it did during all or most of the later stages of gas accretion, then the planetesimal would have been accreted. If the planet had shrunk to a size comparable to its current dimensions, then the escape velocity at its surface would have been large enough to scatter the planetesimal gravitationally to other parts of the solar system (Uranus and Neptune) or entirely out of the solar system (Jupiter and Saturn). In this case, a large fraction of the planetesimals would have either been lost from the solar system or sent out to the Oort cloud. Such a situation must have prevailed for the vast majority of the planetesimals in the outer solar system or the giant planets would have ended up with too

large a high- Z mass. This conclusion may be readily seen from the following logic. The surface density of planetesimals had to be large enough so that the giant planets reached or came close to a critical core mass before the solar nebula dissipated. In that case, it took a range of radial distances of only a few tenths of an AU to supply Jupiter, for example, with about $15 M_{\oplus}$ of planetesimals. However, Jupiter's high- Z mass is no more than several times larger than this value and it could have accreted planetesimals that were as much as a factor of 30 times further away than the outer limits of this early feeding zone. Similar conclusions hold for the other giant planets.

E. Planetesimal Dissolution

In discussing the core instability model for the formation of the giant planets, we may have given the impression that their two major building blocks—planetesimals and gases—remained spatially separated from one another, with the high- Z material located exclusively in a segregated core. Certainly, this picture is a good approximation to the situation during the early phase of formation, when the core mass was not more than a few M_{\oplus} . However, as the envelope grew in mass, it was increasingly difficult for planetesimals to reach the core before dissolving in the envelope (e.g., see Fig. 5) (Pollack et al. 1986; Podolak et al. 1988). Here, we briefly review the physics of the interaction of planetesimals with the envelopes of the forming giant planets and the implications for the interior structure and atmospheric abundances.

Figure 9. Distance from planet center to which a planetesimal penetrates for core masses of 1.0, 2.5, 6.0, 12.0, and $16.8 M_{\oplus}$ for rock planetesimals.

As a planetesimal passed through a giant planet's envelope, it was slowed down by gas drag; it was heated and vaporized by radiation from the shock in front of it (when its speed was supersonic) and from the warm ambient gases; and it was subjected to compressional stresses by gas dynamic pressure, that broke it into small "digestible" pieces when this pressure exceeded its compressional strength. Figures 9 and 10 show the distances from the planet's center (in units of the core's radius) at which rocky and icy planetesimals, respectively, would have been totally vaporized as a function of the size of the planetesimal (Pollack et al. 1986). The five curves in each figure correspond to 5 different stages in the growth of a giant planet, as denoted by the value of its core mass, for case 1 of Bodenheimer and Pollack (1986) (see Fig. 2). According to these results, which are representative of other cases of Bodenheimer and Pollack (1986), all but the smallest-sized planetesimal (less than a km) can penetrate to the planet's core when its core mass is less than several M_{\oplus} . However, only planetesimals larger than the size of the Earth are capable of penetrating this far when the core mass approaches its critical value. Thus, a significant fraction of the planetesimals that formed the giant planets, especially the later arriving ones, were dissolved in their envelopes.

Figure 10. Distance from planet center to which a planetesimal penetrates for core masses of 1.0, 2.5, 6.0, 12.0, and 16.8 M_{\oplus} for ice planetesimals.

This result has several interesting implications. First, some nontrivial amount of mixing between the low- and high-Z components of the giant planets characterizes their present interiors, in accord with recent model results.

Second, there could exist significant molecular weight gradients within the envelopes of the giant planets, which could significantly affect the transport of heat from the planet's interior to its photosphere. This possibility may be important for understanding the current excess luminosities of the giant planets, as has been pointed out by Stevenson. Third, those dissolved high- Z elements that were mixed up to the observable atmosphere could lead to marked enhancements in the abundances of certain gas species. For example, the abundances of CH_4 in the present atmospheres of the giant planets imply C/H ratios that are factors of several (Jupiter) to several tens (Uranus and Neptune) larger values than that expected from solar elemental abundances. This result can be attributed to a combination of the giant planets forming preferentially from planetesimals as opposed to gas, and the dissolution of a significant fraction of the planetesimals in the envelopes of the forming giant planets (Pollack et al. 1986; Simonelli et al. 1989). Indeed detailed modeling of the data suggest that 10% or more of the carbon in the outer solar nebula was present in the solid component of the nebula (Simonelli et al. 1989). Finally, materials formed from the dissolved planetesimals, if mixed towards the top of the envelopes, served as the source material for making satellites, according to one model of their formation, which is discussed below.

F. Origin of Satellites

The origin of both the irregular and regular satellites of the giant planets is tied in intimate ways to the early history of their parent planets. Here, we briefly summarize some of the more popular hypotheses on the origin of each of these classes of satellites, and relate them to the early evolution of the giant planets. A more detailed discussion of some of these matters may be found in review articles by Stevenson et al. (1986) and Pollack et al. (1991).

The irregular satellites formed within the outer solar nebula, as was discussed above, and were subsequently captured into planet circling orbits. Table II summarizes some of their key properties. To affect capture, the relative velocities of the bodies needed to be reduced to below the escape velocity from the planet's gravitational field. This may have been accomplished either through the gas drag they experienced in passing through the outer envelope of the planet or its associated nebular disk (Pollack et al. 1979; McKinnon and Leith 1990) or through collision with a regular satellite or another planetesimal (Columbo and Franklin 1971; Harris and Kaula 1975; Goldreich et al. 1989).

First consider the gas drag capture hypothesis. For the velocity of a planetesimal to be substantially reduced, it needed to encounter a gas mass comparable to its own mass along its trajectory (Pollack et al. 1979). This requirement can be met by models of the outer envelopes of the giant planets when they filled a fair fraction of their Hill spheres (Pollack et al. 1989) or by models of the disks within which the regular satellites formed (McKinnon 1989). In both cases, the gases needed to extend out to several hundred planetary radii to be consistent with the present locations of the irregular

satellites (note that McKinnon's [1989] gas drag model of Triton's capture supposes that its semimajor axis just after capture was much larger than its present value and that it tidally evolved to its present location).

Figure 11. Tidal radius of Saturn and Uranus as a function of time. Also shown are the positions of some of Uranus' satellites.

Following the capture of a planetesimal, gas drag continued to act on it, causing a reduction in its semimajor axis. If this occurred for too long (tens to thousands of orbital periods, depending on the initial capture conditions), the planetesimal would have evolved into the planet's deep interior and therefore would have been lost from the satellite system. Relatively rapid removal of gas from the position of the captured body is needed to prevent its loss. This requirement can be met by some plausible scenarios of the early history of the giant planets. For example, following tidal truncation of the solar nebula, the outer radius of the envelopes of the giant planets may have shrunk very rapidly, as illustrated in Fig. 11 (but, see the discussion below). Finally, the occurrence of "families" of the irregular satellites of Jupiter (irregular satellites that have orbits with similar semimajor axes and inclinations) can be accounted for by postulating that gas dynamical pressure experienced during the initial capture exceeded the compressional strength of the original object, causing it to fragment into several large pieces (Pollack et al. 1979).

Alternatively, the irregular satellites may have been captured by colliding with another planetesimal passing through the Hill sphere of the giant planet (Harris and Kaula 1975) or with a regular satellite (Columbo and Franklin 1971; Goldreich 1989). In this case, capture occurred after the giant planet evolved to a small size and/or after its regular satellites had formed. Given the large number of planetesimals that were accreted to form each of the giant planets, most of the time with the capture radius being much smaller than the tidal radius, it seems almost inevitable that pairs of planetesimals would have collided within the planet's gravitational sphere of influence, but outside of its envelope. Furthermore, such collisions would almost certainly fragment

the original bodies, thus accounting for the occurrence of two families of irregular satellites around Jupiter. It is not clear, however, why Saturn's Phoebe and Neptune's Nereid do not apparently have companions. If the irregular satellites were captured by collision with a regular satellite, then the regular satellites were initially present to much larger distances than they currently are (cf. Table II). It is then a bit puzzling why there is not a greater overlap in the locations of the irregular and regular satellite systems.

In contrast to the irregular satellites of the giant planets, the regular satellites formed within circumplanetary disks that were situated in the equatorial planes of their parent (true rather than adopted) planets. These disks could have formed in at least four different ways (Pollack et al. 1991). The disks may have formed directly from gases and solids in the surrounding solar nebula that flowed into the Hill spheres around the giant planets (accretion-disk model); from the outermost portions of the envelopes of the giant planets that rotated rapidly and so were left behind as the envelope contracted (spin-out model); from the blowout of part of the planet's envelope that accompanied the impact of a massive planetesimal (blow-out model); and from the collision of a pair of planetesimals (co-accretion model). The nature of these models and their pros and cons are extensively discussed in Pollack et al. (1991). Here, we focus on the two most plausible models: the accretion-disk and spin-out models and relate them to aspects of the early histories of the giant planets.

Consider first the accretion-disk model. This model postulates that near the end of the gas accretion phase, a giant planet shrank to a size not much larger than its present size and the inflowing solar nebula material formed a disk around the planet, rather than being directly accreted. If the solar nebula failed to supply gas quickly enough to fill the region vacated by the contracting envelope, then the planet would have shrunk on a very short time scale from dimensions comparable to its tidal radius to dimensions not much smaller than its present size (Bodenheimer, personal communication). In that case, the angular momentum of gas flowing into the Hill sphere may have been enough for it to have formed a disk around the planet. Although Kepler shear caused the gas outside the Hill sphere to have retrograde angular momentum, it would have been changed to prograde angular momentum due to three-body gravitational effects (Sun/planet/gas) as it flowed into the Hill sphere (Coradini et al. 1989). The solids that flowed in with the gas (e.g., small grains) as well as planetesimals that were captured by gas drag in passing through the disk could have provided the raw materials from which the regular satellites formed before the gas component of the disk was dissipated (e.g., by viscous processes that caused most of it to flow into the planet).

Alternatively, the satellite-forming disks of the giant planets were derived from the outer envelopes of the giant planets. According to this model, the spin-out disk model, the outermost portions of the envelope were rotating sufficiently rapidly when the planet filled a sizeable fraction of its Hill sphere, that they reached centrifugal force balance as the planet contracted follow-

ing the end of gas accretion. Korycansky et al. (1990) have investigated the viability of this hypothesis by simulating the transfer of angular momentum within the envelopes of the giant planets during their accretion and subsequent contraction phases. They assumed that convective regions of the envelope tended towards a state of uniform angular rotation on a turbulent viscous time scale, as estimated from mixing length theory; and they derived a parameterization for the time scale and final state for angular momentum transfer in radiatively stable zones when there is an unstable gradient of specific angular momentum, j (j increasing with decreasing radial distance). In the latter case, the radiative zone tends towards a state of constant j .

Figure 12 illustrates the distribution of j within the envelope of a forming giant planet at three stages in its accretion, as marked by the value of the planet's total mass. For this simulation, the accreted gas was assumed to have a time-independent value of specific angular momentum. Thus, the large gradients in j shown in this figure are strictly the result of a very efficient outward transfer of angular momentum. In this figure, convective regions are places where j increases steeply outward, while radiative zones are locations of approximately constant j . By the time the planet reached a mass comparable to that of Saturn, the outermost envelope had a j that is about 4 orders of magnitude larger than that of the innermost region. In fact at this point, a large fraction of the envelope's total angular momentum is concentrated in the outer few percent of the envelope's mass. Very similar results were obtained for other choices of the specific angular momentum associated with the accreted gas.

When gas accretion ceased, the model planet began a sustained contraction phase. During the early phases of this contraction, there was an inner and an outer convection zone, with a radiative zone sandwiched in between. The planet soon reached a stage where the outermost zones had rotation rates comparable to those needed for centrifugal force balance and hence were left behind as contraction proceeded. When the evolution reached the point where the two convection zones coalesced together, a net inward transfer of angular momentum occurred due to the nonhomologous nature of the contraction. This prevented further shedding from occurring.

Figure 13 illustrates the nature of the disk shedding that accompanied the early part of the contraction of a model for which the accreted gas had a j that increased somewhat as the mass of the planet increased. The subpanels in this figure show the planet's radius and rate of mass shedding as a function of time after the end of accretion and the initial surface mass density of the resulting nebula. For this particular model, the disk's mass is about $1 M_{\oplus}$; the total angular momentum of the disk is about twice that of a minimum-mass satellite-forming disk around Saturn; the disk ends up with about 80 % of the system's angular momentum; and the planet retains a total angular momentum that is about 1/3 that of current Saturn. In this regard, the simulated properties of the disk and its planet are comparable to those of the Saturn system. However, the initial disk extends out to several hundred planetary radii, about

Figure 12. Distribution of specific angular momentum within the envelope of a forming giant planet for core masses of 1.07, 21.5 and 97.5 M_{\oplus} .

an order of magnitude larger than the dimensions of the current system of regular satellites.

Thus, these first detailed simulations of the spin out disk model yield results that bear some resemblance to an actual giant planet system. Perhaps, more to the point, they indicate that outward transfer of angular momentum could have been a very effective process during the formation and early contraction of the giant planets and therefore the spin out model offers a possibly viable means for forming satellite-making disks around the giant planets. However, there are many issues that must be resolved before this model can be considered highly successful. These issues include obtaining a more quantitative match to the observed properties of the giant planets and their satellite systems, determining the degree to which the shed portions of the envelopes contain an adequate amount of high-Z material to form satellites (especially whether they have enough silicates), and having an improved understanding of the transition from gas accretion to contraction (e.g., is there a rapid contraction before gas accretion halts?).

IV. Giant Planet Evolution

It is instructive to estimate the highest temperature that could be attained within a giant planet following a process of rapid accumulation. If a spherical body is assembled from cold mass fragments which are initially at rest at

Figure 13. Planet radius, rate of mass shedding, and initial surface density of the resulting subnebula as a function of time after the end of accretion.

infinite separation, the resulting object has a gravitational binding energy

$$\Omega = -q \frac{GM^2}{a} \quad (9)$$

where a is the radius of the body, and the dimensionless coefficient q depends on the distribution of mass within the body. For a body like Jupiter, theoretical models give $q \sim 3/4$. Since the initial energy of the fragments was zero, an amount of energy equal to $-\Omega$ has been dissipated. If we assume that the accumulation was so rapid and efficient that none of this energy was radiated

into space, then the energy must show up as heat in the accumulated body, whose resulting mean temperature T_{max} we may estimate according to

$$T_{max} \sim -\Omega/MC \quad (10)$$

where C is a mean heat capacity per unit mass, which we may estimate as $C \sim k_B/Am$. Here k_B is Boltzmann's constant, m is the atomic mass unit, and A is the mean atomic mass of the accumulated material, assumed to be ~ 1 for Jupiter and Saturn, and ~ 6 for Uranus and Neptune.

It turns out that T_{max} is quite similar for all four giant planets, and is $\sim 10^5$ K. Furthermore, this value of T_{max} is coincidentally quite close to the degeneracy temperature of these bodies, which is the temperature above which the pressure equation of state would approach that of an ideal gas, and below which the pressure equation of state would become insensitive to the temperature.

Theoretical calculations of the thermal evolution of the giant planets can provide important information about the initial accumulation of these bodies. The problem is (in its simplest version) a well-posed one: at time $t = 0$ we form a giant planet at temperature T_{max} , and we follow the thermal evolution of the body until $t = 4.5$ Gyr, at which point the theoretical value of the effective temperature T_e (the temperature of a blackbody with the same bolometric power as the planet) is evaluated and compared with the observed value $T_{e,o}$. If $T_e \sim T_{e,o}$, the model of rapid and efficient collapse of the protoplanet is validated. A result that $T_e > T_{e,o}$ suggests that the initial accumulation was a slow or inefficient process, or that the current radiation of stored heat of accumulation is impeded by a process which is not considered by the model. A result that $T_e < T_{e,o}$ implies that the planet possesses energy sources in addition to stored heat of accumulation.

A. Model Results for Jupiter and Saturn

The simplest thermal evolution model for Jupiter or Saturn assumes that there are no phase boundaries in the interior, and that the temperature distribution in the interior follows an adiabat in the form

$$T = f(g, T_e) \rho^\gamma \quad (11)$$

where ρ is the mass density, γ is the Grüneisen parameter, and $f(g, T_e)$ is a coefficient which depends on the planet's surface gravity g and effective temperature T_e . Such a model gives the result

$$t \sim \frac{\alpha}{2.757} T_e^{-2.757} \quad (12)$$

where α is a constant which depends on the planet's mass and composition (Hubbard and Stevenson 1984). This model has no free parameters, and requires only that the effective temperature be much larger than the present

value when t is much smaller than the present value. For Jupiter, the model gives $T_e \sim T_{e,o}$ at the present t , but for Saturn, it gives $T_e \sim T_{e,o}$ at $t = 3.9$ Gyr, so that $T_e < T_{e,o}$ at present. The most commonly accepted explanation of this discrepancy is that Saturn derives a significant component of its present luminosity from unmixing of helium from hydrogen due to immiscibility at high pressures (Stevenson 1975).

Thus, both Jupiter and Saturn have present interior heat flows which are consistent with an initial high-temperature, high-luminosity state, and with initial interior temperatures approximately one order of magnitude higher than present values.

B. Model Results for Uranus and Neptune

A simple thermal evolution model for Uranus or Neptune gives results similar to Eq. (12), but with a smaller value of α (Hubbard and MacFarlane 1980a). However, $T_e > T_{e,o}$ for both planets. For Uranus, the most recent determination from Voyager 2 measurements gives $T_{e,o} = 59.1 \pm 0.3$ K, which is not significantly different from the effective temperature that the planet would have solely from equilibrium reradiation of absorbed sunlight, $T_{eq} = 58.2 \pm 1.0$ K (Pearl et al. 1990). Neptune has an almost identical effective temperature, $T_{e,o} = 59.3 \pm 1$ K, but a lower value of T_{eq} because of its greater distance from the Sun, $T_{eq} = 46$ K (Conrath et al. 1989; Lowenstein et al. 1977).

Hubbard and MacFarlane supposed that these results imply slow, inefficient accumulation of both planets, such that initial interior temperatures were much smaller than T_{max} , and were in fact only slightly higher than present values. Thus the accumulation of Uranus and Neptune may have been a much different process than that of Jupiter and Saturn, with the higher value of T_{eq} for Uranus compared with Neptune playing a crucial role in the planet's subsequent thermal evolution. On the other hand, Podolak et al. (1991) argue that the accumulation of Uranus and Neptune must have been rapid enough to cause substantial heating in any case, and that the present low heat flow from Uranus is a result of poor transport of internal heat, with convection substantially impeded by chemical gradients.

Current interior models of Uranus and Neptune posit an outermost layer of nebular hydrogen and helium, extending to pressures ~ 100 kbar. The adiabatic variation of temperature with density in hydrogen is quite rapid, and if it is followed throughout this region, one infers temperatures of several thousand K at the highest pressures. The temperature variation in deeper ice-rich layers is much more modest, so that present-day interior temperatures are primarily established by the outermost $\sim 10\%$ of the planetary mass in adiabatic models. At present there is little direct evidence that such a rapid temperature rise actually exists in the deep atmosphere of either Uranus or Neptune. More work is needed on these planets' thermal state.

V. Conclusions

Modeling the interiors of the outer planets has shown that these planets all have departed significantly from solar composition. In all cases these planets have cores, composed primarily of rock and/or ice of between 5 and 20 M_{\oplus} . Surrounding these high density regions are regions of much lower density, composed primarily of hydrogen and helium. The observed differences in the He/H ratio among the outer planets is probably the result of a rearrangement of helium in the planetary interior, and does not reflect the actual volume integrated abundance. The C/H ratio shows a steady increase with increasing distance from the Sun. This does seem to reflect the actual abundance of the high-Z material in these bodies. The core-instability model provides a means for understanding both the structure and composition of the outer planets (the low observed abundance of N on Uranus and Neptune is still a problem, however). In addition, it seems to be capable of explaining the observed properties of the satellite systems of these bodies. For the most part, these explanations are still qualitative, but it is hoped that when the next Protostars and Planets volume is written, some stronger results will be available.

ORIGINS OF OUTER-PLANET SATELLITES

JONATHAN I. LUNINE and WILLIAM C. TITTEMORE

University of Arizona

The natural satellites of the planets represent a collection of physically and chemically diverse objects which originated in a number of distinct ways. In the context of the present book, which concerns the formation of planetary systems as a general phenomenon of galactic evolution and as a specific event in the case of our solar system, we present a highly selective treatment of the physics and chemistry of outer solar system satellites. Models for the formation of the regular satellite systems of the giant planets generally invoke a disk of material, but the origin of the disk, and its genetic relationship to the solar nebula and the forming giant planet are vigorously debated. In the case of Neptune, the only remains of a regular satellite system appears to be the small inner satellites discovered by Voyager 2; Triton was probably captured from solar orbit. Much of what we see today in terms of satellite surface geology and recorded tectonic activity may in principle be a result of tidal heating induced by resonant interactions between satellites as their orbits tidally evolved early in the history of the solar system. The volatile budgets of the large icy satellites and Pluto/Charon provide an interesting set of compositional constraints on the relationship between interstellar gas and grains, and the material which formed planetesimals in the outer solar system. The ratio of CO to CH₄ on both Titan and Triton suggest significant chemical evolution beyond the original interstellar composition, and beyond the mixture seen in comet Halley. The abundance of deuterated methane on Titan and elsewhere in the outer solar system has been used to argue that there is a component of relatively unaltered interstellar material preserved today in Titan; however, other mechanisms may have operated after formation of Titan to enhance its atmospheric deuterium abundance.

The natural satellite systems of the planets constitute a field of study in their own right, (Burns and Matthews 1986, eds.). Ideas regarding the origins of satellites are diverse and numerous, due not merely to uncertainty but also to the intrinsic variety of the systems themselves. Recent review articles dealing with satellite origins include Stevenson et al. (1986), who discuss the general issue of satellite formation, and reviews specialized to the outer solar system (Coradini et al. 1989), and the regular satellite systems of Saturn (Pollack and Consolmagno 1984) and Uranus (Pollack et al. 1991). Earlier reviews of Jovian satellite formation exist but should be regarded as out of date. For the inner solar system, the Martian satellites are covered by Burns (1992) and the Earth's Moon by an entire book (Hartmann et al. 1986). The present review, then, is intended to be highly selective and addresses those aspects of satellite origin and evolution which bear on the formation of the solar system itself. We have further chosen to specialize the chapter toward the chemical evidence contained in satellites concerning the modification of

interstellar material which went to form the solar system. This is an area which has seen the acquisition of qualitatively new data in the past five years both for satellite and comet composition, and for abundances in interstellar clouds (see Chapters by Mumma et al. and Van Dishoeck et al.). In addition, we cover new results on the tidal evolution of outer-planet satellite systems, as this process is significantly more important than previously thought in determining satellite properties.

The chapter is organized as follows. In Sec. I we briefly outline the gross physical and chemical properties of the satellite systems of the outer planets, largely deferring to previous reviews for older information which remains up to date. Section II then outlines models for regular satellite formation, as understanding the physical and chemical processes occurring during formation is a prerequisite to relating satellite properties to the larger issue of solar system formation. The subsequent evolution of the satellites, with particular emphasis on tidal evolution, is covered in Sec. III, including a discussion of the dynamical origin of Triton, an important cosmochemical tiepoint. Section IV then concerns the volatile budgets of Titan, Triton and Pluto/Charon, and presents models for the origin of these budgets which tie them to the larger set of processes associated with solar system formation. Finally, we summarize in Sec. V with a list of some outstanding issues in this field.

I. PROPERTIES OF THE SATELLITE SYSTEMS

A. Physical Properties

The basic physical properties of the satellite systems of the giant planets are summarized in Table II in the Chapter by Podolak et al., updated from Pollack et al. (1991). The interesting systematics and regularities provide a compelling argument for a common origin for at least the Jupiter, Saturn and Uranus systems (Pollack et al. 1991). The Neptune system is distinguished from the other three by having fewer satellites, a truncated spatial extent of regular satellites, and a much higher satellite system angular momentum (relative to the planet). All these features support models in which Triton is captured from solar orbit and evolves to its present state while collisionally consuming, or interrupting the formation of, a regular satellite system (McKinnon 1984; Goldreich et al. 1989). One might ask why the mass of Triton normalized by that of Neptune comes so close to the value for the satellite systems of the other giant planets. If this is simply a coincidence, then one turns to the broader issue of why Pluto/Charon and Triton exist at all, what determined their sizes, and how many other such objects are in solar orbit (Stern 1991).

The irregular satellites appear to have no systematic properties from planet to planet. Those in the Jupiter system are best explained as the result of a head-on collision of circum-Jovian material with a solar orbiting body, thereby producing families of pro- and retrograde satellites (Colombo and Franklin 1971); although fragmentation due to gas drag has also been invoked

(Pollack et al. 1979). Insofar as this type of collision is now invoked as a way of locking Triton into a retrograde Neptunian orbit (Goldreich et al. 1989), the formation of the Jovian irregular satellites has become of increased interest.

B. Chemical Properties

Rock-to-Ice Ratios. The satellite systems contain bodies with densities consistent with compositions ranging from pure silicate to essentially pure water ice. The validity of this statement is predicated on the notion that elemental abundances (Anders and Grevesse 1989) are such that the two most abundant condensibles are silicates ("rocks") and water ice. In fact, rock should include iron, nickel and other metals; water ice, depending on the temperature, may include ammonia hydrate, carbon dioxide ice, and condensed or trapped methane, carbon monoxide, noble gases, etc. Involatile organic species may be hard to assign to either category. Unless an object has a density, corrected for the effects of internal compression, which falls outside the range encompassed by silicates and ice (between 3.5 and 0.92 g cm⁻³), one cannot make a more precise statement without applying detailed chemical models.

One can, however, compare the inferred rock-to-ice ratio in the satellites with predicted values for the environment of the solar nebula and circumplanetary formation regions (which are described in Sec. II). Simonelli et al. (1989) and Simonelli and Reynolds (1989) have most recently done this for the outer solar system, and their results are to be preferred over earlier similar computations. The conceptual argument goes as follows: the amount of oxygen available to form water is primarily determined by the solar photospheric C/O ratio. For quite some time, this was thought to be 0.60 (Anders and Ebihara 1982), but was revised downward to 0.43 by Anders and Grevesse (1989). A new determination puts the number at 0.47 (Grevesse et al. 1991). Examination of molecular chemistry in the H₂-rich gas of the solar nebula indicates that oxygen is taken up in the following order: refractory (silicate) minerals, carbon monoxide, water (Prinn and Fegley 1989). Other molecules like CO₂ will also remove oxygen, but not to an extent sufficient to affect the water abundance. When one computes the resulting rock-to-ice ratio for CO being the dominant carbon-bearing species (Chapter by Prinn), it corresponds to a rock mass fraction of 0.51 to 0.71. (This rock mass fraction is relative to rock plus ice, and corresponds to C/O ranging from 0.42 to 0.60 according to calculations from Simonelli and Reynolds [1989].) On the other hand, if a body formed in a disk of material in which most of the carbon was in the form of methane (as we will argue for some of the satellites), much more oxygen is available for making water molecules, and the resulting rock mass fraction is between 0.34 and 0.39. Note that, for a C/O value of 0.60, the rock mass fraction is a very sensitive function of the oxidation state of the carbon, ranging from 0.39 to 0.71. With the new, lower C/O value of 0.43, the range is much smaller: 0.34 to 0.51 from CH₄-rich to CO-rich. A small additional effect comes from the state of hydration of the silicates, as shown by Prinn and Fegley (1989). The magnitude of the uncertainty introduced is

much less than that caused by the uncertainty in the elemental C/O ratio, and is therefore ignored in the present chapter. A superb summary table of rock and ice mixing ratios is given in Zharkov and Gudkova (1991).

The resulting rock mass fractions can be tied to the satellite densities and masses by constructing interior models which take account of the varying compressibilities of the materials. This has been done by many groups over the years (an example of the early work is Lupo and Lewis 1979). As better information on physical properties has become available through spacecraft encounters (and for Pluto/Charon, mutual eclipses), the calculations have been revised. Current results are presented in Fig. 1 for objects of interest to us in this chapter, along with the expected rock mass fractions for objects formed in the solar nebula versus highly reducing protosatellite nebulae. Values for $C/O = 0.43$ and $C/O = 0.60$ are presented.

When interpreting the numbers in this figure, it is crucial to bear in mind that we are assuming that the rock-to-ice ratio in the feeding zones for various bodies reflects cosmic elemental abundances (as defined by the solar photosphere and meteorites). This may not be the case for objects forming in disks around giant planets, because physical processes in such disks and in the atmospheres of the proto-giant planets may alter the rock-to-ice ratio, as described in Pollack et al. (1991) and reviewed below. Even in the case of the solar nebula, one can envision processes in the disk which may alter the rock-to-ice ratio from that inferred from cosmic elemental composition (see, e.g., Stevenson and Lunine 1988). Thus, the results one might obtain from Fig. 1 are only a part of the story.

The icy Galilean satellites Ganymede and Callisto, as well as Titan, contain less ice than one would predict for a high-pressure, fully reduced disk around Jupiter or Saturn (Prinn and Fegley 1981). The simplest explanation is that these objects were large enough to lose water during accretion (Stevenson et al. 1986), which is energetically possible because the gravitational potential energy, per unit mass, for these bodies is comparable to or greater than the latent heat of vaporization. Alternative explanations, that Titan and the Galilean satellites formed from an admixture of solar nebula material, or that the Jovian and Saturnian nebulae were more rock-rich than the models predict, do not seem to be consistent with the lower densities of the other Saturnian satellites.

The Uranian satellites represent the interesting case of bodies which are clearly part of a regular satellite system, are too small to have undergone significant water loss during accretion, but have proportionately less ice than their comparably sized Saturnian counterparts. The extreme obliquity of Uranus has led to the suggestion that the satellite disk was spun out as a result of a giant impact, with consequent shock chemistry producing a water-depleted nebula (Stevenson 1984). On the other hand, disks formed in the absence of a giant impact may have a silicate enrichment relative to cosmic abundance (Pollack et al. 1991), and the very similar normalized masses and specific angular momenta of the Saturnian and Uranian systems suggest like

Figure 1. Rock (silicate) mass fraction, relative to total rock plus ice, in outer solar system objects, compared to predictions for nebular disks in which CO or CH₄ is the dominant carbon species. The objects are assumed to be purely silicate and water ice. The upper-end of each field corresponds to the elemental C/O determination of Anders and Ebihara (1982); the lower end to Anders and Grevesse (1989). The fields are from Simonelli and Reynolds (1989). Object silicate mass fractions are shown as vertical lines. In each case, the range represents uncertainties in densities, and assumptions regarding the interior models: differentiated vs undifferentiated, and (anhydrous) silicate densities of 3.36 to 3.66 g cm⁻³ (see discussion in Simonelli et al. 1989). The Pluto/Charon model is based on a differentiated Pluto model and the bulk density determined for Pluto and Charon combined. For other references for object mass fractions see Johnson et al. (1987), and Smith et al. (1989), with some adjustments.

origins. In this instance, the chemical difference expressed by the rock-to-ice ratios goes unexplained, but may be found in the disparate sizes of the parent planets and/or random effects.

The Neptunian satellite Triton and the Pluto/Charon system have remarkably similar densities (Binzel 1989; Tyler et al. 1989), very close to that predicted for rock-ice objects formed from a CO-rich solar nebula for C/O of 0.60. However, the notion that these are "classical" solar nebula objects runs into three problems: (1) for the Anders and Grevesse C/O value of 0.43, these objects are significantly overdense compared to the predicted value for the solar nebula; (2) we do not know yet Pluto's density independent of Charon's; (3) there is some expectation that significant water loss may have occurred on Pluto during formation of the binary (McKinnon 1989), and some water loss

could have occurred during the capture of Triton or subsequent tidal evolution of the orbit (McKinnon 1984; Goldreich et al. 1989). The difficulty lies in arranging the amount of water loss (per total mass) to be the same for the two bodies, which is a peculiar requirement given that their histories are thought to be unrelated.

Volatile Species. The most volatile components of the satellite systems, as well as refractory organic phases, cannot be determined uniquely from density information, but must be directly detected on surfaces and in atmospheres. Material more volatile than water ice has been detected on Titan, Triton, Pluto and comets. Relatively involatile organic phases have been detected in meteorites and inferred to be present on the rings and satellite surfaces which exhibit a very dark, reddish component. It is unclear whether such material is primordial or processed from methane by energetic chemistry after formation, but the latter hypothesis has been generally favored for the rings and satellites (see, e.g., Thompson et al. 1987a). Inference has been made of the presence of ammonia or other compounds which produce low melting point aqueous liquids based on the existence of resurfaced areas on small Saturnian and Uranian satellites (Stevenson 1982b; Croft et al. 1988; Jankowski and Squyres 1988). Any ammonia present on the surface of a body exposed to magnetospheric or charged particle irradiation is likely to have been converted to molecular nitrogen or perhaps intermediate products, and have escaped the satellite or migrated to polar regions.

Io, Titan and Triton are the only satellites which have an extensive surficial inventory of materials more volatile than water ice. Pluto is in a class with these objects as a small icy planet with surficial volatiles and an atmosphere. On Io, sulfur dioxide and possibly hydrogen sulfide (Nash and Howell 1989; but see Lellouch et al. 1990) appear as atmospheric constituents and surface frost deposits. Both of these volatiles are likely the product of an involved chemical chain involving sulfur, silicates, and possibly water at some time in the past. The extensive tidal heating of Io (Peale et al. 1979) has ensured significant chemical alteration of this satellite's volatile budget. Lewis (1982) argued that metal-free C3V or C2M chondrites would evolve into buoyant, sulfur-rich liquids and SO_2 upon heating at depth in Io. Whether these are plausible starting materials for Io cannot be evaluated at present; nor can alternative models involving leaching of sulfur during silicate dehydration (Fanale et al. 1974). Further progress in these areas may come from remote sensing of Galilean satellite mineralogy from the Galileo Near Infrared Mapping Spectrometer (NIMS). A thorough review of Io's atmosphere is given by Johnson and Matson (1989); we shall not say more about Io in this chapter.

Titan, Triton and Pluto are known to contain methane in their atmospheres (Kuiper 1944; Fink et al. 1980; Broadfoot et al. 1989). Methane surface frost is known or strongly suspected to be present on Triton and Pluto (Cruikshank and Apt 1984; Cruikshank and Brown 1986), and a surface reservoir containing liquid methane appears to be required on Titan to sustain the prodigious photochemical destruction of that molecule (Lunine et al. 1983).

The atmospheres of Titan and Triton are both dominated by molecular nitrogen (Lindal et al. 1983; Broadfoot et al. 1981,1989). In each case, the predominance of N_2 over CH_4 is a volatility effect, and does not directly correspond to the surface plus atmosphere ratio of these species, much less the original, bulk-interior value. In the case of Triton, the atmospheric nitrogen is almost assuredly in equilibrium with surface nitrogen ice, discovered spectroscopically from Earth (Cruikshank et al. 1984); if a deep methane-ethane ocean exists on Titan, then the atmosphere supports a significant dissolved nitrogen component at the surface of that satellite (Lunine et al. 1983). The 1988 stellar occultation by Pluto provided indirect evidence that its atmosphere contains N_2 and/or CO, though deciding how much of each is not possible at present (Yelle and Lunine 1989). The nitrogen or carbon monoxide in Pluto's atmosphere, curiously enough, cannot be in equilibrium with surface frosts if the IRAS-inferred temperature (Sykes et al. 1987) is correct (Hubbard et al. 1990b).

Other constituents in Titan's atmosphere include carbon monoxide, carbon dioxide and a suite of hydrocarbons and nitriles, all of which abundances are controlled by photochemical processes. Even the CO and CO_2 , which on the basis of cosmochemistry would be present in the primordial satellite, appear to be controlled by photochemistry. The abundance of argon is very poorly constrained, and the other noble gases are completely unknown. In the case of Triton, an atmospheric upper limit on the mixing ratio CO to N_2 of 0.01 is obtained from Voyager ultraviolet spectrometer data (Broadfoot et al. 1989). Both CO and CO_2 frost have been detected on the surface from groundbased spectroscopy (Cruikshank et al. 1991), although abundances relative to N_2 or CH_4 are not yet determined. As noted above, the CO/ N_2 value for Pluto's atmosphere is undetermined. The argon abundance is unknown on both Triton and Pluto.

Spectroscopic evidence strongly suggests that Charon's surface is composed of water ice with no methane (Marcialis et al. 1987); some weak evidence for an atmosphere exists but no quantitative limits are available (Elliot et al. 1991). Finally, observation of a coma development around the solar orbiting object Chiron has been interpreted as driven by "CO or a gas of similar volatility" (Meech and Belton 1990); we point out that N_2 has a vapor pressure which is similar. Comet composition is a complex subject unto itself; the best inventory to date is that provided by the extensive observations of Comet Halley. Though still controversial, the currently understood inventory is given in Table V of the Chapter by Mumma et al. and Table X of the Chapter by Van Dishoeck et al.

Table I summarizes the abundance ratios of key cosmochemical species in the atmospheres and on the surfaces of the volatile-rich bodies Titan, Triton and Pluto. Where appropriate, total mass estimates for individual species are also given. Figure 1 and Table I offer the basis for the treatment of satellite origin from the cosmochemical point of view in Sec. IV. We now set the stage by discussing physical environments of satellite formation.

TABLE I
Volatile Budgets of Selected Objects

Object	Total CH ₄ , g	Total N ₂ , g	Total CO, g
Titan			
Atmosphere	3×10^{20}	9×10^{21}	10^{18}
Dissolved in ocean	1×10^{22}	3×10^{21}	$10^{17} - 10^{18}$
In ocean & sediment as higher hydrocarbons	6×10^{22}		
Total ocean plus atmosphere	7×10^{22}	1×10^{22}	$1-2 \times 10^{18}$
Triton			
Atmosphere	3×10^{12}	5×10^{16}	$<5 \times 10^{14}$
Surface ^a	$>10^{19}$	10^{20}	$\leq 10^{19}$
Bulk primordial ^b	$1-20 \times 10^{22}$	2×10^{21}	$1 - 7 \times 10^{23}$
Pluto			
Atmosphere	$2-5 \times 10^{15}$	$\rightarrow 3-6 \times 10^{15} \leftarrow^c$	

^a Nitrogen and carbon monoxide numbers assume of order 1 meter thickness of nitrogen ice over one hemisphere (this is the maximum amount which can be moved from the summer to winter hemisphere over a major season). Methane is based on the rate of photolysis (Broadfoot et al. 1989), and thus includes methane already photolyzed and present as a surface deposit of higher hydrocarbons. Carbon monoxide number is based on atmospheric upper limit (Broadfoot et al. 1989) as discussed in text; CO frost has been detected spectroscopically (Cruikshank et al. 1991) but no estimated abundance is available.

^b Estimated from cometary abundances given in the Mumma et al. Chapter.

^c Approximately one-half the atmosphere by number is carbon monoxide and/or nitrogen, but the relative proportions cannot be distinguished (Hubbard et al. 1990b).

II. MODELS FOR THE FORMATION OF REGULAR SATELLITE SYSTEMS

As detailed in Pollack et al. (1991), the normalized masses and specific angular momenta of the regular satellite systems of Jupiter, Saturn and Uranus strongly suggest a common mechanism for formation. Angular momentum constraints dictate that a disk of material must be involved, but whether this disk was gaseous or particulate, derived from solar nebula material or the atmosphere of the proto-giant planet is at issue. Four distinct disk models can be enumerated (Pollack et al. 1991):

- a. *Accretion disk*: By analogy with the solar nebula, material falling into the giant planet's gravitational well is redirected into an equatorial disk by virtue of its angular momentum. The disk material consists of grains, plus gas of solar-nebula composition. Further chemical evolution of the

- gas in the high-temperature, high-pressure portion of the disk will cause alteration of the trace molecular composition toward a more reduced state.
- b. *Spin-out disk*: As the distended envelopes of the forming giant planets contract, material is left behind in the form of a disk, again by virtue of its angular momentum. The gas is a mixture of solar nebula gas and sublimated solid material, chemically reprocessed in the protoplanetary envelope. Additionally, some solid material may have survived entry into the envelope without sublimating, and was then spun out with little reprocessing. This disk could have an elemental and molecular composition very different from the solar nebula.
 - c. *Blow-out disk*: A giant impact with the protoplanetary atmosphere may spin out a disk of material. The impact generates high temperatures enabling shock chemistry and subsequent quenching to alter the molecular composition of the gas from that of the protoplanetary atmosphere (Stevenson 1984).
 - d. *Co-accretional disk*: Collision of planetesimals within the protoplanetary sphere of influence will generate a disk of particles, which may reaccrete to form satellites. Such disks consist of a mixture of rock and ice dictated by the original planetesimal composition, altered possibly by the thermal effects of the collision.

As discussed in Pollack et al. (1991), disk model (d) is implausible because it predicts a satellite system whose size is slightly less than the Hill sphere radius of the planet, which is orders of magnitude larger than the observed extent of the regular satellites. Model (a) requires certain constraints on the timing of giant planet envelope contraction relative to the lifetime of the solar nebula: for the solar nebula gas to be the direct source of the satellite systems, the parent planet envelopes must have contracted to a point inward of roughly $2 R_p$, where R_p is the current planetary radius. Model (c) is compelling for Uranus, given the planet's axial tilt, but the similarities between the Uranian satellite system and those of the other giant planets (see Table II of the Chapter by Podolak et al.) are not predicted by the impact model.

We now focus on the implications of conditions within satellite forming disks for the current composition of the satellites. We dispense quickly with the co-accretional disk because it appears not to explain the extent of regular satellite systems, but may be relevant to the irregular satellites, for which composition and density data are essentially nonexistent. The composition of satellites derived from such a disk depends upon the rock-to-ice ratio and volatile budget of the original impactors, and therefore on the original gaseous nebulae (solar or circum-planetary) from which they formed. The details of the collision process, and final particle size distribution, will tend to increase the refractory component fraction, as vaporized constituents may not recondense and in fact could be swept out of the system by magnetospheric processes (Stevenson et al. 1986).

Disk model (a), in which material is captured from the solar nebula, will have a total elemental gas and condensate composition identical to that of the solar nebula. However, processes associated with the infall and subsequent steady-state thermodynamic condition of the disk will alter the molecular composition of the material, including the rock-to-ice ratio. Such processes include (i) sublimation and chemical reactions associated with gas dynamic heating at the surface of the circumplanetary disk, and (ii) thermochemistry in gas-phase and gas-grain reactions. Although these effects have been examined for the solar nebula (Lewis and Prinn 1980; Hollenbach and Neufeld 1990; Lunine et al. 1991), only (ii) has been quantified for giant planet disks (Prinn and Fegley 1981). Process (i) is primarily of interest as a means of subliming water ice and more volatile constituents; the importance of this effect can be crudely estimated by comparing the latent heat of sublimation to the kinetic energy dissipated by gas drag as the grains go into Keplerian orbit. For infalling water ice achieving Saturn orbit at Titan's radial position, this ratio is roughly 0.4, indicating that substantial quantities of water may sublime off of grains (the actual mass fraction sublimed depends on particle size, and hence emissivity, as well as the rock fraction of the original grain). For Uranus, at the orbit of Oberon, the ratio is approximately unity, indicating less potential for water ice sublimation. In both systems, a portion of the water ice and other volatiles may be in the gas phase with the remainder in grains, complicating the chemical history of satellite-forming material.

Process (ii) acts upon molecules which may be transported inward by radial mixing either in the gas phase or on grains swept inward by gas drag and then sublimated. The outer solar nebula is expected to have $\text{CO}/\text{CH}_4 > 1$, and perhaps $> > 1$ if radial mixing is efficient (Chapter by Prinn). CO_2 is never more than 1% of the total carbon. The predicted outer solar nebula NH_3/N_2 value is less certain, since it depends very strongly on whether material was mixed toward the inner portion of the solar nebula where ammonia is effectively destroyed, and on the poorly-determined ratio in interstellar material (Chapter by Van Dishoeck et al.). When solar nebula material is mixed into the inner parts of circumplanetary disks, thermochemistry will act to increase the CH_4 abundance, to the point where it dominates over CO (Prinn and Fegley 1981); consequently the rock mass fraction drops from > 0.5 to as low as 0.34 (Fig. 1). CO_2 continues to be a minor species, but may become competitive in abundance with CO. The NH_3 abundance in the circumplanetary disk equals or exceeds that of N_2 . In the simplest view, then, we expect satellites formed in an accretion disk to have densities consistent with most of the oxygen locked up in water, abundant methane and ammonia, and little carbon monoxide and nitrogen.

Complicating the story is the realization that radial mixing of material from outer portions of the disk to the inner, higher temperature parts may not have been efficient enough to process most of the material available to make satellites. Although we make this statement by analogy with the solar nebula (Stevenson 1990; Prinn 1990), its validity is dependent upon detailed

models of the transport of angular momentum and mass in circumplanetary nebulae, which have not been constructed. Also, although temperature profiles have been constructed for accretion disks around Jupiter and Saturn (Prinn and Fegley 1981; Lunine and Stevenson 1982), the same is not true for Uranus and Neptune. It is conceivable that around these smaller planets, the high temperature zones were sufficiently close in and limited in extent that chemical processing of most of the disk material is implausible. Pollack et al. (1991) point out that this type of disk may be decoupled from the planetary envelope, so that high temperatures may not be accessible at all in the Uranus and Neptune disks, and one might even argue in favor of this possibility for Jupiter and Saturn.

If we consider disk models (b) and (c), the chemical predictions become even more ambiguous. Model (c) postulates a shock event, for which the temperature and pressure history can be formulated and used to compute molecular abundances after cooling and consequent quenching (Stevenson 1984); such models predict an enhancement of CO, and increase in the rock mass fraction, relative to the accretion disk chemistry described above. However, as the source material for the disk is now the shocked planetary envelope itself, the total elemental inventory and specifically the abundances of rocky and icy materials are poorly constrained. There is no compelling argument that the inventory need be solar, because much of the rocky planetesimals (if large enough) could have survived to greater depths in the envelope without sublimating than could the water ice. Such compositional gradients may have survived in the face of convection (Stevenson 1985; Pollack et al. 1991). Alternatively, the impactor may have gouged deeply enough such that the source material for the blow-out disk contained a near-solar mix of species.

Model (b) suffers from similar uncertainties, as again the disk material is derived from the planetary envelope, in this case contracting from a highly distended configuration. If the dissolution of rocky and icy planetesimals in the envelope proceeded to differing degrees, the gaseous disk would have a nonsolar elemental abundance which altered the relationship between the rock mass fraction (observed through the satellite bulk density) and the oxidation state of the carbon-bearing species in the nebula (Simonelli et al. 1989). The fact that the intermediate-sized Saturnian satellites, which likely did not lose water during accretion (Stevenson et al. 1986), have rock-to-ice ratios consistent with a highly reducing nebula, is weak evidence that the rock-to-ice ratio of the Saturn disk was unaffected by the dissolution process. However, the Uranian satellite system implies just the opposite: if formed via model (b), the densities of those satellites suggest an enhancement in the rocky component of the disk.

The conclusion to be drawn is that the predicted oxidation state of satellite-forming material is highly uncertain, and even the satellite densities may reflect a long suite of processes which modified the basic elemental abundances of rock- and ice-forming materials from their solar values. One additional effect which must be considered is loss of water during accretion. Comparison

of the virialized energy of collapse to the latent heat of vaporization of water shows that, energetically, the Galilean satellites and Titan could have lost substantial quantities of water during accretion, and plausibly enhanced their rock-to-ice ratios above that of the planetesimals from which they formed. Both Triton and Pluto/Charon suffered significant dynamical effects during their early evolution to the current state, and jetting of water during the formation of the Pluto/Charon binary has been proposed by McKinnon (1989). The similar observed densities of Triton and the Pluto/Charon system raise the interesting issue of whether their separate dynamical histories could plausibly produce similar final densities. Nonetheless, if the Grevesse et al. (1991) elemental abundances are correct, such water loss is required to explain the current densities if these bodies began with a solar mix of oxygen, carbon, silicon, etc., even for a CO-dominated nebula (Fig. 1; Simonelli and Reynolds 1989).

With regard to the deuterium-to-hydrogen ratio in the satellite disks, little work has been done. It is impossible, given the lifetime of protosatellite disks (~ 0.1 Myr; Stevenson et al. 1986) to create significant enhancement in deuterated methane and other heavy species, relative to their "solar" (essentially Jovian; Lutz et al. 1990) abundance. In fact, if the methane which we see in Titan today is assumed to have been produced thermochemically in the Saturn circumplanetary nebula, the required temperatures would have produced an enhancement factor of deuterated methane of only 1 to 2, less than the observed enrichment (Lutz et al. 1990). Either Titan's methane is of interstellar origin, unprocessed in the solar nebula or circumplanetary nebulae, and retentive of an enhanced deuterium signature, or processes occurred after Titan's formation to produce an enhancement (Pinto et al. 1986). We will return to this important point in Sec. IV where the volatile budgets of individual objects are examined more closely. Beyond Titan, and excepting comets, deuterium has not been detected in any icy body. Clearly this is a key measurement to be attempted in the coming years.

In this section, we have illustrated the complexity of the molecular composition of gases and grains which went to form satellites and other icy bodies of the outer solar system. Although there is no evidence for gross deviations from solar in the rock-to-ice ratios in the outer planet satellites, modest variations mask the chemical state of the gaseous disk from which these objects formed. As yet, we cannot decide between the three gaseous disk models [(a)-(c)], on chemical grounds, though dynamical considerations associated with giant planet formation (Chapter by Podolak et al.) weakly favor (b) over (a), and there is no compelling reason to argue that the Uranian satellites had to form in the blow-out disk rather than the spin-out disk (Pollack et al. 1991). The densities of the Saturnian satellites suggests that the disk carbon was sequestered in CH_4 , with Titan having lost water during accretion. The Uranian satellites have a slightly higher density than the intermediate-sized satellites of Saturn, implying perhaps a much less massive satellite disk in which thermochemical conversion of CH_4 was incomplete, or alternatively

the signature of differential planetesimal dissolution in the Uranian envelope. Before examining in greater detail the origin of the volatile budgets of Titan, Triton and Pluto/Charon, we consider the history of satellite systems after accretion.

III. SUBSEQUENT PHYSICAL EVOLUTION OF SATELLITES

Subsequent to the formation of the outer-planet satellite systems, a number of important physical processes have modified their dynamical and geophysical properties. Tidal interactions between the satellites and their primaries have altered their rotational and orbital states. Thermal histories have been affected by radiogenic, and in some cases tidal, heating. In this section, we consider the effect of these processes on the evolution of satellite systems.

A. Tidal Evolution of Satellite Spins and Orbits

Neighboring objects tidally distort one another, because of the dependence of the gravitational force on distance. If the tidal distortion of a planet or satellite varies with time, frictional dissipation of energy occurs in the interior of the body. This energy dissipation may have profound effects on the rotational and orbital states of the satellites as well as their thermal histories. By decreasing the dynamical energy of the system, tidal evolution tends to drive a planet and its satellite towards a stable state where both rotate synchronously and the tidal distortion on all objects is invariant with time, unless the satellite(s) either escape or collide with the planet (see, e.g., Counselman 1973). The Pluto-Charon system is an example of a system that appears to have reached the stable state (Peale 1986); all of the other outer planet satellite systems are currently tidally evolving. Because the differential tidal force depends inversely on the cube of the distance between objects, inner satellites are affected by tides much more than the outer ones.

The rotation states of most planetary satellites are highly evolved, with the exception of the small, irregular outer satellites of Jupiter, Saturn and Neptune. Therefore, the current rotational states of most satellites do not well constrain their initial states. Extensive reviews of the processes affecting rotation may be found in Peale (1977,1986); here we briefly summarize these processes.

The rotation of a solid body results in a slight oblate distortion of its figure. If the rotation axis is not coincident with one of the principal axes, motion of the rotational bulge with respect to the figure of the object dissipates energy due to internal friction. For a nearly spherical body, the rotational energy is approximately

$$E = \frac{L^2}{2I} \quad (1)$$

hence if rotational angular momentum L is conserved, the minimum energy state corresponds to rotation about the principal axis corresponding to the maximum moment of inertia I . Any initial rotation state of a body will be

rapidly driven towards this state by internal friction, on a time scale (Peale 1977)

$$T_{\text{wobble}} = \frac{3GIQ}{k_2 R^5 \omega^3} \quad (2)$$

where G is the gravitational constant, Q is the specific dissipation function, k_2 is the Love number, R is the equatorial radius, and ω is the angular rate of rotation. For planetary satellites, this time scale is much shorter than the age of the solar system (Peale 1977).

Differential gravitational forces cause a slight prolate distortion of a satellite's figure along the direction to the planet. If the rotation period of a satellite is different from its orbital period, the body of the satellite moves with respect to the tidal distortion potential. Because of internal friction, there is a time lag in the response of the body to the tidal potential, which results in a slight displacement between the satellite's tidal bulge and the satellite-planet direction. The planet therefore exerts a net torque on the satellite, driving the latter's rotation rate towards a state where the net torque is zero on a time scale (Peale 1977)

$$T_{\text{despin}} = \frac{2\Delta\omega m a^6 Q}{15k_2 GM^2 R^5} \quad (3)$$

where $\Delta\omega$ is the change in spin rate, m and M are the masses of the satellite and planet, respectively, and a is the orbital semimajor axis. Except for the small irregular outer satellites of Jupiter, Saturn and Neptune, the despinning time scale is shorter than the age of the solar system (Peale 1977).

For a satellite without a permanent asymmetric mass distribution and which moves in an eccentric orbit, the final spin rate is slightly larger than the orbital mean motion (Goldreich 1966). However, if certain conditions are met, the planetary torque on any permanent asymmetry in the satellite may counteract the torque on the displaced tidal bulge, preventing the satellite from completely despinning. These conditions may be met at spin-orbit resonances, which occur when the rotational and orbital periods form near-integer ratios (Goldreich and Peale 1966). Many such resonances may be encountered by a tidally despinning satellite. Exact spin-orbit resonance occurs when the axis of largest principal moment of inertia coincides with the planet-satellite line at periape, which ensures that the torque on the permanent asymmetry is zero when the differential gravitational force is strongest. For nearly spherical satellites with low orbital eccentricities, the dynamical behavior at spin-orbit resonances can be described using a pendulum-like model, and the probability of being captured into such a state can be determined analytically (Goldreich and Peale 1966; Counselman and Shapiro 1970). For satellites with very irregular shapes and/or relatively large orbital eccentricities, the dynamical behavior is more complex, capture into resonance occurring via a chaotic zone (Wisdom et al. 1984; Wisdom 1987a).

The strongest spin-orbit resonance, with the largest probability of capture, is the synchronous rotation state. Almost all tidally evolved bodies in the

solar system rotate synchronously. The exceptions are Mercury, which was captured into a 3:2 spin-orbit resonance (Goldreich and Peale 1966), and Hyperion (Wisdom et al. 1984). Because of Hyperion's large orbital eccentricity and very irregular shape, the synchronous spin-orbit resonance is unstable, and Hyperion probably tumbles chaotically.

If a satellite has a free obliquity, i.e., its rotational axis is not coincident with the orbit normal, the tidal bulge is pulled alternately above and below the rotational equator as the satellite revolves about the planet. This also dissipates energy through internal friction, driving the obliquity towards zero on a time scale similar to the despinning time scale. However, if the satellite orbit is inclined and precessing, the obliquity is forced due to occupancy of a Cassini state (Peale 1969, 1973, 1977; Jankowski et al. 1989). In this case, the rotational and orbital motions are coupled, and the damping of the satellite's obliquity due to tidal dissipation leads to a decrease in the orbital inclination. The damping occurs on a much longer time scale than the damping of the free obliquity (see, e.g., Yoder and Peale 1981). For most outer-planet satellites, the forced obliquity is small.

A synchronously rotating satellite on an eccentric orbit is subject to a varying tidal potential (see, e.g., Kaula 1964; Peale and Cassen 1978). As the distance to the planet varies during an orbital period, the magnitude of the tidal distortion changes. More importantly, the orbital angular speed varies while the rotational angular speed remains nearly constant, which results in an oscillation of the tidal bulge relative to the satellite-planet direction (Yoder 1979*b*). The resulting torques on the tidal bulge rock it back and forth relative to the principal axes of the bodies. These variations in the tidal potential result in the dissipation of energy due to internal friction, which may significantly heat the interiors of some satellites. For a locked rotation state, the dissipated energy must come from the orbit, and the orbital semimajor axis tends to decrease as the orbital eccentricity damps at a rate (see, e.g., Goldreich 1963)

$$\frac{de}{dt} = -\frac{21}{2} k_2 n \frac{M}{m} \left(\frac{R}{a} \right)^5 \frac{e}{Q} \quad (4)$$

where n is the orbital mean motion. The eccentricity decay time scales are much shorter than the age of the solar system for the inner large satellites of Jupiter (Yoder and Peale 1981), Saturn (Peale et al. 1980), Uranus (Squyres et al. 1985), and Neptune (Chyba et al. 1989*a*). We would therefore expect these satellites to have negligible eccentricities currently. However, some of the inner satellites of Saturn (Peale et al. 1980) and Uranus (Squyres et al. 1985) have anomalously large orbital eccentricities. The orbital eccentricities of some of the satellites of Jupiter and Saturn are forced due to orbital resonances, and the anomalously large orbital eccentricities of the inner large Uranian satellites are most likely remnants of past orbital resonances (see below, and also Tittlemore and Wisdom 1988, 1990).

Orbital eccentricity decay may have played a major role in the orbital and thermal history of Triton (McKinnon 1984; Goldreich et al. 1989). If

Triton was captured from heliocentric orbit into an elongated orbit around Neptune, tidal dissipation in the satellite would have led to circularization of the orbit into its present configuration on a time scale of order 100 Myr. Any pre-existing satellites beyond about $5 R_N$ would have been cannibalized by the massive Triton as it periodically crossed their orbits, and Nereid may have been perturbed into its current very eccentric orbit (Goldreich et al. 1989).

A satellite raises a tidal bulge on the planet (Darwin 1880; MacDonald 1964). If the planet rotates at a different rate than the satellite revolves, friction in the planetary interior results in a time lag in the response of the planet to the tidal potential, and therefore a phase lag between the orientation of the tidal bulge and the planet-satellite direction. This results in a net torque between the tidal bulge of the planet and the satellite. The effects of this torque depend on the relative rates of planet rotation and satellite revolution. If the satellite motion is prograde with an orbital period longer than the planetary rotation period, the torque tends to decelerate the planet's rotation and accelerate the orbital motion of the satellite, tending to increase the semimajor axis. The orbits of most outer planet satellites are tidally evolving in this manner. If the satellite motion is prograde with an orbital period shorter than the rotation period of the planet, the torque accelerates the planetary rotation rate and decelerates the orbital motion of the satellite, tending to decrease the semimajor axis. For example, Phobos is spiralling in towards Mars, and may collide with the surface in about 50 Myr (Burns 1986). Likewise, if the satellite motion is retrograde, the planetary rotation rate increases and the satellite spirals in; Triton is currently undergoing this process, although it is in no danger of crashing into Neptune anytime soon (Chyba et al. 1989a). The rate of tidal evolution of the orbital semimajor axis of a satellite is given by (Darwin 1880):

$$\frac{1}{a} \frac{da}{dt} = 3k_{2p} n \frac{M}{m} \left(\frac{R_p}{a} \right)^5 \frac{1}{Q_p} \text{sign}(\omega_p - n) \quad (5)$$

where k_{2p} , Q_p and ω_p are, respectively, the Love number, specific dissipation function, and frequency of rotation of the planet. Planetary tides also result in slow changes in the orbital eccentricity (Kaula 1964)

$$\frac{1}{e} \frac{de}{dt} = \frac{19}{8} \frac{1}{a} \frac{da}{dt} \quad (6)$$

and inclination (Darwin 1880)

$$\frac{1}{i} \frac{di}{dt} = -\frac{1}{4} \frac{1}{a} \frac{da}{dt} \quad (7)$$

of the satellite.

As discussed above, tidal forces evolve the system towards a configuration where the tidal distortion of objects is invariant with time. For a planet

with a single satellite, these conditions would be met if the satellite is on a circular, equatorial orbit and both planet and satellite rotate synchronously (this ignores effects of the Sun, other planets, and the Galaxy). The Pluto-Charon system has apparently reached this end state (Peale 1986). For the giant planets, however, the effect on the planetary rotation rate is negligible; the most important effect of planetary tides is to increase the semimajor axes of satellite orbits.

The regular satellite systems of Jupiter and Saturn are involved in many mean motion resonances, which occur when the ratio between the orbital periods of two satellites is near a small integer. The inner three Galilean satellites, Io, Europa and Ganymede, are currently involved in the Laplace resonance, in which the orbital period of Io is approximately half that of Europa, which is in turn approximately half the orbital period of Ganymede. In the Saturnian system, Enceladus occupies a 2:1 resonance with Dione, Mimas and Tethys occupy a 4:2 orbital resonance, and Titan and Hyperion a 3:2 resonance. Goldreich (1965) showed that the tidal expansion of satellite orbits could lead to the establishment of some of these resonances. In contrast, the Uranian satellite system is currently devoid of mean-motion resonances, although the satellite orbits may have undergone significant tidal evolution (Goldreich and Soter 1966; Tittlemore and Wisdom 1989,1990). The reasons for this may be understood by considering the nature of the dynamical interactions between satellites at a mean motion resonance.

The gravitational attraction between a pair of satellites is strongest near conjunctions. At a mean-motion resonance, conjunctions occur with the satellites in nearly the same configuration. Under these conditions, the cumulative effects of many conjunctions can significantly perturb the shapes of the orbits. A mean motion resonance is exact when the configuration of the satellites is the same at successive conjunctions, i.e., conjunctions are stationary in a coordinate frame referred to one or both orbits, both of which precess due to planetary oblateness. At, for example, a 3:1 mean motion resonance, the most important resonances affecting the orbital eccentricities involve the following combinations of angles:

$$\begin{aligned} 3l_O - l_I - 2\varpi_I \\ 3l_O - l_I - \varpi_I - \varpi_O \\ 3l_O - l_I - 2\varpi_O \end{aligned} \quad (8)$$

where l is the mean longitude and I and O refer to the inner and outer satellite, respectively. Near a 3:1 mean motion resonance, these angles may either circulate or oscillate: each may be described by a pendulum-like Hamiltonian function in the absence of other perturbations (see, e.g., Peale 1976). The longitudes of the pericenter ϖ and ascending node (Ω) circulate at rates

$$\frac{d\varpi}{dt} \approx \frac{3}{2}nJ_2\left(\frac{R_p}{a}\right)^2 \approx -\frac{d\Omega}{dt} \quad (9)$$

where J_2 is the second order spherical harmonic of the planet. These rates are sensitive functions of the orbital distance, and may be significantly different for two satellites. Therefore, the frequency of each of the above resonance angles is slightly different. If the planetary oblateness is large, then at a given semimajor axis ratio the effects of one resonant term may dominate the effects of the others, in which case the motion may be described analytically, and the probability that the resonant combination of angles is captured into oscillation can be determined (Yoder 1979a; Henrard 1982; Henrard and Lemaître 1983, 1984; Borderies and Goldreich 1984). In this case, if the satellites are captured into a resonance, this may lead to an increase of one or both orbital eccentricities and/or inclinations, until the system reaches an equilibrium state determined by the rate of tidal energy dissipation in the satellite(s). However, if the planetary oblateness is small, the resonant terms may interact strongly, resulting in more complicated behavior.

Dermott (1984) suggested that mean-motion resonances among the Uranian satellites might be chaotic and therefore unstable, because of the relatively small oblateness of that planet. In addition, because of the relatively large satellite masses, there are strong secular interactions between the Uranian satellites (Greenberg 1975; Laskar 1986; Dermott and Nicholson 1986), resulting in variations of the orbital precession rate, which further complicate their motions. Modern methods in nonlinear dynamics have enabled us to determine the nature of the behavior at resonances among the Uranian satellites. Specifically, the motion is "chaotic" (Tittlemore and Wisdom 1988, 1989, 1990; Tittlemore 1990b; Dermott et al. 1988; Malhotra and Dermott 1990), i.e., it is characterized by irregularities and extreme sensitivity to initial conditions. At the mean-motion resonances that may have been encountered by the Uranian satellites, one or more resonant angles may be temporarily captured into oscillation; however, the resonance ultimately becomes unstable and is disrupted. During the temporary phase of resonant behavior, the orbital eccentricities and/or inclinations may undergo significant increases. For example, Miranda's anomalously large orbital inclination has been explained as a consequence of passage through the 3:1 mean-motion commensurability with Umbriel (Tittlemore and Wisdom 1989). Miranda's orbital eccentricity may also have increased considerably during evolution through this commensurability (Tittlemore and Wisdom 1990; Malhotra and Dermott 1990); the large orbital inclination had a significant effect on the evolution through the eccentricity resonances (Tittlemore and Wisdom 1990). Ariel, too, may have undergone a large increase in orbital eccentricity during passage through a 4:1 mean-motion resonance with Titania, as shown in Fig. 2 (Tittlemore 1990b). By determining which resonances lead to unstable, chaotic behavior, Tittlemore and Wisdom have strongly constrained the rate of internal tidal energy dissipation in Uranus: $11,000 \lesssim Q_U \lesssim 39,000$ (Tittlemore and Wisdom 1989, 1990).

Chaotic motion may also have played an important role in the Jovian satellite system. Prior to the establishment of the current Laplace resonance

Figure 2. The orbital eccentricity of Ariel increasing dramatically during evolution through the 4:1 mean-motion commensurability with Titania (Tittmore 1990*b*). Shown are the maximum and minimum eccentricities as a function of time. Initially, the eccentricity increases in a regular manner and can be analytically modeled; however, at $e_M \sim 0.04$, the orbits become chaotic, and eventually escape from the resonance. During evolution through the 4:1 resonance, and afterwards as the eccentricity damps, the interior of Ariel may have been warmed by up to 20 K, perhaps triggering the geologic activity that led to its late resurfacing.

among the Galilean satellites, Europa and Ganymede may have been involved in a chaotic 3:1 mean-motion resonance, leading to large increases in both orbital eccentricities (Tittmore 1990*a*; Malhotra 1991). Although the J_2 of Jupiter is much larger than that of Uranus, the relatively large orbital distances of Europa and Ganymede result in orbital precession rates comparable to those among the inner Uranian satellites, and the satellite-to-planet mass ratios are similar, resulting in strong interactions between resonances and chaotic behavior at the 3:1 commensurability.

B. Thermal Evolution of Satellites by Tidal Heating

Satellites may be heated by a number of sources (Schubert et al. 1986); here we focus on tidal effects, which over the past few years have assumed increased importance in the literature. Tidal flexing of a satellite frictionally dissipates energy, heating the interior of a satellite. For a synchronously rotating satellite with a small obliquity θ and orbital eccentricity, the rate of tidal heating is

approximately (Peale and Cassen 1978)

$$\frac{dE}{dt} = -\frac{k_2 M n^3 R^5}{a^3 Q} \left(\frac{21}{2} e^2 + \frac{3}{2} \theta^2 \right). \quad (10)$$

For most outer-planet satellites, the eccentricity term dominates because the forced obliquities are very small, and free obliquities are damped on a very short time scale.

Tidal heating due to the decay of a free eccentricity is probably not important to the thermal history, because of the short time scale (see, e.g., Cassen et al. 1982). A notable exception to this rule may be Triton. As discussed above, if Triton was captured from a heliocentric orbit, its initial orbit about Neptune may have been very eccentric, and estimates of the tidal heating rate indicate that the water ice component of Triton could have melted and remained largely liquid as the eccentricity decreased (McKinnon 1984; Goldreich et al. 1989).

Satellites involved in mean motion resonances may have significant forced eccentricities. Io, the innermost Galilean satellite, moves in an eccentric orbit forced by its interactions with Europa and Ganymede in the Laplace resonance. Peale et al. (1979) predicted that the tidal heating of Io was intense enough to cause melting in its interior, possibly with observable surface activity; a week later, the Voyager 1 spacecraft discovered that this satellite is indeed volcanically active (Morabito et al. 1979). Europa's orbital eccentricity is also forced by the resonant interaction, and tidal heating may be sufficient to maintain a liquid layer beneath the satellite's smooth icy crust (Cassen et al. 1979, 1980, 1982; Squyres et al. 1983a; Ross and Schubert 1987; Ojakangas and Stevenson 1989), although the heating is not currently large enough to initiate melting of water ice in a completely frozen ice mantle. Currently, tidal heating of Ganymede in the Laplace resonance is negligible (Cassen et al. 1982). However, both Ganymede and Europa may have been strongly tidally heated in the past, during passage through a 3:1 resonance (Tittlemore 1990a; Malhotra 1991). These satellites may have reached large orbital eccentricities during passage through a chaotic zone, followed by escape from the resonance and subsequent evolution into the Laplace resonance. Tidal distortion may have fractured the rigid lithospheres of both satellites, and melting of water ice in the mantles may have occurred leading to episodes of resurfacing. Because this resonance provided Ganymede with a large heat source that Callisto lacked, this could explain the dichotomy between these satellites, which have similar bulk properties but apparently very different thermal histories.

Tidal heating has most likely played a role in the thermal history of Enceladus, which is relatively small but has had a very active geologic history (Smith et al. 1982). However, its current forced orbital eccentricity due to the 2:1 resonance with Dione is only 0.0044. According to elastic tidal heating models, this value is about a factor of 20 too small to initiate melting of water

ice, and 5 to 7 times too small to maintain a molten interior (Squyres et al. 1983*b*); however, consideration of viscoelastic effects suggest that the tidal heating rate in fact may be much larger (Ross and Schubert 1989).

The orbital resonances encountered by the Uranian satellites may have had an important effect on the thermal histories of Ariel and Miranda. During evolution through the 4:1 resonance with Titania, about 3.8 Gyr ago or earlier, the orbital eccentricity of Ariel may have reached a value up to about 0.045 before the satellite escaped from the resonance (Tittlemore 1990*b*). During resonance passage, and afterwards as the eccentricity decayed, the internal temperature of Ariel may have increased by up to 20 K. Before the resonance was encountered, Ariel's internal temperature was probably around 220 K due to accretional and radiogenic heating. The increase of internal temperature to about 240 K conceivably may have triggered the geologic activity that led to the resurfacing of Ariel, by thinning the rigid lithosphere and thus increasing thermal stresses on it. Surface fracturing may have resulted, providing conduits to the surface for relatively buoyant, mobile materials such as ammonia dihydrate. During evolution through the 3:1 resonance with Umbriel, the internal temperature of Miranda may have exceeded the minimum melting point of ammonia dihydrate (approximately 176 K), however, resonance passage most likely did not result in significant melting of water ice (Tittlemore and Wisdom 1990; Malhotra and Dermott 1990).

If a satellite is not rotating synchronously, e.g., during the initial spindown or a phase of chaotic rotation, the rate of tidal heating may be enhanced over the rate for synchronous rotation by a factor of order $1/e^2$, with a corresponding decrease in the eccentricity decay time scale (Wisdom 1987*a*). This may result in a very intense but brief heating episode, which has been suggested as a mechanism for thermally altering the surface of Miranda (Marcialis and Greenberg 1987; however, see Wisdom 1987*a*; Tittlemore and Wisdom 1990). Hyperion, despite having both a chaotic rotation state and a significant forced orbital eccentricity, is too small and too far from Saturn for tidal heating to be important in its thermal history.

IV. ORIGIN OF THE VOLATILE BUDGETS OF OUTER SOLAR SYSTEM BODIES

The accumulation of data on the volatile component of solid bodies in the outer solar system provides another approach to understanding the environments which produced regular satellites and the double planet system of Pluto/Charon. In this section, we explore the following particular assertions:

1. The volatile budgets of Pluto and Triton reflect partial processing of interstellar material in the outer solar nebula. In particular, sublimation of volatiles from infalling interstellar grains was followed by selective retrapping onto grains, which preferentially excluded carbon monoxide and molecular nitrogen. The molecular nitrogen seen on Triton was con-

verted from ammonia, by photochemical or shock-chemical processing after Triton's formation.

2. Methane in Titan's atmosphere-surface system is the result of thermochemical processing in the circum-Saturnian disk from which it formed. The deuterium enhancement seen in Titan's atmosphere is not necessarily a sign of interstellar origin of methane, but may be related to processes occurring after formation.

Table I contains a partial reconstruction of the total surface and atmosphere volatile budgets for Titan and Triton. The Titan reconstruction (Lunine 1985a) is based on the ethane ocean model for resupply of methane to Titan's atmosphere (Lunine et al. 1983), and uses a photolysis rate for methane from Yung et al. (1984) and the thermodynamics discussed in Lunine and Stevenson (1985). The values for Triton are lower limits computed assuming the minimum amount of nitrogen required to provide year-round coverage of each hemisphere with a layer of nitrogen (which corresponds to of order 1 meter thickness), and with the areal methane fraction estimated from groundbased spectroscopy. For Pluto, where the atmospheric and surface properties are more poorly known, this exercise is less well constrained than for Triton, and we therefore do not attempt an estimate.

A. Origin of the Volatile Budgets of Triton and Pluto

In Sec. II we argued that the bulk densities of Triton and the Pluto/Charon system are to some degree consistent with formation in a relatively water-poor environment, plausibly due to sequestration of oxygen by carbon monoxide as has been proposed for the solar nebula by Lewis and Prinn (1980). The atmospheric value of $\text{CO}/\text{N}_2 < 0.01$ (Broadfoot et al. 1989) limits the ratio of surface-exposed CO to N_2 to < 0.15 , using vapor pressure data from Brown and Ziegler (1979) and Raoult's law for an ideal solid solution

$$x_{\text{CO}} = \frac{e_{\text{N}_2}}{e_{\text{CO}}} y_{\text{CO}} \quad (11)$$

where x_{CO} , y_{CO} are the mole fractions of CO, relative to N_2 , in the surface ice and atmosphere, respectively, and e_i is the vapor pressure of component i . (The reader is cautioned that a numerical error exists in the coefficients for nitrogen latent heats in Brown and Ziegler [1979]. However, the vapor pressure coefficients are correct, and can be used with the Clausius-Clapeyron relationship to derive latent heats if these are desired.)

The liquid solution of CO and N_2 is nearly ideal, meaning it obeys Eq. (11) (Verschoyle 1931), and the solid solution is expected to be likewise, particularly if the presence of α -CO stabilizes α - N_2 a few degrees above the latter's α - β transition temperature of 35 K (see the phase diagram in Scott [1976]). Therefore, the estimate afforded by Eq. (11) is probably good to better than, say, a factor of 2.

As Triton's atmospheric CH_4 mixing ratio (again relative to N_2) is close to the saturated value of 10^{-4} at 38 K (Herbert and Sandel 1991), we cannot use

the atmospheric CO/CH_4 as an indicator of their relative surface abundances. In Table I, we use the rate of photochemical destruction of CH_4 (Broadfoot et al. 1989), along with the argument that we do not view Triton at a special time in its history, to argue for a minimum reservoir of CH_4 at or near the surface which will not be depleted by photochemistry for at least hundreds of Myr. We would then conclude from Table I that $\text{CO}/\text{CH}_4 < 1$.

We are therefore presented with the possibility that Triton's surface carbon budget consists at best of comparable quantities of CH_4 and CO , or even more extreme, that CO is a minor species. Perhaps CO was not outgassed with the same efficiency as CH_4 , or was preferentially destroyed by atmospheric chemistry over the age of the solar system. Neither of these is particularly plausible, based on analogous studies of Titan (Samuelson et al. 1983; Lunine and Stevenson 1985).

Table I also gives an estimated primordial volatile budget for Triton, based on cometary abundances from the Chapter by Mumma et al. Most striking in comparing surface and primordial abundances is the loss of CO relative to N_2 and CH_4 . The loss relative to CH_4 could be explained by fractionation effects associated with sublimation and recondensation of infalling precursor interstellar grains (Lunine et al. 1991), provided such a process did not similarly alter comet grains. This requires cometary grains to have entered the nebula at a somewhat larger radial distance than those which went to form Triton. Alternatively, the higher volatility of CO compared to CH_4 could have resulted in preferential escape of the former after formation. In either case, most of the N_2 should have been lost as well. The problem therefore reduces to explaining the present predominance of nitrogen.

The most sensible way out of the nitrogen dilemma is to assume that Triton's nitrogen was brought in as ammonia, NH_3 . This molecule is fairly abundant in comet Halley and interstellar clouds. Ammonia's low volatility compared to carbon monoxide, and strong propensity for hydrogen bonding with itself and water ice, allowed it to be retained or recondensed during most energetic processes associated with nebular infall of grains (Lunine et al. 1991). The resulting composition of Triton-forming planetesimals was rich in ammonia and methane, and poor in carbon monoxide.

Subsequent to the formation of Triton, conversion of ammonia to molecular nitrogen may have occurred photochemically (Atreya 1978) or through thermochemistry generated by shock-heating of the atmosphere or surface by a projectile (Jones and Lewis 1987; McKay et al. 1988). Photochemical conversion requires warm conditions (in excess of 150 K) to avoid freezeout of the intermediate product hydrazine (Atreya et al. 1978). If Triton was captured from solar orbit, such a warm environment, in the form of a massive "greenhouse" atmosphere, may have been possible early on, as tidal evolution circularized Triton's initially eccentric capture orbit around Neptune (Lunine and Nolan 1992). With ammonia present in the warm atmosphere, and scaling the photochemical yield of N_2 from Titan (the limiting factor being solar flux), we find it is possible to produce a layer of nitrogen hundreds of meters

thick, which may be an underestimate if shock chemistry was also operative (McKay et al. 1988).

A key test of this hypothesis, that NH_3 is the source of Triton's present-day N_2 , is measurement of the atmospheric ratio of argon to nitrogen. As described for Titan in Lunine et al. (1989), because argon is excluded from the planetesimal ice to nearly the same degree as CO and N_2 , the Ar/N_2 ratio in the atmosphere of Triton should be orders of magnitude less than the solar elemental value of 0.1, if the present-day N_2 had been manufactured from ammonia. A ratio close to 0.1 would be more consistent with the N_2 being primordial, and brought into Triton (along with argon) trapped in water ice. Unfortunately, the Voyager UVS instrument was not sufficiently sensitive to provide a useful upper limit on argon.

With regard to Pluto, although methane is the only species spectroscopically detected there, evidence from a stellar occultation observed in 1988 indicates the presence of a heavier gas, most plausibly N_2 or CO (Yelle and Lunine 1989). The fact that the surface temperature and atmosphere pressure are not consistent with the existence of either species as a surface ice leads to a dilemma, because the estimated escape rate of the atmosphere corresponds to a 3 kilometer layer of CO or N_2 ice over the age of the solar system (Hubbard et al. 1990*b*). Alternative surface models include slow outgassing of the heavier species, from subsurface clathrates or deeper interior reservoirs. Until a surface model consistent with the data and loss processes is developed, it will be impossible to estimate Pluto's volatile budget and hence test the hypothesis presented above for Triton. The expectation that N_2 should dominate over CO is only valid if the NH_3 - N_2 conversion was operative on Pluto as it was on Triton. The dynamical histories of these bodies are so different that such an assumption is not a safe one. If conversion of ammonia to nitrogen did not occur, CH_4 should be very much overabundant compared to N_2 as well as CO in Pluto's bulk volatile budget, CO should be more abundant than N_2 , and neither species may be sufficiently plentiful to produce significant deposits of ice (in contrast to CH_4). Other speculations on the volatile composition of Pluto may be found in Simonelli et al. (1989) and McKinnon and Mueller (1988).

B. Origin of Methane on Titan

Prinn and Fegley (1981) established that methane was an important, if not dominant, carbon-bearing molecule in the disk of material from which the Saturn satellites formed. This conclusion is robust provided that the disk is of elemental solar composition, gaseous, optically thick and continues sufficiently close in to Saturn that high (>600 K) temperatures could be obtained. Such a disk is consistent with the accretion disk model of Lunine and Stevenson (1982), or the spin-out disk concept described in Pollack et al. (1991). Given that CH_4 dominated the carbon budget, it would also have sequestered most of the adsorption or cage sites in the water ice planetesimals which formed Titan (Lunine and Stevenson (1985). Consequently, little CO

or N_2 could have been incorporated in Titan (Lunine and Stevenson 1987), and the observed nitrogen is likely a product of ammonia photolysis or shock chemistry (Atreya et al. 1978; Jones and Lewis 1987; McKay et al. 1988).

This picture, while consistent with Titan's bulk density and other details of satellite formation, has been challenged by the observation of a deuterium enrichment in atmospheric methane on Titan (Lutz et al. 1990). Adopting a $D/H_{\text{primordial}} = 3 \times 10^{-5}$ (Anders and Grevesse 1989), the D/H value of 0.4 to 1.5×10^{-4} , $\pm 50\%$, (de Bergh et al. 1988) in Titan's atmosphere corresponds to a factor of 3 to 10 enrichment over the primordial value. If this reflects Titan's initial, bulk deuterated methane abundance, it is straightforward to show that Titan's methane could not have been manufactured by high-temperature thermochemical processes in the solar nebula or a circumplanetary disk. According to Prinn and Fegley (1989), the minimum temperature at which the $CO-CH_4$ interchange reactions could have proceeded, over the lifetime of the solar nebula, was 600 K. This is also close to the quench temperature for deuterium fractionation between HD and heavier molecules (Grinspoon and Lewis 1987), and would yield a D/H enrichment in methane of 1.4 to 1.5. Clearly, if the observed enrichment is primordial, then Titan's methane must contain a significant component of interstellar origin, which has not been subjected to high temperatures.

Alternatively, methane in Titan may have started with only modest deuterium enrichment which was then enhanced through physical and chemical processing. Pinto et al. (1986) examined various possibilities, including cloud formation, partitioning between hydrocarbon ocean and atmosphere, and photochemical evolution of the atmosphere. The latter process proved to be most promising. Methane photolysis occurs mainly through a catalytic cycle involving the key reaction $C_2H + CH_4 \rightarrow C_2H_2 + CH_3$, followed by photolysis of the acetylene to reform the catalyst, the C_2H radical; direct photolysis of methane is much slower. Pinto et al. (1986) proposed that the analogous reaction for deuterated methane was slower, because of the higher binding energy of the deuterium atom, and estimated rates 3/4 to 7/8 of that for the nondeuterated methane. The enrichment of deuterium then depends on the ratio of the total initial methane reservoir to the total present reservoir.

The result is plotted in Fig. 3, adapted from Pinto et al. (1986). Models of a surface ocean on Titan (Lunine et al. 1983; Dubouloz et al. 1989) posit an ethane-methane mix of 15 to 80% methane. The ocean's ethane is regarded as the primary product of methane photolysis, with solid acetylene (at the ocean base) the secondary product at 20% of the ethane abundance (Yung et al. 1984). Hence the ocean ethane to methane ratio, with the ethane augmented by 20% to account for acetylene, constitutes the ratio of total-initial to total-present CH_4 reservoir. The maximum ratio then, is roughly 8, which corresponds to an atmospheric enrichment of deuterium of no more than 1.7. If we allow for slight vapor-pressure differences between methane and its deuterated form, there is an additional ocean-atmosphere partitioning which gives an enrichment of at most 1.3. Combined with the allowable

Figure 3. Deuterium enrichment from photochemical destruction of methane in Titan's atmosphere, redrawn from Pinto et al. (1986). The D/H enrichment over the primordial value is plotted as a function of R , the ratio between the total initial reservoir of methane and the present reservoir. The two curves represent different assumptions about the rate of photolysis of CH_3D , either $3/4$ or $7/8$ the rate of CH_4 photolysis. The calculation assumes that photosensitized dissociation of methane is the dominant destruction mechanism, as described in Yung et al. (1984).

enrichment in the Saturn nebula of 1.4, the total enrichment from these two processes is ~ 3 , marginally consistent with that derived from the observations of de Bergh et al. (1988).

Although consistent with the deuterium data, the case would be more convincing if additional enhancement mechanisms could be found. There is compelling evidence for an early period of high ultraviolet flux from the Sun (Zahnle and Walker 1982), with consequent increased rate of photolysis. This, plus other processes such as shock chemistry due to impacts might increase the amount of methane processed, and hence the atmospheric deuterium enrichment. This would have had to occur, however, after the departure of the massive hydrogen envelope of the Saturn nebula, to prevent re-equilibration of deuterated species with H_2 . Such a requirement is plausible, and consistent with the fact that the primitive Titan atmosphere only contained molecular hydrogen as a minor constituent soon after formation (Lunine 1985b).

More restrictive, however, is the requirement that the primordial photochemical products not interact thermodynamically with the present-day liquid methane-ethane reservoir. If, for example, ethane or propane were the primary product of the early enhanced photolysis, they would be present in the current ocean, whose composition determines the measured atmospheric methane

abundance. By this argument, the Voyager data on the composition of Titan's lower atmosphere constrain the total amount of surficial ethane, propane and other soluble compounds which have been produced since the formation of Titan. Acetylene, however, is a solid, and it as well as other heavy organics have only limited thermodynamic contact with the liquid. If primordial photochemical products exist today as acetylene and other heavy organics, rather than ethane, one could select a larger x -axis value in Fig. 3, without violating the Voyager constraints on the present-day composition of the ocean. Ongoing processing of ethane to solid organics by surface chemistry (driven by impacts, perhaps) would achieve this end.

To produce a deuterium enhancement of 3, solely by photochemistry, would require depositing 10 km of primordial photochemical detritus on the surface (Pinto et al. 1986). If this material were solid and sufficiently porous ($> 10\%$), the proposed ocean of Lunine et al. (1983) could largely be confined to pore spaces within the sediment. Interestingly, such a configuration might simultaneously satisfy the requirements of the ethane ocean model and explain recent radar data, which appear to have detected a solid surface (Muhleman et al. 1990).

V. SUMMARY OF OUTSTANDING ISSUES

Our current picture of the formation of regular satellites and the Pluto/Charon system has benefitted greatly from the era of outer planet exploration, and from the spacecraft and groundbased investigations of comet Halley. The chemical information is at the stage wherein useful comparisons can be made between observed volatile abundances (and ice/rock ratios, through the bulk densities) on the one hand, and models of chemical and associated physical processes in the solar nebula, protosatellite disks, and interstellar clouds on the other. At the same time, models of giant-planet formation have become sufficiently detailed that they now make rather specific predictions concerning the nature of protosatellite disk systems. A complete, detailed list of currently outstanding issues would be lengthy; we close this chapter with an eclectic choice of the most interesting:

1. The origin and chemical nature of protosatellite disks must be clarified, particularly with regard to the ice-to-rock ratio and the accessibility of high-temperature, chemically active, inner zones. The first *in-situ* measurements of the Jovian atmosphere from Galileo may help in constraining giant-planet formation, which will certainly bear on the properties of the disks.
2. Elemental abundances, particularly C/O, in primitive solar system material remain controversial but are crucial to interpreting bulk densities of satellites in terms of origins scenarios.
3. The abundances of volatile molecules in molecular clouds, particularly methane, ammonia and carbon monoxide, must continue to be deter-

mined to higher spatial resolution and increasing sensitivity. Also, our understanding of the parent molecule composition of comets is poor and it is of high value to improve these numbers.

4. The natures of the surfaces of Titan, Triton and Pluto are still incompletely understood and hinder our ability to construct volatile budgets for these objects. The origin of methane, nitrogen and carbon monoxide on these three bodies must be tied together, but these relationships are still only dimly perceived.

Acknowledgments. Careful reviews by C. F. Chyba and D. P. Simonelli improved the content and writing. Conversations with D. J. Stevenson, W. B. McKinnon, A. G. W. Cameron, J. F. Kerridge, D. M. Hunten, J. B. Pollack and E. Van Dishoeck were stimulating and helpful. Preparation of this chapter, and some of the work herein, was supported by grants from NASA's Planetary Atmospheres and Geology and Geophysics Programs.

COMETS AND THE ORIGIN OF THE SOLAR SYSTEM: READING THE ROSETTA STONE

MICHAEL J. MUMMA

PAUL R. WEISSMAN
Jet Propulsion Laboratory

and

S. ALAN STERN
Southwest Research Institute

Comets are the most primitive bodies in the solar system and preserve a cosmochemical record of the primordial solar nebula at the time of their formation. Spacecraft missions to, and intensive groundbased studies of comet Halley (and other recent comets) have strongly reinforced this view, and given us the first detailed insights into the nature of the refractory solids and frozen volatiles contained in cometary nuclei. The volatile record reflects a composition similar to that observed in dense molecular cloud cores, with little evidence of reprocessing in the solar nebula or in giant planet subnebulae. From the measured volatile abundances, it appears likely that comets formed at temperatures near or below ~ 60 K and possibly as low as ~ 25 K. Grains in comet Halley were found to be of two types: silicates and organics. The organic grains consist of the elements carbon, hydrogen, oxygen and nitrogen (CHON) and appear to act as an extended source of molecules in the cometary coma. Isotopic evidence shows that comet Halley formed from material with the same compositional mix as the rest of the solar system, and is consistent with comets having been a major contributor to the volatile reservoirs on the terrestrial planets. A variety of processes have been shown to modify and reprocess the outer layers of comets both during their long residence time in the Oort cloud and following their entry back into the planetary system. These include: irradiation by energetic photons and particles, heating by passing stars and nearby supernovae, competing accretion and erosion by interstellar gas and grains, regolith gardening by debris impacts, and solar heating during perihelion passage. The last process results in sublimation of volatiles to form the visible cometary coma, and also causes the transformation of amorphous water ice to crystalline ice, thermal stressing of the nuclear surface and structure, and the likely formation of a lag-deposit crust of larger silicate and organic grains on the nucleus surface. However, the pristine nature of cometary materials at depth within the nucleus appears to be well preserved. The most likely formation site for comets is in the Uranus-Neptune zone or just beyond, with dynamical ejection by the growing proto-planets to distant orbits to form the Oort cloud. A substantial flux of interstellar comets was likely created by the same process, and may be detectable if cometary formation is common in planetary systems around other stars.

I. INTRODUCTION

Comets are the most pristine bodies in our solar system, and their compositions and structure encode seminal information on processes that affected their formation and subsequent evolution. For this reason, the nature of the cometary nucleus is the central problem in cometary science. Prior to 1986, studies of the composition of cometary nuclei were entirely remote, being based on spectroscopy and radiometry of the dust and of (mainly) dissociation products of the volatile ices. Production rates of dust were measured, grain sizes were estimated, and silicate components were identified. The volatile parents of observed radicals and ions were identified in a few cases, notably water and carbon dioxide (the parent of CO_2^+), and water production rates were obtained for many comets. Direct quantitative detections of candidate parent volatiles, however, were limited to CO in two comets (West 1976 VI and Bradfield 1979 X), along with a few tentative detections of other species at radio wavelengths.

In recent years, however, our perspective of comets has changed dramatically. The combination of improved understanding of spectral line formation in the coma and advances in instrumentation has enabled direct spectroscopic study of parent volatiles in many comets. These produced quantitative detections of H_2O , CO_2 , H_2CO , CH_3OH , H_2S , HCN, and CO, and provided a provisional detection of CH_4 in a new comet while setting important upper limits for it in two other comets. The detection of crystalline silicates and of the so-called organic-grain feature in comet P/Halley (1986 III) (and in every bright comet since then) introduced a similar revolution in the remote study of cometary dust. By far the most significant development, however, was the enormous effort expended on the study of comet Halley, involving a fleet of spacecraft and virtually every significant astronomical observatory on the ground, in the air, and in space. Two of the most stunning advances were the discovery of a previously unknown population of organic grains, and the finding that fully reduced species are underrepresented among cometary volatiles. The results returned by these and subsequent investigations revolutionized our understanding of cometary compositions, and of the messages carried by comets on their origin and subsequent evolution.

Cometary material may have experienced various kinds of processing while enroute from the dense molecular cloud core that predated our solar system to the final cometary nucleus. Understanding the nature and degree of that processing is a principal objective of cometary studies. Interstellar ices are subject to substantial processing in the natal cloud core (e.g., by ultraviolet photons; see Chapter by van Dishoeck et al.), and may be vaporized while falling into the solar nebula. If the latter occurs, volatile species may be chemically modified before recondensing as cometary ices. Even after aggregation into the nucleus, cometary material is not necessarily free from further change. Cometary nuclei are exposed to a variety of processes while in the Oort cloud, and after injection into the inner solar system, and so have

been modified to varying degrees. Energetic particles and photons, acting over the long residence time in the Oort cloud, chemically and physically modify the surface layers of cometary nuclei. These nuclei are also subjected to heating by passing stars and nearby supernovae, to collisional gardening by Oort cloud debris, and to episodic erosion by impact of interstellar grains during encounters of the solar system with molecular clouds. Following their orbital evolution into the inner solar system, the nuclei of short-period comets experience insolation-induced heating that may modify the structure of their ices (from amorphous to crystalline). This modification may occur throughout the entire body in some cases, and may mobilize highly volatile molecules within the ice-organic-silicate matrix. Although the plausibility of these effects is supported by detailed modeling and by laboratory experiments, many key cometary and environmental parameters are highly uncertain and thus the significance of the predicted effects can be fully assessed only after making measurements on real cometary nuclei.

Each process imposes its characteristic signature on cometary material, and this is preserved as a record in the form of chemical, elemental, isotopic and isomeric compositions, and in the morphology and physical structure of the material within the nucleus. New capabilities in remote sensing and the possibility of detailed investigations of cometary material and of cometary nuclei by future spacecraft (see Sec. V), promise major advances in our ability to read this record, the "Rosetta stone" of cometary and solar system origin.

A. The Problem of Cometary Origins

The origin of cometary nuclei is still unclear. Several possibilities have been advanced, and are presented here in the context of defining key tests for them. Most associate the formative region with the solar nebula, but Cameron (1973) suggested that comets formed in associated satellite-nebulae (fragments of the pre-solar nebula), while Clube and Napier (1982) proposed formation in giant molecular clouds with subsequent capture when the solar system traverses such clouds. A schematic representation of processes relating comets to the formation and evolution of the solar system is shown in Fig. 1.

The solar-nebula hypotheses are distinguished primarily by the degree of reprocessing experienced by interstellar material prior to formation of cometary nuclei (see Lunine [1989*b*], Prinn and Fegley [1989], and Fegley and Prinn [1989] for recent reviews of chemistry in the solar nebula). The present models may be regarded as single-component and dual-component accretional scenarios. In one single-component model, comets accreted from unmodified ice- and organic-mantled interstellar grains (cf. Greenberg 1982; Greenberg and Hage 1990) at distances greater than about 20 AU from the proto-Sun, and at temperatures < 100 K. Alternatively, accretion could have occurred after the volatiles in icy mantles were vaporized, then were chemically processed in the main solar nebula, and later were recondensed onto the grains which finally aggregated into macroscopic cometesimals. The dual-component models represent admixtures of interstellar and processed fractions. For example,

comet Halley. The various accretion models can thus be tested by comparing cometary compositions with model predictions.

Temperatures in Cameron's accretion-disk model of the solar nebula range from about 180 K at the orbit of Jupiter to about 18 K at 100 AU. The range is 130 K to 25 K in Hayashi's radiative steady-state model (Cameron 1978a; Hayashi 1981). These temperature profiles are compared in Fig. 2, and the distances at which various volatiles would be stable as ices are indicated (Yamamoto 1985) (see also Table I). Lewis and Prinn (1980) examined chemical conversion in this region of the solar nebula, and demonstrated that reduction of CO and N₂ could not be achieved in the nebular collapse time. Thus, the conversion was said to be "quenched." In this scenario, comets would contain volatile carbon and nitrogen mainly as CO and N₂, with very little in the reduced forms (CH₄, NH₃), and would contain almost no easily reacted or destroyed interstellar material such as H₂CO and S₂.

Early reports of significant amounts of fully reduced volatile carbon (CH₄) and nitrogen (NH₃) in comet Halley stimulated work on ways to bring chemically equilibrated material into the trans-Uranian region of the solar nebula, where comets presumably formed. Proposed mechanisms include processing in the giant planet sub-nebulae (Fegley and Prinn 1989b), and radial diffusion of inner solar-system material (Lunine 1989b; Engel et al. 1990). Chemical reduction of oxidized species (e.g., CO to CH₄, N₂ to NH₃, etc.) can proceed efficiently in regions of relatively high temperatures and densities, such as the giant planet sub-nebulae. Comets formed from this material would be rich in reduced species, but extremely poor in "interstellar" chemicals such as CO, N₂, H₂CO and S₂. The high temperatures and densities predicted by models of giant planet sub-nebulae would also seem to be inconsistent with the survival of CHON particles and POM, which vaporizes at about 400 K. Further difficulties lie in providing a mechanism for removing this material (or alternatively, icy planetesimals) from the local gravitational wells of the giant planets. The radial diffusion models differ primarily by transporting equilibrated material from the inner solar nebula outward to the comet-forming zone, thus avoiding the need for an escape mechanism from the gravitational wells of the giant planet sub-nebulae. However, the abundance estimates of reduced volatiles in comet Halley have been revised downward to the point where it may not be necessary to invoke dual-component models at all.

In this chapter, we begin by reviewing the evolution of the Oort cloud from its formation to the present time, and the processes which may modify cometary nuclei while in the Oort cloud and after re-injection into the inner solar system. We then review key results obtained from detailed investigations of comet Halley, and of several comets since then, and we compare them with current models of cometary formation and evolution. Finally, we review present and expected future capabilities for reading the information encoded in a significant number of comets. By doing so, it should be possible to establish the statistical properties of groups of cometary nuclei and the significance of individual comets, within the context of the origin of our solar system.

TABLE I
Sublimation Temperatures of Observed Cometary Volatiles and Corresponding Distances
in the Solar Nebula, and a Comparison of Cometary and Interstellar Abundances

Species	Temperature ^a (K)	Distance ^a (AU)	Comets	ISM-gas	ISM-ice
H ₂ O	152	3.4–5.4	100	≤100	100
CH ₃ OH	99		1–5 ^c	0.01–0.1	7–40
HCN	95		0.02–0.1 ^d	0.01–0.1	4

^a Temperature and distance of sublimation/condensation in models of the solar nebula. The first distance given represents a radiative equilibrium model (Hayashi 1981) while the second represents an accretion disk model (Cameron 1978a). Gas density of $n = 10^{13}$ cm⁻³ and mixing ratio H₂O/H₂ = 10⁻⁴ are assumed. After Yamamoto (1985). ^b Relative abundances are for comet Halley, except as noted (see also Table V). For the interstellar medium, we follow van Dishoeck et al. (see their Chapter) for values in low-mass star-forming regions (see their Tables VI and IX), while for interstellar ice we adopt the values given in Table VI of this Chapter. ^c 1% in comet Levy (1990 XX), 5% in comet Austin (1990 V). See Hoban et al. (1991a) and Bockelée-Morvan et al. (1991). ^d Both NH₃ and H₂CO were temporally variable in comet Halley. It is assumed that NH₃ is the sole parent of NH₂. See text. ^e Typical of several comets. See Kim and A'Hearn (1991). ^f In comet Austin (1990 V), assuming a parent distribution. See Colom et al. (1992). ^g In comet Levy (1990 XX). See Brooke et al. (1991b). ^h Range exhibited by recent comets. See text, and Feldman (1983). ⁱ In comet IRAS-Araki-Alcock (1983 VII), but in no other comets.

Radiative Equilibrium Model for the temperature of the nebular gas (Hayashi).

Adiabatic Model for the temperature of the nebular gas (Cameron).

Figure 2. Temperature profiles in the solar nebula and sublimation distances for volatile ices. (a) Radiative equilibrium model (Hayashi 1981) for the temperature of the nebular gas. (b) Adiabatic model (Cameron 1978a) (figure after Yamamoto 1985).

II. COMETARY RESERVOIRS AND ORBITAL DYNAMICS

A. Comets and the Oort Cloud

Cometary orbits are classified as either long or short period, depending on whether their periods are greater than or less than 200 yr, respectively. The orbits of long-period (LP) comets are randomly oriented on the celestial sphere, whereas the short-period (SP) comets are generally confined to direct orbits with inclinations less than $\sim 30^\circ$. Most of the known SP orbits have periods between 5 and 20 yr, while the LP orbits range up to 10 Myr.

Approximately one third of all long-period comets observed passing through the planetary region are on weakly hyperbolic orbits. However, it is only the osculating (instantaneous) orbits that appear hyperbolic. Integration of the orbits backward in time to points outside the planetary region, and conversion from a heliocentric to a barycentric coordinate system (Bilo and van de Hulst 1960), showed that those comets in fact had highly eccentric but still gravitationally bound orbits. Planetary perturbations (primarily by Jupiter) scatter the LP comets in orbital energy, either ejecting them on hyperbolic orbits or capturing them to more tightly bound ellipses.

The distribution of orbital energies for the observed LP comets is shown in Fig. 3 (Marsden 1989). The numbers of comets are plotted versus $1/a_0$, the inverse original semimajor axis of the orbit (prior to entry into the planetary region), which is proportional to orbital energy. Positive $1/a_0$ values indicate bound orbits, while negative values denote hyperbolic ones. The distribution is characterized by a sharp spike of comets at nearly zero (but bound) energies, and a low continuous distribution of comets in more tightly bound (less eccentric) orbits.

Oort (1950) showed that this unique distribution could be explained by a vast spherical cloud of comets surrounding the planetary system and extending halfway to the nearest stars. Oort demonstrated that comets in the cloud are repeatedly scattered by perturbations from random passing stars. The orbits diffuse in velocity phase space and occasionally are perturbed to perihelia within the planetary region.

However, once comets enter the planetary region they are scattered in $1/a_0$ primarily by Jupiter, with a typical $\Delta(1/a)$ of $\pm 630 \times 10^{-6} \text{ AU}^{-1}$ on each perihelion passage (van Woerkom 1948; Everhart 1968). This is more than six times the width of the Oort cloud spike in Fig. 3. Thus, the comets rapidly diffuse in $1/a_0$. A typical LP comet from the Oort cloud makes an average of 5 returns with a mean time of 6×10^5 yr between its first and last perihelion passage. Approximately 65% of LP comets are hyperbolically ejected to interstellar space, 27% are randomly disrupted (they break up for reasons that are not well understood), and the rest are lost to a variety of mechanisms such as perturbation to a Sun-impacting orbit (Weissman 1979). A very small fraction of the long-period comets, on the order of 10^{-3} to 10^{-4} , evolve to short-period orbits.

The few hyperbolic comets in Fig. 3 are believed to be the result of small

Figure 3. The distribution of original inverse semimajor axes for 264 long-period comets as found by Marsden (1989). The large spike at very small positive values of $1/a_0$ corresponds to comets in very long-period orbits, extending to interstellar distances. These are the “dynamically new” comets from the Oort cloud. The low continuous distribution with $1/a_0 > 1 \times 10^{-4} \text{ AU}^{-1}$ are returning comets which have been scattered in $1/a_0$ by planetary perturbations, primarily by Jupiter.

errors in their orbit determinations and/or nongravitational forces (i.e., jetting of volatiles from the nuclear surface), which cause the orbits to appear more eccentric than they actually are. True interstellar comets would be expected to have $1/a_0$ values on the order of -0.50 AU^{-1} , for hyperbolic encounter velocities of 20 km s^{-1} (the average velocity of the Sun relative to nearby stars), more than 600 times greater than the largest value observed.

The dynamical evolution of LP comets is controlled by the combined action of planetary and stellar perturbations, by rare encounters between the solar system and giant molecular clouds (GMCs), by the tidal field of the galactic disk (and to a lesser extent the galactic nucleus), and by nongravitational forces from jetting during perihelion passage. Monte Carlo numerical simulations of the comets' dynamical evolution in the Oort cloud (Weissman 1982, 1985a; Fernandez 1982; Heisler and Tremaine 1986; Heisler 1990), can be used to estimate the cloud population by comparing the predicted and observed flux of LP comets through the planetary region, after correction for observational selection effects (Everhart 1967). The current best estimate for the classical Oort cloud (Fig. 1) is $\sim 10^{12}$ comets (Weissman 1990).

Studies of the integrated perturbations on comets in the classical Oort cloud have shown that their typical dynamical lifetime is only about half

the age of the solar system (Hut and Tremaine 1985). Thus, it has been suggested that the cloud needs to be replenished. The two possible sources are an unseen inner Oort cloud which is not dynamically sampled except by the largest perturbations (i.e., those due to penetrating stellar passages or encounters with GMCs), and the capture of comets from interstellar space. Capture has been shown to be highly improbable at typical stellar encounter velocities (Valtonen and Innanen 1982; Valtonen 1983). On the other hand, dynamical models (Duncan et al. 1987; Shoemaker and Wolfe 1984) have shown that an inner Oort cloud with a probable population 5 to 10 times greater than that of the outer cloud is a natural consequence of the dynamical ejection of comets from the planetary region (Fig. 1). The inner cloud is capable of replenishing the outer Oort cloud as comets there are stripped away by stellar and GMC perturbations. The estimated population of the Oort cloud (inner and outer) is then 6 to 11×10^{12} comets. Assuming an average nuclear mass of 3.8×10^{16} g (Weissman 1991a), the total mass of comets in the Oort cloud is between 38 and 70 Earth masses (M_{\oplus}). Because estimates of cometary masses are highly uncertain, some Oort cloud mass estimates are much larger, up to $\sim 500 M_{\oplus}$ (Bailey 1990). A more complete review of Oort cloud dynamics is given in Weissman (1990).

B. Formation of the Oort Cloud

Hypotheses on the origin of the Oort cloud can generally be divided into two groups: (a) that comets are of primordial origin, and were formed coincident with the Sun and planetary system, or (b) that comets were formed and/or were captured episodically, either once or many times over the history of the solar system.

The many different proposals for cometary origin are reviewed in detail in *Protostars and Planets II* (see Weissman 1985b). The major primordial origin hypotheses include:

1. Formation as icy planetesimals in and/or just beyond the outer planets zone, followed by dynamical scattering to distant orbits in the Oort cloud by the growing proto-planets (Oort 1950; Kuiper 1951; Safronov 1972; Cameron 1978b);
2. *In-situ* accretion in the solar nebula at large solar distances (Biermann and Michel 1978; Hills 1982; Bailey 1987);
3. Formation in satellite nebulae of the solar nebula (Cameron 1973);
4. Formation of the Sun in a closely spaced cluster of stars such that comets formed around each star were dynamically mixed, populating each of their respective Oort clouds (Donn 1976).

The episodic hypotheses include:

5. Gravitational focusing of material in the solar wake after solar system passage through interstellar clouds (Lyttleton 1948);

6. Eruption from the giant planets and/or their satellites (Vsekhsvyatskii 1967);
7. Formation in compressed interstellar clouds at galactic spiral-arm shocks (McCrea 1975);
8. Formation in GMCs, followed by capture during encounters with the solar system (Clube and Napier 1982).

All the episodic hypotheses have serious difficulties and will not be discussed further here (see discussion of problems and weaknesses in Weissman [1985*b*]). Of the “primordial origin” hypotheses, (1) and (2) are the leading candidates. A cometary origin among the outer planets provides for formation in a relatively dense but still cold region of the solar nebula, with the problem that scattering to Oort cloud distances is dynamically inefficient. Conversely, formation at Oort cloud distances is dynamically efficient but is difficult to understand given the very low nebular densities expected at 10^3 to 10^4 AU from the proto-Sun. The first four hypotheses are illustrated schematically in Fig. 1.

Oort (1950) suggested that comets were dynamically ejected from the asteroid belt by Jupiter and the other giant planets. Kuiper (1951) pointed out that the proposed icy composition of comets required that they be formed farther from the Sun, at the orbit of Jupiter or beyond. Safronov (1972) subsequently showed that gravitational scattering by Jupiter and Saturn tended to eject most planetesimals from their zones into hyperbolic orbits, rather than to bound orbits in the Oort cloud. However, Safronov also showed that the lower masses and larger heliocentric distances of Uranus and Neptune would allow them to provide considerable dynamical scattering, with far fewer ejections. This work has served as the basis for the most widely accepted and widely studied theory of cometary origin.

The present ideas about planetesimal formation are reviewed elsewhere in this book (see Chapter by Weidenschilling and Cuzzi). Icy planetesimals, formed in the outer solar system, are thought to have been the building blocks of the cores of the giant planets. They probably also provided a substantial fraction of the mass of Uranus and Neptune, which apparently formed after much of the nebular gas had dispersed. The composition of icy planetesimals undoubtedly varied with temperature (and hence, with heliocentric distance) in the solar nebula, though dynamical scattering by the growing protoplanets may have blurred those differences somewhat.

Safronov (1972) showed that if the current masses of Uranus and Neptune were dispersed into small planetesimals in their zones, their accretion times would be $\sim 10^{11}$ yr, longer than the age of the solar system. To surmount this difficulty, Safronov suggested that the original mass of planetesimals in the Uranus-Neptune zone was 10 times larger than the current masses of the two planets combined. According to Safronov, most of this material was ejected to hyperbolic orbits but about 1 to 2% of it reached distant elliptical orbits to form the Oort cloud.

Numerical simulation of this dynamical scattering (Fernandez and Ip 1981, 1983) confirmed many of Safronov's ideas, but also found some important differences. Fernandez and Ip showed that material was placed in the Oort cloud most efficiently by Neptune, with 72% of all ejecta ending up in the Oort cloud, the rest escaping to interstellar space or being sent to short-period orbits among the inner planets. The comparable Oort cloud fractions are 57, 14 and 3% for Uranus, Saturn and Jupiter, respectively. These efficiencies are considerably greater than the values of 2, 1.2, 0.5 and 0.2% for Neptune, Uranus, Saturn and Jupiter found by Safronov (1972). A portion of the disagreement can be attributed to Safronov's use of a much narrower capture range in orbital energy for the Oort cloud. Scaling Safronov's work to the same capture zone would lead to probabilities of 5.4, 3.2, 1.3, and 0.5%, still a factor of 6 to 17 less than those of Fernandez and Ip. The remaining disagreement may be due to other differences in the models. For example, Fernandez and Ip considered capture to short-period orbit to be an endstate, whereas in reality those comets continue to circulate and eventually will most likely be dynamically ejected.

Greenberg et al. (1984) constructed another model simulating accretion, and studied the problem of forming Neptune while simultaneously populating the Oort cloud. They found that the planet and comet cloud had to be built from a primordial population of relatively small bodies, ~ 4 to 8 km in radius. Larger initial sizes on the order of 100 km diameter did not lead to a sufficient number of comets in the Oort cloud. It is interesting to compare the resulting size distribution of icy planetesimals in Fig. 4 with the mass distribution for cometary nuclei found by Weissman (1991b), based on Everhart's intrinsic distribution of cometary magnitudes, corrected for observational selection effects. The two distributions have similar bimodal forms and slopes, with the size break occurring at nearly the same radius (~ 7 –8 km). It is notable that these two relatively independent approaches arrive at such similar mass distributions for cometary nuclei. Note that a substantial number of large comets are accreted, some up to 10^3 km in diameter or more. Stern (1991) also argued that a substantial number of icy bodies similar in size to Triton and Pluto may have accreted, and may be resident in the Oort cloud or may have been ejected to interstellar space. The accretional and collisional evolution of this population of large comets in the Uranus-Neptune zone, prior to their ejection to the Oort cloud, may provide for some degree of physical processing of the proto-comets. Fernandez (1980) also suggested that large comets, $\sim 10^3$ km diameter, were required to perturb comets out of the hypothetical ring of comets beyond the orbit of Neptune (see Kuiper belt discussion below).

Ejection of comets to large aphelion distances is not, by itself, sufficient to create the Oort cloud, because the comets will return to small perihelion distances where they can again be perturbed by the giant planets. However, Duncan et al. (1987) showed that comets with aphelia of ~ 5 to 6×10^3 AU would be sufficiently perturbed by galactic tides during a single orbit to

raise their perihelia out of the planetary region. In this manner, a large inner Oort cloud could be populated. Cometary orbits would continue to evolve in the cloud under the combined influence of stellar, GMC, and galactic tidal perturbations. The net effect of those perturbations is to pump angular momentum into the cloud, randomizing the inclinations of the comet orbits and further raising their perihelia. Duncan et al. showed that the Oort cloud would be essentially randomized at semimajor axes $> 8 \times 10^3$ AU. At semimajor axes $> 2 \times 10^4$ AU, typical perturbations by random passing stars and the galactic tide are sufficient to throw some comets back into the planetary region where they are observed as "dynamically new" comets.

Figure 4. Size distribution of accreted and disrupted planetesimals in the Uranus-Neptune zone after a simulated evolution of 1.4×10^5 yr, as modeled by Greenberg et al. (1984). The initial planetesimal size distribution, shown at upper left, was chosen to match the number and size distribution of observed comets. A runaway accretion results in the formation of Neptune, but also leaves a bimodal double-sloped spectrum of smaller-sized bodies which are the protocomets.

The dynamical problems associated with populating the Oort cloud from the outer planet region are eliminated if comets formed at Oort cloud distances, $\sim 10^3$ to 10^4 AU. One possible description of this process is provided by Hills (1982) and Hills and Sandford (1983*a,b*). They suggested that infalling,

low opacity dust clumps in the outer solar nebula experienced a net external radiation pressure which forced them to collapse, forming cometary nuclei. An important assumption in their study is that the Sun was a member of a star-forming cluster and that the dust clump experienced a roughly isotropic radiation field, forcing material in toward the center of the clump. Hills (1982) estimated that an initial clump with a radius of ~ 0.02 AU, a dust density of 4×10^{-20} g cm $^{-3}$, and a gas density of 2×10^{-18} g cm $^{-3}$, would collapse in about 400 yr, considerably less than the 5×10^3 yr needed for the clump to fall into the proto-Sun. The resulting comet nucleus would have a radius of 1 km and a mass of 4×10^{15} g. Hills and Sandford (1983*a, b*) showed that the radiation field need not be perfectly isotropic for collapse to proceed, but also that the radiation field from only two protostars would not focus material towards the center of the clump sufficiently for proto-comets to form.

Although this is an intriguing and novel idea that could explain the origin of some comets, several aspects must be explored before it can be regarded as robust. Unanswered questions include: what is the effect of turbulence in the nebula on the formation of irregular dust clumps? How efficient is the coupling between radiation and grains in this irregular field of objects, i.e., do clumps shadow one another? What is the total number of comets that could be formed by this mechanism and what is their subsequent interaction with the inner nebula? Late infalling clumps may be delayed by their own angular momentum and this may also prevent them from falling directly into the proto-Sun, but is it sufficient to prevent them from interacting gravitationally with the growing proto-planets? If not, they could be scattered to interstellar space just like the icy planetesimals formed in the inner nebular disk.

A somewhat different mechanism was proposed by Whipple and Lecar (1976) and developed by Bailey (1987). Whipple and Lecar suggested that a strong protosolar wind, akin to observed T Tauri winds, would produce a turbulent boundary layer between infalling nebular and outflowing protosolar material, and that material in this region would be driven into a thin circumstellar shell. Densities may be sufficient to allow rapid accretion of dust grains which are then sufficiently massive to de-couple from the gas motion. Local concentrations of dust grains may then collect and gravitationally collapse into cometary-sized bodies. In this manner, it may be possible to produce a large number of cometary bodies, either bound to the proto-Sun or circulating in nearby interstellar space. The problems with this scenario are similar to those of the previous one; the effects of turbulence, heating at shock boundaries, and subsequent dynamical evolution are not well understood or quantified.

If comets are formed in nearly circular orbits about the proto-Sun, then those in the region between roughly 10^2 and 2×10^3 AU experience no dynamical mechanism for being perturbed either into the planetary region or far enough outward to fall under the influence of perturbations by stellar and galactic tides. Thus, this population of comets would circulate indefinitely without ever producing visible comets. One possible means for increasing the semimajor axes of such orbits would be rapid loss of mass by the central

protostar and nebula (Cameron 1978*b*). In particular, if the mass loss is slightly less than 50% of the total central mass, nearly circular orbits are transformed into nearly parabolic ones, thereby populating the Oort cloud. However, the range of values for the mass loss that would produce this transformation is very narrow, and thus relatively unlikely. Dermott and Gold (1978) proposed a solution to this problem by suggesting that the loss of central mass in a number of smaller, repeated steps could pump up comets a bit at a time to Oort cloud distances. An important requirement is that the mass loss must be accomplished on a time scale long compared with the orbital periods of the planets, but short compared with the cometary periods. The required scenarios are probably too constraining to be physically plausible. Although mass ejection rates up to $10^{-5} M_{\odot} \text{ yr}^{-1}$ are observed in some T Tauri stars, the total integrated mass loss for solar-mass stars probably does not exceed $0.5 M_{\odot}$, or about one-third of the initial nebular mass.

The discussion so far has emphasized orbital dynamics as tests of theories of cometary origins, but these theories also have implications for the orbital histories of the major planets. Marochnik et al. (1988) estimated that the angular momentum of the Oort cloud is 0.5 to $2 \times 10^{53} \text{ g cm}^2 \text{ s}^{-1}$, 2 to 3 orders of magnitude greater than the total angular momentum of the current planetary system. They argued that had this angular momentum been ejected from the planetary system, the giant planets would have spiraled in toward the Sun. Thus, they suggested that comets must have formed *in situ* at Oort cloud distances. However, Weissman (1991*b*) showed that most of the angular momentum in the present-day Oort cloud resulted from the action of external perturbers over the history of the solar system. In addition, some Oort cloud parameters used by Marochnik et al. tend to be higher than current best estimates. Weissman showed that the total angular momentum of the current Oort cloud is probably in the range 0.6 to $1.1 \times 10^{51} \text{ g cm}^2 \text{ s}^{-1}$, and that the original angular momentum was perhaps a factor of 5 smaller. These more modest estimates are consistent with comets having been ejected from the Uranus-Neptune zone.

This point was also examined by Fernandez and Ip (1984) who modeled the exchange of angular momentum between the giant planets and the evolving protocomets. They showed that the giant planets scatter material both inward and outward, resulting in little net movement in the semimajor axes of the protoplanets. Jupiter is responsible for most of the hyperbolic ejection because it has no larger planet to which to pass the evolving comets, but because of its great mass, Jupiter only moves inward a few tenths of an AU.

C. Extra-Solar Oort Clouds and Interstellar Comets

Presumably, the same processes that led to the formation of our solar system's Oort cloud also occur around other forming stars. Because the expected dimensions of Oort clouds are so large, it may be possible to detect and resolve such comet clouds. One approach is to search for thermal radiation from dust grains, created by collisions and sputtering in the cloud. Stern et

al. (1991) analyzed IRAS 60 and 100 μm sky flux plates for 17 nearby stars with known infrared excesses (e.g., β Pictoris, ϵ Eridani). They searched for infrared excess emission in summed circular annuli at distances of several thousand AU from each star; however, no detections were made. They also showed that the expected brightness of Oort clouds with populations similar to our own was below the IRAS detection limits, because dust at Oort cloud distances will be very cold, and radiation pressure and collisions with interstellar dust and gas should rapidly sweep fine dust from the comet clouds (Stern 1990). Stern et al. (1990) also proposed searching for Oort clouds around red giant stars. These stars are sufficiently luminous that comets in their Kuiper belts (see short-period comet discussion below), if present, would be actively sublimating at rates comparable to the gas production rates of comets at 1 AU in our own solar system. Stern et al. suggested that observed OH/IR stars may be examples of this phenomena.

It is interesting to speculate on the fate of the many comets ejected to interstellar space in forming the Oort cloud, and over its history. Dynamical ejection is the most common loss mechanism for comets in the cloud, either due to close stellar and GMC encounters or as a result of Jovian perturbations during passes through the planetary system.

If other planetary systems exist and have generated Oort clouds in a similar fashion, then there should be a substantial population of comets in interstellar space, and our solar system should occasionally encounter these interstellar wanderers. However, no comet has ever been observed passing through the planetary system on a clearly interstellar trajectory. Sekanina (1976) showed that this fact sets an upper limit on the space density of interstellar comets of $6 \times 10^{-4} \text{ M}_{\odot} \text{ pc}^{-3}$ ($\sim 4 \times 10^{12}$ comets pc^{-3} , using Sekanina's mean nuclear mass of $3 \times 10^{17} \text{ g}$). For comparison, this is ~ 300 times smaller than the density of material in the solar neighborhood ($\sim 0.185 \text{ M}_{\odot} \text{ pc}^{-3}$; Bahcall 1984), so interstellar comets cannot contribute significantly to the "missing mass" problem in the Galaxy. It is about half the space density of comets in the outer Oort cloud, assuming a population of 10^{12} comets in a sphere of radius 10^5 AU centered on the Sun. Thus, the limit is not very strict.

The same problem was studied by McGlynn and Chapman (1989) who suggested that at least 6 interstellar comets should have been observed passing within 2 AU of the Sun in the past 150 yr, even after accounting for the fact that only 7% of all long-period comets passing within 2 AU are expected to be discovered. Their estimate was based on an average ejected population of 10^{14} comets per star, or $\sim 8 \times 10^{12}$ comets pc^{-3} . This is twice Sekanina's upper limit of 4×10^{12} comets pc^{-3} . The reason for this difference is not clear, though it may not be significant.

The above limits can be compared with the estimated space density of interstellar comets, derived by assuming that all stars produce cometary clouds. Dynamical models estimate that between 3 (Fernandez and Ip 1981) and 50 (Safronov 1972) times as many comets are ejected by the protoplanets

as are placed in the Oort cloud (though, as discussed above, Safronov's estimate is extreme because it assumes a too narrow range of semimajor axes for capture to the Oort cloud). Of the original population placed in the Oort cloud, one-half to two-thirds have been ejected over the history of the solar system. Thus, taking a nominal current Oort cloud population of 7×10^{12} comets, the solar system has ejected $\sim 4 \times 10^{13}$ to $\sim 10^{15}$ comets to interstellar space. Taking a mean volume per star in the solar neighborhood of $\sim 12 \text{ pc}^3$ (Allen 1976) and assuming that all stars produce comet clouds similar to our Oort cloud, the predicted space density is 3×10^{12} to 9×10^{13} comets pc^{-3} . This is 0.8 to 23 times the upper limit estimated from the absence of observed comets on interstellar trajectories (Sekanina 1976).

Because half of all stars form in multiple systems, and that process may prevent the formation of a protoplanetary disk leading to icy planetesimals (though that conjecture has not been demonstrated), the factor of 0.8 excess is probably not a problem. However, a factor of 23 excess is not consistent with the Oort cloud models and population estimates presented here, and thus represents a difference that clearly needs to be resolved. As noted above, at least a factor of 2.7 (and probably twice that) reduction can be obtained by assuming a wider range of Oort cloud semimajor axes than in Safronov's work. The remaining difference clearly merits further study.

D. Origin of Short-Period Comets

It has generally been thought that the SP comets are LP comets which have random-walked to orbits with small semimajor axes as a result of perturbations by Jupiter and the other planets. Capture of comets to short-period orbits in a single planetary encounter is highly unlikely (Newton 1893) and could not provide the observed number of SP comets. Planetary perturbations are larger for direct, low-inclination orbits and it was suggested that this acted as a selection mechanism for producing the direct, low-inclination SP comet population. However, evolution from an Oort cloud orbit to a short-period one would be expected to take approximately 400 returns (Weissman 1979), and it is most likely that a comet would be ejected over that time, or destroyed by one of several poorly understood physical mechanisms (e.g., disruption, sublimation). A variation which results in improved capture efficiency was proposed by Everhart (1972) who suggested that comets with perihelia among the outer planets random walk in $1/a$ without ever coming close to the Sun, and then are dumped into small perihelia orbits late in their dynamical evolution. In this manner, the SP comets can be spared some of the physical loss associated with solar heating or passage through the more densely populated regions of the planetary system. This also increases the planetary system's cross-section for capturing LP comets to SP orbits, thus more easily supplying the observed number of SP comets.

Estimates of the number of short-period comets produced by planetary perturbation from the Oort cloud have varied considerably (Joss 1973; Delsemme 1973), with some suggestion that the above mechanisms can not

produce the observed number of SP comets. An alternative suggested source of SP comets is a belt or ring of comets beyond the orbit of Neptune (cf. Fig. 1) (Kuiper 1951; Whipple 1964; Fernandez 1980). Dynamical injection from this source may be up to 300 times more efficient than repeated perturbation of LP comets from the Oort cloud. Fernandez (1980) pointed out that some massive comets, $\sim 10^2$ to 10^3 km in diameter, would be required in the distant comet ring, slowly perturbing other comets back into the planetary region and providing the SP comet flux.

Duncan et al. (1988) compared the two proposed sources and found that LP comets tended to preserve their inclinations as they evolved inward to SP orbits. Thus, if SP comets were initially LP comets from the Oort cloud, far more high inclination SP comet orbits would be expected. Duncan et al. (1988) showed that the observed distribution of inclinations was more consistent with a low-inclination trans-Neptunian population of comets as the source of the SP comets. They called this population the Kuiper belt in honor of Gerard Kuiper who first suggested its existence in 1951. Subsequently, Torbett (1989) showed that planetary perturbations would lead to chaotic motion in a disk of comets beyond Neptune, throwing those with perihelia near 30 AU into Neptune-crossing orbits in only 10^7 yr. However, Torbett and Smoluchowski (1990) showed that the motion would not be chaotic for Kuiper belt orbits with perihelia >45 AU. Levison (1991) confirmed this by studying the evolution of orbits with perihelia >30 AU and aphelia <100 AU, and showed that many can persist over the age of the solar system, in particular those with initially low-eccentricity orbits beyond 45 AU.

Stagg and Bailey (1989) and Bailey and Stagg (1990) raised a number of questions with regard to the Kuiper belt scenario. First, physical loss mechanisms might remove high inclination LP comets during their longer evolution inward from the Oort cloud to SP comet orbits (longer because of the smaller average perturbations for high inclination orbits), leading to a predominantly low-inclination population of observed SP comets. This would remove the objection raised by Duncan et al. (1988) to this source for the SP comets. Second, they suggested that the combination of LP comet evolution from the Oort cloud plus Kuiper belt might produce too many SP comets, and that this possibly implied a lower than estimated population for the Oort cloud or the Kuiper belt, or both. Finally, they noted that Duncan et al. (1988) had increased the planetary masses by a factor of 40 to speed the numerical integrations, a common technique in simulations of celestial mechanics but one that could lead to erroneous results. However, Quinn et al. (1990) repeated the integrations with the mass enhancement factor reduced to 10 and obtained identical results for the Kuiper belt comet evolution. In addition, Wetherill (1991) was able to recreate the same results with no mass enhancement, using a simpler Öpik-type integrator for simulating the evolution of cometary orbits.

Duncan et al. (1988) estimated that $0.02 M_{\oplus}$ (1.2×10^{26} g) of comets are required in the Kuiper belt to maintain the current population of SP comets. Duncan et al. used an average cometary mass of 3.2×10^{17} g, implying

a population of 3.8×10^8 objects. However, using the average mass of 3.8×10^{16} g noted above (Weissman 1991a), the same number of Kuiper belt comets would have a total mass of $\sim 0.0025 M_{\oplus}$, a factor of eight smaller.

Observational searches for Kuiper belt comets have so far been negative. Based on a search of 4.9 square degrees of sky near the ecliptic, Levison and Duncan (1990) set an upper limit of less than one object brighter than magnitude $V = 22.5$ per square degree. Magnitude $V = 22.5$ corresponds to a 60 km radius cometary nucleus with albedo of 0.05 at 50 AU from the Sun. This limit translates to $N \leq 10^{10}$ objects (total mass $\sim 3.8 \times 10^{26}$ g, or $\sim 0.06 M_{\oplus}$) if the Kuiper belt comets are in orbits between 35 and 60 AU from the Sun. Yeomans (1986) set an upper limit of $\sim 1 M_{\oplus}$ on the unknown mass just beyond the orbit of Neptune, based on the absence of observed gravitational perturbations on the orbit of comet Halley. An earlier limit of $5 M_{\oplus}$ was found by Anderson and Standish (1986) based on tracking of the Pioneer 10 spacecraft. Future tracking of the Voyager and Pioneer spacecraft can be expected to further refine these limits.

III. EVOLUTION OF COMETARY NUCLEI

A. Evolution of Comets in the Oort Cloud

Because the Oort cloud is cold, remote, and relatively sparsely populated, it was long believed to act as a perfect storage environment for comets. However, over the past decade several physical processes have been shown to modify the outer layers of cometary nuclei while they are in the cloud. These are: irradiation by high-energy photons and charged particles, heating by luminous passing stars and supernovae, erosive interactions with grains in the interstellar medium, and gardening by debris impacts within the Oort cloud. We review the effects of each process individually, and then comment on the net effects of these acting in concert.

Radiation Damage. Radiation bombardment of icy surfaces falls into two categories: photon bombardment and charged particle bombardment. We consider photon bombardment first.

Ultraviolet photons (i.e., $h\nu > 3$ eV) provide the energy necessary to initiate substantial chemical changes in cometary surfaces. In a classic series of laboratory experiments and theoretical studies, J. M. Greenberg showed that ultraviolet irradiation would produce significant alteration of the composition, color and volatility of icy mantles on silicate grains in the interstellar medium prior to their aggregation into cometary nuclei (cf. Greenberg 1982). Further work on the spectroscopic effects of ultraviolet irradiation of volatile ices was performed by Thompson et al. (1987), who demonstrated that ultraviolet photons induce chemical changes accompanied by surface darkening and color change (i.e., reddening). Such optical effects were shown to become progressively more severe with dose. The expected interaction depth of ultraviolet photons in a cometary surface is just a few optical depths, so the expected

processing damage is likely to be confined to the outermost layer, only a few tens to hundred atoms thick (1–10 nm).

More energetic X-ray photons from the galactic and cosmic background, and from nearby supernovae (Stern and Shull 1988) penetrate to greater depths, perhaps as deeply as 10 to 100 μm below the cometary surface. Ionizing radiation deposits ~ 30 to 35 eV for each ion electron pair produced, and much of this energy is dissipated thermally. For this reason, X-ray interactions could cause more extensive thermal and structural changes in the ice than ultraviolet photons. Because of the relatively small depths affected, photoprocessing is most important for pre-cometary ices, e.g., icy mantles on grains in dense molecular cloud cores or in the solar nebula, prior to accretion of cometary nuclei. A detailed discussion of such processing exceeds the scope of this chapter (see the Chapter by van Dishoeck et al.; see also Greenberg 1982; d'Hendecourt et al. 1986; Allamandola et al. 1988).

Charged particle radiation is capable of breaking bonds, inducing chemical reactions, and re-ordering or mechanically disturbing the ice matrix to much greater depths than ultraviolet and X-ray radiation (Strazzulla and Johnson 1991). The column density (g cm^{-2}) to which charged particles penetrate depends strongly on their energy, and to a lesser extent on the specific composition of the material. Low-energy solar protons of 1 to 300 keV penetrate only about 10^{-3} g cm^{-2} before being stopped. Cosmic-ray protons with typical energies of ~ 100 MeV penetrate about 1 g cm^{-2} ; while those with energies of 1 GeV penetrate 100 to 200 g cm^{-2} (Johnson et al. 1987; Strazzulla and Johnson 1991). Figure 5 illustrates the variation in energy dose with depth for the expected cosmic-ray fluence on comets (integrated over the age of the solar system). Because penetration depth is inversely proportional to the density of surface material, lower-density ices suffer damage to proportionately greater depth. If cometary surfaces are indeed low in density, then the radiation damaged crust may extend to many meters in depth.

Laboratory experiments simulating high-energy electron, proton and ion bombardment of cometary surfaces have been performed for over a decade now. In such experiments, keV to MeV accelerator beams have been used to irradiate various pure and aggregate mixtures of H_2O , CO_2 , NH_3 , SO_2 , S_2 and CH_4 frosts to fluences of 10^{12} to 10^{19} ions cm^{-2} . Such experiments (Moore et al. 1983; Johnson et al. 1984, 1985, 1987; Lanzerotti et al. 1987) have confirmed that cosmic-ray bombardment introduces important structural and chemical changes to these ices. The effects resulting from bombardment by higher-energy (GeV) cosmic rays are estimated by theoretical scaling, because the limited energy range of the accelerators used precludes direct measurement. In a recent detailed review of these effects, Strazzulla and Johnson (1991) report simultaneous increases in the porosity and density of proton- and ion-bombarded ices. Such bombardment also causes preferential breaking of hydrogen bonds, leading to the formation of C—C, C—N, C—S, C—O, S—O and S—S bonds. Free H atoms created by the bond-breaking irradiation migrate in the ice matrix to form substantial amounts of

Figure 5. Cosmic-ray energy deposition in H₂O vs depth for an exposure age of 4.5 Gyr. Upper curve: extracted from atmospheric data (see Strazzulla and Johnson 1991). Lower curve: sum of dose rates given by Moore (1981) and Ryan and Draganic (1986) (note difference from that in Johnson et al. [1987], based on Ryan and Draganic data which were plotted incorrectly). Dashed: extrapolation. The inset panel shows the fraction of chemical bonds altered by radiation processing vs depth (after Johnson 1989).

the extremely volatile H₂ molecule, and may initiate spin conversion in water and other symmetric molecules through exchange reactions (Johnson 1991). In addition, reactive molecular radicals are generated in the resulting matrix. The resulting surface layer loses its original chemical identity as new volatiles (e.g., S₂ from S₈, and CO from CO₂) and organic solids (with many CH₂,

CH_3 , C=O and C=C groups) are created. The similarity of some end products of these processes to exotic cometary material (e.g., S_2 , CHON grains and long chain hydrocarbons; see Sec. IV) has been noted.

Radiation processing experiments relevant to comets have also been conducted on refractory solids, including graphite, organics, amino acids and a number of commercial polymers (G. Strazzulla, personal communication; Caffee et al. 1988). Such materials have been subjected to both ion and ultraviolet irradiation; apparently, the effects of galactic cosmic rays on such materials have not been studied. The effects of such bombardment are that with increasing fluence, organic and refractory materials exhibit increasingly disordered structures, increased C/H, C/N and C/O ratios, and the loss or conversion of weakly bonded molecular volatiles such as NH_3 , H_2 and CO_2 (cf. Strazzulla, personal communication 1991; Foti et al. 1990). These changes in turn result in sample compaction, densification, spectral reddening, darkening, and then flattening in the 400 to 800 nm regime (Thompson et al. 1987; Andronico et al. 1987). As a result of these studies, it is clear that the nonvolatile component of cometary surfaces also undergoes substantial radiation-induced chemical and structural change in the Oort cloud. However, the depth of penetration of ion and ultraviolet radiation is small (millimeters, micrometers, respectively), and the evidence of such irradiation may not survive when comets are close enough to the Sun for study. As with ices, energetic cosmic rays should penetrate refractory solids 10 to 100 times more deeply than either ions or ultraviolet photons, and should induce substantial damage and chemical conversion in the refractory material.

For sufficiently cold environments, such as in the Oort cloud, the time required for radicals and most newly created volatiles to diffuse to the surface is so long as to be essentially infinite (with the exception of H_2). Therefore, the newly created species (excepting H_2) remain trapped in the ice-dust matrix until the comet is heated or the surface becomes otherwise exposed e.g., by erosional effects. The irreversible conversion of the original, water-dominated ice matrix to this more complex "crust" may lead to darkening and reddening of the optically active ice surface, by forming long-chain hydrocarbons. A nonvolatile surface crust may form, beginning the process of sealing off the nuclear surface against sublimation even before the onset of crustal development during perihelion passage (Brin and Mendis 1979). Further, the radicals and volatiles produced by radiation bombardment may be responsible for observed activity at large solar distances (i.e., 5–10 AU) during the approach of dynamically new comets to perihelion. However, other processes may mitigate the observable consequences of radiation damage.

Heating by Passing Stars and Supernovae. A second process which acts to modify cometary surfaces in the Oort cloud is heating by luminous stars and supernovae. It has long been recognized that passing stars regularly penetrate the Oort cloud (cf. Smoluchowski et al. 1986). This process results in the diffusion of comets from the inner cloud to the outer cloud, and the dynamical randomization of orbits in the outer cloud. Stern and Shull (1988) modeled

the implications of such encounters for the heating of comets in the cloud. They found that although several thousand encounters between stars and the Oort cloud should have occurred, the vast majority involved dwarf stars which are too faint to heat a significant fraction of the comets. Further, most comets heated by encounters with low-mass stars are gravitationally ejected from the cloud during the heating event. However, the rare encounters with luminous O and supergiant stars can heat the *entire* Oort cloud to interesting temperatures from distances so great that they do not substantially perturb orbits in the cloud. For example, a typical O star with luminosity $5 \times 10^5 L_{\odot}$ can heat the Oort cloud to 20 K from about a parsec (pc) away, but such a star would have to pass within a few thousand AU to eject comets from the cloud. Because vapor pressures vary exponentially with temperature, this thermal regime contrasts sharply with the ambient 5 to 6 K environment in the cloud. By combining the encounter rate of various stellar types with the influence of each stellar type on the Oort cloud, Stern and Shull showed that luminous passing stars have probably caused all comets to undergo at least one long (i.e., $\sim 3 \times 10^4$ yr) heating episode to 19 to 22 K.

Stern and Shull also estimated the effects of nearby supernovae on Oort cloud heating. Because supernovae are so much more luminous than even the brightest main-sequence stars, a typical supernova exploding at 19 pc can raise surface temperatures on comets to 30 K. Using supernova luminosity and formation-rate statistics (Tammann 1982; Narayan 1987), it was found that ~ 30 supernova heating events to 30 K should have occurred since the formation of the Oort cloud, that there is a high probability that the Oort cloud should have experienced one supernova heating event to 50 K, and that there is a 50% probability of a supernova heating event to 60 K over the age of the solar system. Figure 6 summarizes these results. Temperatures in the range 20 to 60 K can induce potentially important effects on cometary surfaces in the Oort cloud; these include mechanical stresses, porosity/densification changes, and the sublimation of highly volatile trace constituents (e.g., S_2 , Ne, Ar, CO, N_2 and CH_4) from the surface. Table II gives additional information on important thermal milestones in this temperature regime.

The depth of penetration of the thermal wave resulting from a stellar or supernova encounter is determined from the diffusion equation, and is based on the diffusivity of the surface ice, the relative orientation of the cometary rotation pole to the encounter plane, and the duration of the encounter. The major uncertainty here is the actual diffusivity of the surface ice, which depends on its composition, porosity and crystal state (i.e., amorphous or crystalline). Adopting a range of surface diffusivities consistent with conductivity measurements on water ice (Klinger 1985), Stern and Shull estimated that the thermal wave of a typical, O star encounter (lasting 3×10^4 yr) could penetrate as far as 150 m into the comet, but is more likely to lie in the range 7 to 50 m. Because their model shows that all comets have unit probability of being heated by passing stars to temperatures ~ 19 to 22 K, one expects the outer layers of all Oort cloud comets to have been heat soaked at these

Figure 6. The number of times a typical comet in the Oort cloud was warmed to a global average temperature (T_e), by supernovae and by stellar transients (cf. Stern and Shull 1988). A cometary surface albedo of 0.04 and emissivity of 0.9 was assumed. Heating by stellar transients is dominated by rare, O-star events. Though less severe in thermal magnitude than supernovae events, the stellar transients last much longer ($\sim 10^4$ yr vs ~ 0.1 yr for supernovae), causing the thermal wave to penetrate several hundred times deeper (after Stern 1989).

temperatures for many centuries. Supernova encounters, while generating a stronger thermal pulse, are much briefer ($\sim 10^7$ s), therefore their thermal effects are estimated to propagate only 0.1 to 2 m into the surface. These heating effects may play an important role in the behavior of "new" comets as they approach the Sun.

Interactions with the Interstellar Medium. The first study of the interaction between comets and the interstellar medium was made by O'Dell (1973), who investigated the accretion of interstellar gas onto cometary surfaces. He found that a layer 10 to 100 mm thick should be accumulated over an interval of 4.5 Gyr. Whipple (1977) speculated that this layer of interstellar volatiles accounted for the anomalous brightness of dynamically new comets on their first pass through the planetary region. However, it now appears that O'Dell's analysis was too simple, leaving out the important effects of impacts by interstellar grains on cometary surfaces. Stern (1986) investigated the competition

TABLE II
Critical Temperatures and Processes in Laboratory
Analogues of Cometary Ices

Temperature (K)	Process
5–6	Ambient Oort cloud temperatures.
6–20	Maximum temperature at 10^4 AU in solar nebula (Cassen and Boss 1988).
16	Neon sublimates (Greenberg 1982).
17–26	Irradiated ices display luminescence (Moore et al. 1983).
25	All neon trapped in water clathrates is expelled.
27	“Yellow stuff” explodes on rapid heating (seconds), or slow warming as a chain reaction in radical chemistry (Greenberg 1986).
31	Argon sublimates (Bar-Nun et al. 1985).
40	Heavy cracking, whitening of mixed water ice (Bar-Nun et al. 1985).
40	Formation of formaldehyde (H_2CO) and formamide (NH_2HCO) (Greenberg et al. 1980).
57	H_2S sublimates.
60	Temperature in Uranus-Neptune zone of solar nebula.
70	40 m s^{-1} grain impact produces spikes to this temperature (Greenberg 1986; d’Hendecourt 1980).
125–150	Exothermic phase transition (to crystalline form) occurs in amorphous water ice. Excess trapped gases are released.
160–170	Water ice sublimation rates become significant.

between grain-driven erosion and gas-driven accretion. Based on laboratory studies of micro-cratering in ices and snows with porosities ranging from 0.01 to 1 (cf. Cintala 1981; Croft 1982*b*; Lange and Ahrens 1987), Stern demonstrated that grain-driven erosion on icy surfaces is some 700 to 1000 times more efficient than gas accretion, causing comets to actually lose material due to interstellar medium interactions. The primary reason for this large erosion-to-sticking ratio is that gas sticking is inefficient (typical sticking ratios of gases being a few percent), while energetic impacts of grains (at typical relative velocities of 20 km s^{-1}) cause much more material to be lost from the cometary surface than the original mass of the impacting grain. Lissauer and Griffith (1989) found similar results in a study of the source mechanisms of fine dust in β Pictoris type stellar disks.

A more recent and comprehensive study by Stern (1990) included four interaction processes: grain erosion, accretion due to molecular sticking, gas sputtering, and thermal evaporation due to grain impacts. This study employed

Figure 7. The modeled mass-loss rate from surfaces in the Oort cloud. The model assumes a random sequence of encounters with the four interstellar medium phases. The total amount of time spent in each phase is proportional to their galactic filling factors. Atomic and molecular cloud encounters typically last 2 to 10×10^5 yr. The depicted encounters have been exaggerated in width by a factor of 10 for readability. Cloud encounters actually occupy only $\sim 3\%$ of the total elapsed time.

a detailed model of the various phases of the interstellar medium, as well as the evolution of the Sun's velocity relative to that medium over time. The results of one such simulation, which assumed erosion on H_2O ice and a constant solar velocity (20 km s^{-1}), are shown in Fig. 7. Owing primarily to strong density gradients between cloud and inter-cloud phases in the interstellar medium, interstellar medium interactions act in a highly time-dependent way. Their cumulative effect causes comets in the Oort cloud to lose 60 to 600 g cm^{-2} of surface material over 4.5 Gyr (Fig. 8). Due to correlations in the location of coronal-phase parcels, the Sun will spend long periods in this rarefied, essentially dust-free environment. During these periods, the erosion rate is reduced to very low levels. Stern's analysis of the typical ejection velocity of eroded material indicates that debris lost from comets in the Kuiper belt does not directly escape the solar system. However, most debris from comets in the inner and outer Oort clouds is injected directly into the interstellar medium, thereby opening up an interesting (if minor) mass and chemical feedback between Oort clouds and the interstellar medium (Stern and Shull 1990).

Collisions in the Oort Cloud. Collisional interaction of comets with small debris in the Oort cloud was first identified as an important process by Stern (1988). A simple particle-in-a-box model was used, and both number density gradients in the cloud and debris feedback to the population were ignored. Power-law distributions with both constant area and constant mass per bin

Figure 8. The time-integrated mass loss experienced by cometary nuclei and other debris in the Oort cloud, from the model of Fig. 7 (after Stern 1990).

were found to produce frequent collisions between comets and small debris bodies (up to 10 m in size) in the inner Oort cloud. The rate of collisions in the outer Oort cloud was found to be much lower. Comet-on-comet collisions were found to be rare throughout the cloud, with an upper limit of perhaps one comet in 10^4 having suffered a catastrophic collision over the age of the solar system. The amount of ejecta produced by comet-on-comet collisions over 4.5 Gyr was evaluated in simulations which started with no objects smaller than ~ 3 km. Such collisions cannot generate enough debris to create either constant area or constant mass per bin population distributions. Stern also found that debris created from collisions in the Oort cloud will not be energetic enough to escape directly to interstellar space but will instead enhance the population of small-sized bodies in the cloud.

Based on these results, Stern (1989) constructed a more complete time-dependent feedback model, with radial gradients for the Oort cloud in both density and velocity. This model included the weathering destruction of small (centimeter to meter class) debris by interstellar medium erosion, the loss of dust from the Oort cloud via interstellar medium-induced gas drag, and the feedback of collisional debris to the Oort cloud population distribution. Dust loss is important because it cleanses the Oort cloud of grains created through high-velocity impacts. However, radial transport of ejecta within the cloud was neglected, i.e., each macroscopic ejected body was assumed trapped in

the (several thousand AU-wide) distance bin in which it had been created.

This model was evaluated for Oort cloud masses ranging from 10 to $10^3 M_{\oplus}$, and for initial population distributions featuring constant area per bin, constant mass per bin, and collisional equilibrium. It was found that collisions do provide an important feedback mechanism for the production of small debris in the cloud, but erosion and drag by the interstellar medium prevent the population of small ejecta from growing without bound. Indeed, by rapidly removing the very numerous centimeter-to-meter-sized bodies that may have initially populated the cloud, erosion and drag act to severely truncate the collision rate within a few hundred Myr after the formation of the cloud. This in turn implies that present-day impact rates throughout the cloud are very low. Modeled estimates of the surface cratering fraction on comets indicate that regolith development can take place in the inner Oort cloud only if: (1) the inner reservoir is massive ($>10^2 M_{\oplus}$); and (2) the number of objects of <30 m size was initially large compared to the comet population itself. The predicted gardened depths are several centimeters to tens-of-centimeters. However, in the denser, inner portions of the Oort cloud, and in the Kuiper belt, the potential exists for significant cometary regolith development over time. This suggests that short- and long-period comets may experience differing degrees of collisional modification while in storage, if they do originate from different parts of the comet cloud.

B. Cometary Processing in the Planetary Region

When cometary nuclei return to the planetary region, their physical evolution is dominated by the heating they receive from direct solar radiation. Other processes such as irradiation by solar-wind protons and impacts by interplanetary dust particles will also intensify, but these are much less significant than solar heating in terms of both mass removal and depth of penetration. Meech (1991) has recently reviewed observational evidence for physical aging in comets.

The effects of heating will manifest themselves in several ways. On a comet's first approach to the Sun, the first effect to occur will be conversion of amorphous water ice to the crystalline form. The amorphous-crystalline phase transition occurs at ~ 140 K. Prialnik and Bar-Nun (1987) showed that the slow heating of the surface of an amorphous ice nucleus, presumably formed at low temperature, <100 K, would cause a transition to crystalline ice at about 5 AU inbound on the first perihelion passage. Because this reaction is exothermic, an additional heat pulse would propagate inward, converting a layer 10 to 15 m thick to crystalline ice. Prialnik and Bar-Nun showed that a chain reaction converting the entire nucleus to crystalline ice does not occur, because the pulse is eventually dissipated as it reaches colder ice layers at greater depths, and by warming of nonvolatile dust mixed with the ice. The amorphous-crystalline ice transition may supply sufficient energy to blow off pieces of the primitive irradiated crust, resulting in the anomalously bright behavior at large solar distance often displayed by dynamically new comets.

After the first perihelion passage inside 5 AU, the amorphous-crystalline transition is predicted not to repeat for several orbits, until a sufficiently thick layer of the overlying crystalline ice has sublimated and the orbital heat pulse can penetrate to the buried amorphous core. Using a more detailed model, which included the effect of a nonvolatile dust crust on the nuclear surface (see below), Prialnik and Bar-Nun (1988) found that the thickness of the crystalline ice layer overlying the amorphous ice was at least ~ 15 m, and was often much thicker, ~ 25 to 40 m.

The second insolation-related process is the sublimation of volatile ices at the nuclear surface, which results in the development of the extended cometary atmosphere, the coma. The evolving gases will entrain solid grains of dust and ice, creating the dust coma and (perhaps) an ice/hydrocarbon halo around the nucleus. Larger grains of nonvolatile materials not entrained by the escaping gas will begin to form a lag deposit on the nuclear surface, accumulating to form a crust that will begin to seal the nucleus against further mass loss and to insulate thermally the layers below it (Brin and Mendis 1979; Prialnik and Bar-Nun 1988).

There are thus two processes likely to contribute to formation of a non-volatile crust. The comet may retain some or all of its original cosmic-ray-irradiated crust, and this may serve as the foundation for additional crustal growth. Or, debris gardening and the energy release from the amorphous-crystalline ice phase transition may blow away all of the primitive crust, and the comet may then grow a new lag deposit of heavy nonvolatile grains, possibly "glued" together by complex organics. A variety of models have been developed to study crustal growth on cometary nuclei. Calculations have shown that a nonvolatile layer only 1 or 2 cm thick would probably be sufficient to insulate the ices below and to reduce greatly the sublimation rate (Brin and Mendis 1979; Fanale and Salvail 1984; Horanyi et al. 1984). Estimates of the number of perihelion returns required to form the crust range from ~ 1 to 20. Various workers have proposed that the crust is either porous, allowing continued gas diffusion through it to the surface, or that it is sealed, resulting in a buildup of pressure beneath it that might cause violent rupture events.

Violent rupture of the crust due to the pressure of evolving gases below it may result in visible outbursts or even a disruption of the nucleus. Further heating of amorphous ice within the nucleus will result in sporadic transitions to crystalline ice, also possibly resulting in visible outbursts. Thermal stresses on the nucleus caused by substantial temperature gradients within the ice may also result in cracking and exposure of "fresh" ices, and possibly outburst or disruption phenomena. The outburst of comet Halley near 14.3 AU post-perihelion (West et al. 1991) may be related to such processes. More subtle effects will include the migration of highly volatile molecules, both outward through the still frozen water ice matrix, and inward towards cooler regions of the nucleus where they will recondense (cf. Espinasse et al. 1991).

As mass is lost from the rotating nucleus, its moments of inertia will

change and the nucleus will precess, changing the orientation of the rotation pole and the balance of insolation across the nuclear surface, with perhaps additional interesting implications. For example, the changing axis orientation will change the rotational stresses, perhaps causing the break off of weakly bonded nuclear fragments and their appearance as secondary nuclei. However, the reasons for cometary splitting are still largely unknown (see Sekanina 1982).

The most important factor in modifying cometary material at depth is the heating of the cometary nucleus. The thermal skin depth δ is defined as

$$\delta = (KP / \pi \rho C)^{1/2} \quad (1)$$

where K is the conductivity, P is the period (rotation period for diurnal skin depth, orbital period for orbital skin depth), ρ is the density, and C is the specific heat. The thermal skin depth is the distance over which a temperature perturbation at the surface will decrease by a factor of $1/e$, upon diffusing into the nucleus. For conductivities typical of solid, crystalline water ice, $\delta = 0.2$ m for a rotation period of 24 hr, or 9.2 m for an orbital period of 6 yr. However, conductivity decreases sharply for porous, low-density structures such as are suspected for cometary nuclei, and actual values of δ may be considerably smaller. Most measured values of surface thermal conductivity in the solar system, including the icy Galilean satellites, are extremely low (though these are usually due to gravitationally bound regoliths which may not be present on comets). If comets are similar, then a more realistic estimate of the orbital thermal skin depth may be only a few centimeters. The detailed thermal/physical properties of the cometary nucleus constitute an important area of future research.

The internal temperature profiles for cometary nuclei are complex functions of their orbital parameters, the obliquities of their rotation poles, and the thermal properties of their surface materials. For example, the variation of temperature with depth for a 1 km radius comet nucleus in an orbit like that of P/Encke, ignoring the diurnal temperature cycle and assuming solid crystalline ice, is shown in Fig. 9 for four points around the comet's orbit (Herman and Weissman 1987). Although the surface layer undergoes extreme temperature variations, the temperature is virtually constant at depths greater than several orbital thermal skin depths. Below this depth, the nucleus is heated to its average orbital temperature, but not appreciably higher.

Temperature profiles for real nuclei may not be as smooth as shown in Fig. 9. Because of the low thermal conductivities expected for cometary nuclei, many hundreds of returns (or more) will be required for a comet to be warmed to its equilibrium internal temperature. The comet's orbit is likely to change significantly over that same period of time and, as the changes are essentially random, some will result in additional internal heating, while others will result in a net cooling of the cometary nucleus. The final result might be a fairly complex interweaving of warm and cooler layers. Nevertheless, the

Figure 9. Equilibrium temperature profiles in the near surface layers of a hypothetical (1 km radius) crystalline ice nucleus in a short-period orbit, for four points around the orbit (after Herman and Weissman 1987).

equilibrium internal temperature of cometary nuclei can be approximated to within $\pm 10\%$ by the mean temperature (T_m) for a nucleus in a circular orbit with the same semimajor axis. T_m is given by

$$T_m = 280 (1 - A)^{1/4} a^{-1/2} \epsilon^{-1/4} K \quad (2)$$

where A is the Bond albedo of the nuclear surface, a is the semimajor axis in AU, and ϵ is the surface emissivity. For comets in noncircular orbits the problem cannot be solved analytically, so numerical techniques must be employed. The intense solar heating near perihelion and increased time for cooling near aphelion, as well as the temperature dependence of the thermal conductivity, lead to a complex behavior of the central temperature as a function of semimajor axis and eccentricity. That behavior is illustrated in Fig. 10 for the case of a (1 km radius) crystalline ice nucleus (Herman and Weissman 1987) where the "normalized temperature" is the calculated central temperature divided by the mean temperature from Eq. (2).

The final central temperature reached by the nucleus is also a function of the thermal conductivity, but is not a function of the nuclear radius (Herman and Weissman 1987). Lower values of thermal conductivity lead to slower heating, and suppress the variations in the central temperatures with orbital eccentricity shown in Fig. 10, giving values even closer to the mean temperature calculated with Eq. (2). Weissman (1987) estimated that the thermal

Figure 10. Variation of central temperature for short-period comets as a function of orbital semimajor axis and eccentricity. The normalized temperature is that for a comet in a circular orbit given by Eq. (2) (after Herman and Weissman 1987).

inertia of the surface ices in comet Halley (1986 III) was about a factor of 10 less than that for solid water ice, based on the turn-on of the Halley coma at 5.8 AU inbound.

The thermal inertia I is given by: $I = (K\rho C)^{1/2}$, where K is the thermal conductivity, ρ is the bulk density, and C is the specific heat. If the cometary surface is a low-density, porous ice structure then low thermal conductivities are expected. Weissman (1987) found $I = 3 \times 10^{-3} \text{ cal cm}^{-2} \text{ s}^{-1/2} \text{ K}^{-1}$, somewhat larger than that for the Moon but not very different from that found for the surfaces of the icy Galilean satellites (Morrison 1977). Low values of the conductivity and/or large nuclear radii lead to very slow internal heating that may take hundreds or thousands of orbits to reach equilibrium, much longer than the time scale for major dynamical changes in the cometary orbits.

As a result of this internal warming, volatile ices with sublimation points below the central temperature could diffuse through the icy matrix and possibly escape the nucleus, unless they are trapped (e.g., as clathrate hydrates).

TABLE III
Estimated Central Temperatures for Several Short-Period Comets^a

Comet	q (AU)	P (yr)	T_c (K)	T'_c (K)
Encke	0.341	3.30	171.0	183.4
Honda-Mrkos-Pajdusakova	0.581	5.28	149.8	154.9
Tempel 2	1.381	5.29	150.8	156.9
Wild 2	1.491	6.17	144.7	148.9
D'Arrest	1.291	6.38	141.9	146.1
Kopff	1.572	6.43	143.4	147.0
Churyumov-Gerasimenko	1.298	6.59	140.8	145.2
Halley	0.587	76.10	67.8 ^b	68.7 ^b

^a Table from Herman and Weissman (1987). T_c includes water ice sublimation; T'_c neglects sublimation of water ice.

^b P/Halley is the only comet (of those tabulated) whose central temperature likely remains low enough to retain amorphous ice in its interior.

The near-surface layers may well be depleted in many of the more volatile ices. As a result, gas production rates (relative to water) for some volatile species may show a temporal dependence: as the comet approaches perihelion, the more volatile ices may not appear until the thermal wave has penetrated deeply enough into the nucleus to reach undepleted layers. In addition, some deeper layers in the nucleus may be enriched in certain volatiles which were sublimated from the warm near-surface layers, diffused into the cooler interior, and recondensed there. Espinasse et al. (1991) have discussed these and other aspects in some detail.

Calculated central temperatures for 8 well-known SP comets, most of which are possible targets for comet rendezvous and/or sample return missions, are given in Table III. The quantity T_c is the equilibrium central temperature for the comet's present orbit, assuming normal water ice sublimation over the entire nuclear surface. T'_c is the central temperature assuming no sublimation, a condition the comet would evolve to as it develops a non-volatile crust covering the nuclear surface. With the exception of P/Halley, all the short-period comets in Table III have a central temperature above 140 K, the transition temperature for amorphous to crystalline water ice. Thus, it is highly unlikely that any sample of nuclear ice returned from such a comet will be in the amorphous form. If so, this certainly would represent a major departure from the state in which the comet formed. For a low-albedo nucleus, Eq. (2) gives a central temperature of 140 K at a semimajor axis of 4.0 AU, or an orbital period of 8.0 yr. Of 155 known periodic comets in the most recent catalog (Marsden 1989), 91 have periods less than that value. Thus, those comets can be expected to have completely converted to crystalline ice in their interiors.

For comets with longer orbital periods, and for those comets recently

arrived in the inner planets region, a sizeable fraction of the nuclear interior can still be expected to be amorphous ice (provided that the comet has not been significantly closer to the Sun in the past). However, according to Prialnik and Bar-Nun (1988), the amorphous ice is located at depths greater than 15 to 40 m beneath the surface.

The results of the spacecraft flybys of comet Halley have produced strong evidence for the existence of an insulating crust on the nuclear surface (Sagdeev et al. 1986), but at the same time have presented us with several apparent paradoxes. The fraction of active area on the nucleus of the comet has been estimated at 20 to 30% of the sunlit surface, based on spacecraft imaging and measurements of the gas production rate (Weissman 1987; Keller 1990). However, it is not clear why such a small fraction of the Halley nucleus is active. Virtually all predictions for Halley were that the nuclear surface would be crust-free, the crust having been blown away by the high gas flux.

Given that 70 to 80% of the nuclear surface was crusted over (cf. Keller 1990), why was it not 100%? Did the few active areas serve as pressure release points for the entire nucleus, implying a highly porous nuclear structure? Did the active areas change as the comet moved along its orbit, or from one perihelion passage to another? Earth-based observations of the comet suggested that the active areas did turn on and off irregularly, and Giotto imaging suggested at least one surface structure that may be a crusted over, formerly active area. On the other hand, some observers alleged a link between active areas observed in 1985–86 and locations of active areas derived from observations in 1910 (Sekanina and Larson 1986), a very tenuous possibility which is exceedingly difficult to prove.

A further question is whether or not the allegedly inactive areas on the Halley nucleus were really inactive. Clearly, the sources of the dust jets appear to be confined to relatively small areas. Is it possible that gas from subliming ices diffuses through the dark porous crust in other areas, while being unable to carry entrained dust with it?

Examination of the total mass lost from Halley on its recent apparition gives another interesting result. Feldman et al. (1987) estimated a total loss of water of 3×10^{14} g, based on IUE observations during the 1986 perihelion passage. Assuming that H_2O represented 80% of the volatiles by mass, and taking a dust:gas ratio of 2, the total mass loss was 1.1×10^{15} g. Given a total surface area of 400 km^2 (Keller et al. 1987; Keller 1990) with 30% of it active, and a mean density of 1.0 g cm^{-3} , then the excavated depth at each active area is ~ 10 m. The IUE-based estimate for the total water lost is almost twice Weissman and Kieffer's (1981) prediction of 1.7×10^{14} g for the total H_2O that could be sublimed from the Halley nucleus (scaled to the Halley dimensions and albedo obtained from the spacecraft encounters). Scaling this estimate in a fashion similar to the IUE results, the predicted total mass loss would be $\sim 6.4 \times 10^{14}$ g, and the excavated depth would be ~ 5 m. The difference may best reflect uncertainties in both the observational measurements and the theoretical model.

Giotto imaging of the Halley nucleus did not resolve the active areas, suggesting that they are <100 m in size. But if the dimensions of the active areas are comparable to the depths above, then shadowing by the crater walls will quickly reduce the total sublimation. How then does the sublimation process not become self-limiting, particularly over repeated perihelion passages?

Another piece of this complex puzzle comes from estimates of nongravitational forces on the motion of comet Halley. The highly elongated nucleus seen in the spacecraft imaging, with its irregular and asymmetrically distributed active areas, would be expected to precess rapidly. But the fitted nongravitational forces on the comet have been virtually constant over the past 2200 yr (Yeomans and Kiang 1981). How then can the nongravitational forces be so constant when the nucleus appears to be so dynamic and ever changing?

A final area of interest here is that of thermo/mechanical stresses on cometary nuclei (Kührt 1984; Green 1986; Tauber and Kührt 1987). The dust jets in the Halley spacecraft images appear to be highly collimated, and appear to occur along linear features (Sagdeev et al. 1987). This suggests deep crevices opened up by stresses on the nucleus, or perhaps freshly exposed voids in a fractal structure. These crevices may penetrate sufficiently deeply into the nucleus to reach relatively unmodified volatile-rich layers, several thermal skin depths below the crusted surface. They also may be the best sites for obtaining samples of the cometary nucleus. However, little is known yet about thermal stresses and researchers in this area cannot even agree on whether the stresses are due to tension or compression. More work in this area is clearly needed.

IV. MEASUREMENTS OF COMETARY COMPOSITION

Theories of cometary origin and evolution can only be tested and refined if the composition and structure of cometary nuclei are measured. Having done so, we may obtain improved insight into processes affecting formation in the early solar system. Until recently, most of our knowledge of cometary composition was obtained indirectly, from studies of decomposition products of the directly sublimed volatiles, and of the dust (cf. Delsemme 1982). Of the 20-some proposed parent volatiles, only two (CO and S_2) had been detected directly before 1985. Even these were problematic, since CO is also a daughter product (e.g., of CO_2) and S_2 may not be original cometary material.

Beginning in 1985, however, a revolution occurred in our knowledge of cometary composition, driven primarily by new capabilities for remote sensing at infrared and millimeter wavelengths, and by *in-situ* investigations carried out with the fleet of spacecraft that visited comet Halley. Together, these provided direct compositional measurements of parent volatiles and dust, a macroscopic view of nuclear properties, and improved knowledge of the physical parameters of the cometary coma. Substantial new insights were gained into the properties of the nucleus itself and the asymmetry of gas

production and outflow from it, and into such coma properties as distributed sources for "parent molecules," the ionization state, bulk outflow and thermal velocities, and rotational and kinetic temperatures. The combined results provided the best picture to date of the true nature of the cometary nucleus. In this section, we review insights gained through *in situ* investigations of comet Halley, and through remote observations of P/Halley and other recent comets, and we discuss important aspects of their nuclear compositions and structure.

A. Cometary Dust: Organics and Silicates

Considering the many pre-solar organic and silicate compounds that could be present in comets (cf. Turner 1989c) and their possible role in initiating pre-biotic organic chemistry on the early Earth (cf. Marcus and Olsen 1991), it is vital to identify those that are actually present. Two of the major surprises in the exploration of comet Halley were the discovery of a new population of grains, composed of carbon, hydrogen, oxygen and nitrogen (called CHON), and the discovery of a new cometary emission feature extending from 3.2 to 3.5 μm . The C-H stretching bands of many organic compounds fall within this wavelength range, and an immediate qualitative connection was made between these two discoveries, extending even to labeling the latter the "organic grain" feature. Both condensed and gaseous hydrocarbon species could contribute to the emission feature, however, and the nature of the progenitors is still uncertain. This spectral region has received intense scrutiny in recent comets, and it is now recognized that while some of the feature is probably contributed by thermal emission from grains, a significant part is due to emission from gaseous species, including methanol (see later discussion). We shall use the term "cometary organic feature" to refer to this new emission, because it originates from both condensed- and gas-phase material.

The composition of cometary dust was addressed by the Particle Impact Analyzer instruments, called PIA on Giotto, and PUMA on Vega 1 and 2. The principal findings have been reviewed recently by Jessberger and Kissel (1991) (also see McDonnell et al. 1991). The PIA/PUMA instruments measured elemental compositions by permitting dust particles to hit a clean target surface (Ag, or Ag-doped Pt), then conducting mass analysis by time-of-flight spectroscopy (see Kissel 1986). Two different chemical end-types were found: an organic phase (CHON) and a Mg-rich silicate phase. The CHON material contributed $\sim 30\%$ of the total mass of the measured particles, which were individually in the range 10^{-16} to 10^{-11} g. About one-third of the measured grains contained no significant organic component, and the remainder were mixtures of the two phases. The pure silicate particles were more heavily represented in the lower mass ranges.

From energy discrimination measurements on the mixed-phase particles, it was found that the CHON elements were produced with significantly higher kinetic energy than were the silicate elements. Krueger and Kissel (1987) inferred a grain structure in which the organic component coats a silicate core. The CHON ions from the refractory organic would leave the impact site

with higher initial energies (up to 150 eV) on average than would ions of the silicate cores (Jessberger et al. 1987). This would seem to confirm Greenberg's model of core/mantle interstellar grains for cometary dust (Greenberg 1982). However, this model is clearly not valid for all cometary grains, because some contained no significant organic material (Jessberger and Kissel 1991). Brownlee and Kissel (1990) have commented that "to state that Halley is actually composed of interstellar grains, all having core/mantle structure, would be a gross over-interpretation." Nevertheless, the discovery of bimodal grain types demonstrates that the refractory component of comets is disequilibrated. Indeed, the pristine nature of the dust in comet Halley is demonstrated by a lack of equilibrium among the grains, as revealed by their diverse chemical, isotopic, and elemental compositions.

The retrieved densities were $\sim 2.5 \text{ g cm}^{-3}$ for the silicates, and $\sim 1 \text{ g cm}^{-3}$ for the mixed particles (Maas et al. 1990). These densities are in the approximate ratio of their constituent (atomic) masses, suggesting that the two grain types are comparably compact. However, if the entire intensity of the cometary organic infrared emission feature was assigned to completely filled CHON grains, the implied dust fluences would exceed the measured value by orders of magnitude (see discussion in McDonnell et al. 1991). Greenberg and Hage (1990) argue that this discrepancy can be resolved if the dust particles are fluffy, with a porosity of $p = 0.97$. Effectively this increases the surface area, while keeping the particle mass unchanged. However, if volatiles contribute significantly to the cometary organics feature, as now seems to be so, this porosity factor would need downward revision. This is in the direction needed to resolve the apparent discrepancy in density implied by the infrared and the PIA/PUMA results.

Elemental abundances in the dust were retrieved by Jessberger et al. (1988) and revised abundances are reviewed by Jessberger and Kissel (1991) (Table IV). The dust is far more enriched in H, C and N than even the most primitive meteoritic material, the CI-chondrites. Thus the dust in comet Halley is the most primitive material ever sampled. The O/C ratio in the gas is ~ 5.9 , while in the dust it is ~ 1.1 , and if the total C/Mg and O/Mg are forced to fit the solar value, then an estimate of the dust/gas ratio can be obtained. The required ratio is 1.7 (Jessberger and Kissel 1991). In deriving this estimate, the average composition of the small grains sampled by PIA/PUMA was assumed to be representative of the mean dust in comet Halley. In this case, H and N are depleted in Halley, by factors of 650 and 3 relative to solar abundances, while all other elements are present in solar abundance, to within a factor of 2 (Table IV). A third possible exception is the Fe/Si ratio, which appears to be low in comet Halley. The discovery that a major portion of cometary carbon is locked in the dust has resolved the "missing carbon" problem, discussed by Delsemme (1982).

A note of caution should be introduced, though. The PIA/PUMA instruments sampled the smallest grains acquired during the spacecraft encounters. The sampled grains, if spherical (and of zero porosity), would have diameters

TABLE IV
Average Elemental Abundances in Comet Halley^a

Element	Halley		Solar System ^b	CI-Chondrites ^b
	Dust	Dust and Ice		
H	2,025	4,062	2.6×10^6	492
C	814	1,010	940	70.5

Co	0.3	0.3	0.21	0.21
Ni	4.1	4.1	4.59	4.59

^a Table after Jessberger and Kissel 1991.

^b All abundances are by number, not by mass. The solar photospheric abundances of the listed elements are practically indistinguishable from the solar-system abundances, with the exception of Fe, which has a photospheric abundance ratio of 123 (Anders and Grevesse 1989).

in the range 0.06 to 3 μm . Grains in this size range represent only a tiny fraction of the total dust mass, however, given the overall mass distribution function (cf. McDonnell et al. 1991). Grains as massive as $\sim 10^{-4}$ g were measured by DIDSY (dusty impact detection system), and perturbations in the Giotto spin axis (as recorded by the on-board HMC camera) were interpreted as resulting from the impact of grains as large as $\sim 2 \times 10^{-2}$ g. A fully filled mixed-phase grain with this mass would have a diameter of several millimeters. Millimeter-sized grains contribute most of the infrared flux seen in the comet trails discovered by the IRAS satellite (Sykes et al. 1986, 1990), and so large grains are apparently common in comets. From the mass in these dust trails and in the measured gas production rates, Sykes and Walker (1992) estimate the dust/gas ratio in comets to be ~ 3 (with a range of 1–5), somewhat larger than the estimate of 1.7 in Halley mentioned above (Jessberger and Kissel 1991). McDonnell et al. (1991) estimate the dust/gas ratio in Halley to be ~ 2 .

The mass-12 and -13 peaks in the PIA/PUMA spectra have been interpreted as ^{12}C and ^{13}C , and the retrieved values of $^{12}\text{C}/^{13}\text{C}$ range from 1 to

5000, compared with the solar value of 89.91. Similar ranges in $^{12}\text{C}/^{13}\text{C}$ ratios are seen in microscopic analyses of carbonaceous chondrite grains. $^{12}\text{CH}^+$ could also contribute to the signal at mass 13, however, leading to smaller apparent ratios of $^{12}\text{C}/^{13}\text{C}$. While the majority of grains show $^{12}\text{C}/^{13}\text{C}$ abundance ratios to be consistent with solar, some others differ substantially. No secure information can be obtained regarding enrichment of ^{13}C , but some grains showed major depletion. Depletions of ten fold were often found and, in the most extreme case, $^{12}\text{C}/^{13}\text{C}$ was ~ 5000 , probably representing a remnant condensed in stellar outflow and not subjected to later modification (it may have formed in a He-burning or explosive H-burning stellar process, see discussion in Jessberger and Kissel 1991).

Although the composition of CHON material is superficially similar to the "tar balls" found in some interplanetary dust particles collected at stratospheric altitudes, the CHON particles are fragile bodies that showed evidence of fragmentation during outflow in the coma of P/Halley. If CHON particles are the antecedents for tar balls, the collected interplanetary dust particles have been severely devolatilized and possibly metamorphosed during their interplanetary period prior to collection in the stratosphere. With respect to other indicators, the distributions in both the $\text{Fe}/(\text{Fe} + \text{Mg})$ ratio and in the system Mg-Si-Fe are quite different in comet Halley than in carbonaceous chondrite matrix and lattice layer silicate interplanetary dust particles. However, they agree much more closely with those found for anhydrous interplanetary dust particles (see discussion in Grün and Jessberger 1990; Jessberger and Kissel 1991).

The cometary organic feature was discovered in IKS (infrakrasnoi spectrometre) spectra of comet Halley acquired on the Vega 1 spacecraft (Combes et al. 1986), and confirmed later by groundbased observers (Wickramasinghe and Allen 1986; Baas et al. 1986; Danks et al. 1987; Knacke et al. 1986). It has also been seen in every suitably bright comet since comet Halley. Possible contributors include thermal emission from CHON grains, emission from small super-hot grains, and resonance fluorescence of volatiles. The relative contributions of condensed phase and gaseous matter are as yet unknown (Encrenaz et al. 1988; Encrenaz and Knacke 1991; Chyba et al. 1989b; Brooke et al. 1991a). Chyba et al. showed that the shape of this feature was reproduced reasonably well by synthetic spectra based on optical constants of organic laboratory analogs. However, its heliocentric intensity evolution was not well reproduced except by small hot grains. Brooke et al. (1991a) found that the heliocentric dependence in several comets varied as expected for a volatile precursor, and methanol has been identified as a contributor in recent comets (see below).

Brooke et al. (1991a) compared the shape of this feature in five recent comets: comets Halley (1986 III), Wilson (1987 VII), Bradfield (1987 XXIX), Okazaki-Levy-Rudenko (1989 XIX) and P/Brorsen-Metcalf (1989 X). Their spectra are shown in Fig. 11. While the shapes resemble one another they are not identical. Brooke et al. argue that, as a group, the cometary spectra exhibit

greater similarity to one another, than do laboratory spectra of synthesized organic compounds. They suggest that the material incorporated in these five comets was more closely related than the synthesized compounds were. This is perhaps noteworthy because two are short-period comets (Halley and Brorsen-Metcalf), while two were dynamically new comets, and one (Bradfield) had an intermediate period. Brooke et al. (1991a; Tokunaga and Brooke 1990) suggest that their similarity results from common origins.

Recent work suggests that both volatiles and refractories contribute to spectral features in the 3.2 to 3.5 μm region. On the basis of their identification of the ν_3 band of methanol at 3.52 μm , Hoban et al. (1991a) commented that four-fold stronger emissions were expected from the ν_1 and ν_9 bands near 3.35 μm , and that these should contribute significantly to the cometary organic feature. Reuter (1992) developed a fluorescence model for these new bands and found that methanol could have contributed 10 to 40% of the total intensity of the cometary organic feature in recent comets.

B. Direct Detection of Parent Volatiles

Prior to 1985, the only cometary parent volatile detected directly was CO, achieved at ultraviolet wavelengths in two comets (West 1976 VI and Bradfield 1979 X; cf. Feldman 1983). S_2 was detected in comet IRAS-Araki-Alcock (1983 VII), but not in ten other comets (cf. A'Hearn et al. 1983; Budzien and Feldman 1992). However, it is not yet clear whether S_2 is a parent volatile.

Through the use of ultraviolet spectroscopy it has been possible to determine water production rates and their dependence on heliocentric distance (through measurements of the OH radical), to measure several key elemental production rates (e.g., O, C, S), to characterize other products such as H, CS and CO_2^+ , and to explore coma aeronomy in detail. Recently, sensitive upper limits to the production rates of SO and SO_2 were also obtained (see later discussion of sulfur chemistry). Selected details are discussed below, and comprehensive reviews are given by Festou (1990a) and Feldman (1991a; see also Feldman 1983, 1991b). A few early infrared searches produced only nonrestrictive upper limits, and are not discussed further in this chapter. The 18-cm radio lines of OH were first detected in comet Kohoutek (1973 XII) (Biraud et al. 1974; Turner 1974), and are now routinely used for productive studies of cometary activity and coma kinematics (see the review by Crovisier and Schloerb 1991). Radio searches for parent volatiles before 1985 were less successful, and provided only tentative molecular detections (e.g., HCN, NH_3 , H_2O and CH_3CN) or upper limits (see the reviews by Snyder [1982] and by Crovisier and Schloerb [1991]).

The direct detection of parent molecules at infrared wavelengths became tractable with the development of theoretical models for fluorescence in their vibrational bands (cf. Crovisier and Encrenaz 1983; Weaver and Mumma 1984), and of suitable instrumentation for observing them. The first successful application of this approach was to the water molecule in comet Halley (Mumma et al. 1986), and it provided the first detection of water vapor in

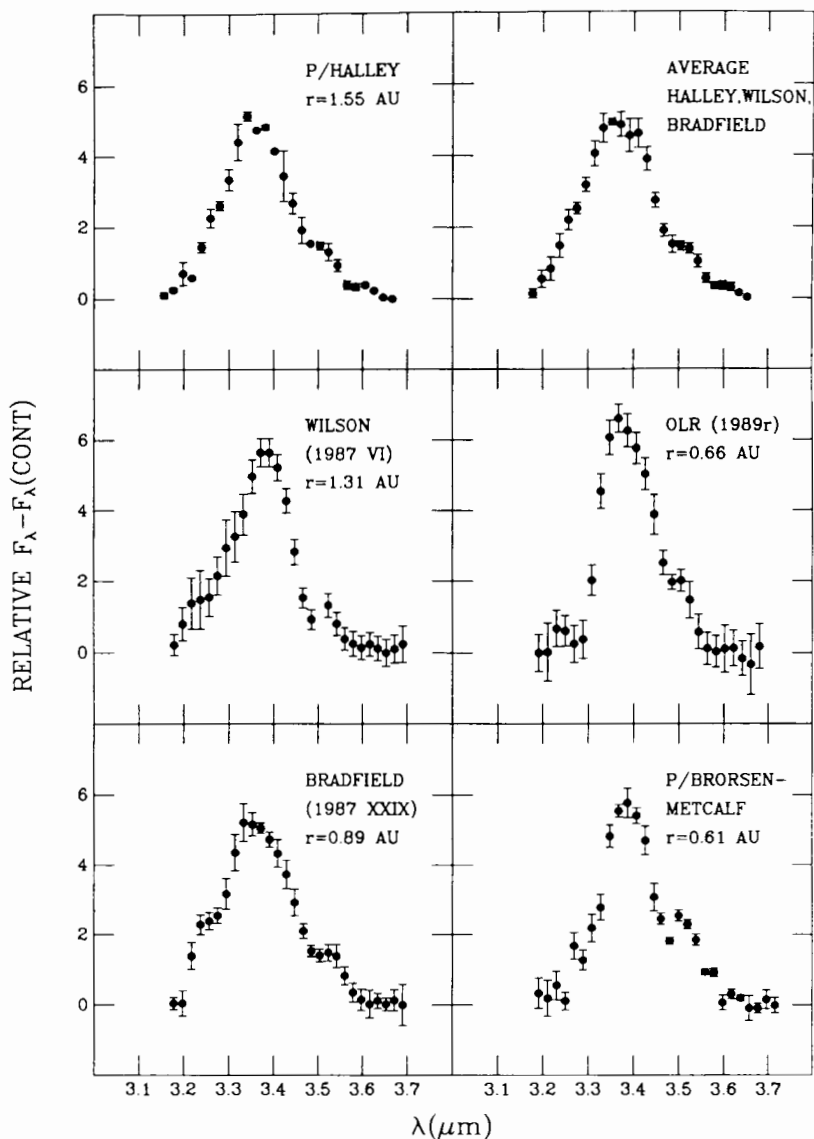

Figure 11. The "organic" feature in five recent comets. The shapes are similar but not identical (after Brooke et al. 1991a).

comets (Fig. 12). Subsequently, spectra of comet Halley were acquired by an infrared spectrometer (IKS) carried on the Vega 1 spacecraft (cf. Combes et al. 1986). A spectrum measured during the flyby on 6 March 1986 is shown in Fig. 13. The IKS featured low spectral resolution but wide spectral coverage

(2.5 to 12 μm), and it achieved the first detections of CO_2 and of the cometary organic feature, as well as the detections of water; formaldehyde (H_2CO), and possibly CO (cf. Moroz et al. 1987, Combes et al. 1988; Mumma and Reuter 1989). Infrared spectroscopy of recent comets has led to detections of CH_3OH , and possibly of CO , and to sensitive upper limits for CH_4 , H_2CO and OCS (Hoban et al. 1991a; DiSanti et al. 1990,1992; Brooke et al. 1991b; Reuter et al. 1992).

Figure 12. Part of the infrared spectrum of comet Halley obtained on 24 December 1985, from the Kuiper Airborne Observatory. The lower trace in each panel shows the emission spectrum from comet Halley, the upper trace the lunar reflectance spectrum. The cometary geocentric velocity causes the H_2O lines to be Doppler shifted by about $\sim 0.43 \text{ cm}^{-1}$ from the terrestrial absorption lines seen in the lunar spectrum. The lines are labeled with quantum numbers and the ortho or para designation (after Mumma et al. 1986).

The first secure detections of parent volatiles at radio wavelengths occurred in comet Halley (see discussion in Crovisier and Schloerb 1991). Velocity-resolved intensity profiles of HCN lines were measured over a wide range of heliocentric distance. From these profiles, production rates were obtained along with their diurnal and seasonal variability and the physics of outflow in the cometary coma was determined (Despois et al. 1986; Schloerb et al. 1986,1987; Winnberg et al. 1987). The advent of large aperture millimeter telescopes enabled the secure identification of H_2CO , CH_3OH , and H_2S in several recent comets, while sensitive upper limits were reported for

Figure 13. A representation of the spectrum of comet Halley acquired on 6 March 1986, with the IKS spectrometer on the Vega 1 spacecraft. This representation emphasizes the portion of the detected flux that is contributed by directly sublimed species. The low instrumental resolution causes each molecular band to appear without rotational structure; however, detections of water, carbon dioxide and formaldehyde are evident. The broad feature spanning 3.2 to 3.5 μm corresponds to the C-H stretch in many solid and volatile species, and both probably contribute to this emission. A comparison of the modeled band shape for H_2CO ν_1 and ν_5 bands at rotational temperature $T = 50$ K, is also shown (Mumma and Reuter 1989). The retrieved production rate (4.5% relative to H_2O) represents a direct nuclear source for H_2CO , to which must be added any extended source that may be present (e.g., POM). Although the shape of the CO (1–0) band is not obvious in this spectrum, the dependence of integrated intensity on distance from the nucleus supports its presence. IKS data from Combes et al. (1988).

other species, e.g., for OCS, SO_2 , H_2CS and HC_3N in comet Levy (1990 XX) (Bockelée-Morvan et al. 1990,1991; Colom et al. 1992).

Production rates and spatial distributions within the coma of comet Halley were also obtained for many parent volatiles by the neutral and ion mass spectrometers on the Giotto spacecraft, including H_2O , CO, CO_2 , H_2CO , CH_3OH , HCN and H_2S . A summary of the parent molecular abundances found in recent comets is given in Table V.

We now examine several key volatile species and their interrelationships in greater detail.

TABLE V
Volatile Abundances in Recent Comets

Molecule	Relative Abundance (by number)	Comments
Comet P/Halley		
H ₂ O	100	Remote and <i>in-situ</i> detections ¹
CO	~7	Direct (native) source ²
	~8	Distributed source ²
H ₂ CO	0–5	Variable ³
CO ₂	3	Infrared (Vega 1 IKS)
CH ₄	<0.2–1.2	Groundbased infrared ⁴
	0–2	Giotto IMS ⁵
NH ₃	0.1–0.3	Variable ⁶ ; based on NH ₂
	1–2	Giotto IMS ⁷
HCN	0.1	Variable; groundbased radio
	<0.02	Giotto IMS
N ₂	~0.02	Groundbased N ₂ ⁺ emission
SO ₂	<0.002	Ultraviolet (IUE)
H ₂ S	—	Giotto IMS ⁸
CH ₃ OH	~1	Giotto NMS and IMS ⁹
Other Comets		
CO	20	West (1976 VI)
	2	Bradfield (1979 X)
	1–3	Austin (1990 V)
CH ₄	<0.2	Levy (1990 XX) ¹⁰
	1.5–4.5	Wilson (1987 VII) ¹¹
CH ₃ OH	1–5	Variable ¹²
H ₂ CO	0.1–0.04	If a parent species ¹³
HCN	0.03–0.2	Several comets ¹⁴
H ₂ S	0.2	Austin (1990 V); Levy (1990 XX) ¹⁵
S ₂	0.025	IRAS-Araki-Alcock (1983 VII) ¹⁶

¹ Water was detected directly by infrared spectroscopy (Mumma et al. 1986; Combes et al. 1986) and by mass spectroscopy (cf. Krankowsky et al. 1986).

² CO was detected directly at ultraviolet wavelengths (Feldman et al. 1987; Woods et al. 1986, 1987) and in neutral mass spectra (Eberhardt et al. 1987*b*). A tentative detection at infrared wavelengths (Combes et al. 1988) provided production rates in agreement with the native source.

³ The H₂CO abundance is variable, relative to water. The largest value found for comet Halley was 4.5%±0.5%, measured by both IKS and Giotto NMS (also IMS, see text), but at other times the production rates were 10 times smaller (cf. Mumma and Reuter 1989). The values retrieved for comets Austin and Levy were much smaller than the values found in comet Halley.

⁴ Retrieved from a single spectral line of CH₄. The range reflects the uncertainty in rotational temperature for cometary CH₄ (50–200 K). The extrapolation from a single line to the ensemble production rate is therefore highly uncertain. See Kawara et al. (1988).

- ⁵ The production rate retrieved from the ion mass spectra on Giotto is highly model dependent, and could be zero in comet Halley (Allen et al. 1987; Boice et al. 1990). Brooke et al. (1991*b*) recently found $\text{CH}_4 < 0.2\%$ in comet Levy (1990 XX).
- ⁶ Assuming that NH_2 is produced solely from NH_3 (Magee-Sauer et al. 1989; Mumma et al. 1990; Krasnopolsky and Tkachuk 1991; Wyckoff et al. 1991*a*).
- ⁷ Allen et al. (1987). Boice et al. (1990) re-analyzed the IMS spectra, retrieving 1%, while Ip et al. (1990) retrieved 0.5% from the Giotto IMS data.
- ⁸ Marconi et al. (1990). An incorrect lifetime was used in deriving the abundance of H_2S (see Crovisier et al. (1991).
- ⁹ See Geiss et al. (1991) and Eberhardt et al. (1991).
- ¹⁰ Based on groundbased infrared spectroscopy (Brooke et al. 1991*b*).
- ¹¹ Based on airborne infrared spectroscopy (Larson et al. 1989).
- ¹² The value in comet Levy was $\sim 1\%$, but in comet Austin it was about 5% (Bockelée-Morvan et al. 1991; Bockelée-Morvan, personal communication); Hoban et al. 1991*a*).
- ¹³ 0.1% in comet Austin (1990 V), and 0.04% in comet Levy (1990 XX). The production rate would be about ten-fold larger if formaldehyde were a daughter product (Colom et al. 1992).
- ¹⁴ In P/Brorsen-Metcalf (1989 X), Austin (1990 V), Levy (1990 XX) (compare Bockelée-Morvan et al. 1990).
- ¹⁵ Crovisier et al. (1991).
- ¹⁶ cf. Kim et al. (1990).

C. Water

Water was long thought to be the dominant volatile species in the cometary nucleus (based on strong indirect evidence), but it was first detected more than 35 years after Whipple (1950) introduced his icy conglomerate model for the cometary nucleus. Infrared spectroscopy of comet Halley on UT 21–24 December 1985 from the Kuiper Airborne Observatory provided a detection of 10 lines of the ν_3 band in emission (Mumma et al. 1986), as predicted by models for solar infrared fluorescence from rotationally relaxed cometary water (Crovisier 1984; Weaver and Mumma 1984). Water was detected on 6 March 1986 in IKS spectra acquired on the Vega 1 spacecraft (cf. Combes et al. 1986, 1988), and in-depth studies were conducted on 20–26 March 1986 from the Kuiper Airborne Observatory (Weaver et al. 1986). Absolute production rates were obtained that, when compared with those for other volatiles, confirmed that water was indeed the dominant volatile species in the cometary nucleus. The production rates were found to vary from day-to-day, in concert with the visible lightcurves. A detailed analysis of the relative line intensities and shapes permitted retrieval of the rotational temperature and outflow velocity in the intermediate coma, and confirmed the predicted transition from collisionally dominated to fluorescence dominated regimes in the outer coma (Larson et al. 1987; Weaver et al. 1987; Bockelée-Morvan and Crovisier 1987; Bockelée-Morvan 1987). The spin temperatures of cometary water were measured in comets Halley and Wilson (1987 VII) with significantly different results (see later discussion in Sec. IV.J).

D. Carbon Dioxide

CO₂ was detected for the first time in comets in infrared spectra acquired on Vega 1, and in mass spectrometric measurements on Giotto. The Giotto neutral mass spectra (NMS) showed a strong peak at 44 amu/e⁻ (Krakowsky et al. 1986; Krakowsky 1991). CO₂, CS, C₃H₈ and several other species are potential contributors to this feature, but it was argued from the measured mass distribution that propane (C₃H₈), acetaldehyde (CH₃CHO), and ethylene oxide ((CH₃)₂O) could contribute no more than one-third of the measured peak intensity. The spatial profile showed no evidence of parent decay over the entire measurement interval from the nucleus (2500–6300 km). However, this is not very restrictive because the largest distance is still much smaller than the scale length of CO₂, while the smallest is much larger than the scale length of the presumed parent of CS (i.e., CS₂). Thus, the measured spatial distribution is consistent with either CS or CO₂. By assigning the entire peak to CO₂, Krakowsky et al. derived an upper limit to its production rate of 3.5% relative to water. CO₂ was also directly detected in infrared spectra of comet Halley (by IKS on Vega 1), through its ν_3 band near 4.3 μ m (Combes et al. 1986). A production rate of 2.7% relative to water was obtained (Combes et al. 1988). CO₂⁺ is ubiquitous in ultraviolet (see, e.g., Festou et al. 1982) and blue (groundbased) spectra of comets, and is potentially a useful tracer for CO₂. However, direct observations of the parent species are most desired, at least until the ionization rates and processes are verified and the fluorescence efficiencies are well in hand. Unfortunately, the strong infrared bands of CO₂ are observable only from space or from balloon altitudes.

E. Methane and Carbon Monoxide

The abundance of CH₄ relative to CO may provide a key test of the manner in which cometary ices formed. Interstellar methane has recently been measured in both the solid and gaseous forms (Lacy et al. 1991) in several dense cloud cores (e.g., W33A) and star-forming regions (e.g., NGC 7538 IRS 1 and IRS 9). The abundance ratio CH₄/CO in the condensed phase was 2.4 in W33A and in the range 3.2 to 5.6 in IRS 1, but only 0.13 in IRS 9. The ratios in the gas phase were 0.001–0.011, 0.0015, and 0.001–0.003, respectively, in agreement with earlier upper limits (Knacke et al. 1985), and the ratios for total CH₄/CO were 0.044, 0.01–0.017, and 0.013, respectively. The ranges correspond to uncertainties in the rotational temperatures for CH₄ and CO. Lacy et al. (1991) suggest that the unusually high abundance ratio in the solid phase is consistent with production of methane on the grains (see Chapter by van Dishoeck et al.). Whether or not this is so, comets that accreted from such grains would exhibit large CH₄/CO ratios (of order unity) while those that accreted at very low temperatures (such that all of the gaseous CO was condensed) would show CH₄/CO ~ 0.01. The variability in the ratio CH₄/CO is much larger for the condensed phase in these three sources than it is for the total abundances, and this may indicate that the ratio CH₄/CO in cometary ice

will depend on the exact temperature of condensation, thermal history, and formation site.

Cometary CO was first detected at ultraviolet wavelengths in comet West (1976 VI), and later in comets Bradfield (1979 X), Halley (1986 III), Austin (1990 V) and Levy (1990 XX) (Feldman and Brune 1976; Feldman et al. 1987; Woods et al. 1986, 1987; Budzien et al. 1990; Sahnou et al. 1990; Feldman et al. 1991). It was searched for, but not detected in several dozen other comets (Festou and Feldman 1987; Festou 1990*b*). The reported production rates (relative to water) varied more than ten fold for the five comets in which CO was detected (cf. Feldman 1983). The rocket detections (West, Halley) yielded production rates ~ 15 to 20% relative to water, while the IUE results (Halley, Austin, Levy) were in the range of 1 to 7%. However, the direct comparison of production rates measured with large (e.g., rocket-UV) and small (e.g., IUE) beam sizes is problematical if CO is a product of both direct and distributed sources. The small beam size emphasizes the direct source at the expense of the distributed one, while the large beam samples CO produced from both sources. Part of the spread in measured values may be due to this effect (see Feldman 1983; Weaver 1989).

Eberhardt et al. (1987*b*) retrieved the production rate of CO from the 28 amu/e⁻ peak in the NMS spectra on Giotto. The production rate was $\sim 15\%$ relative to water, in agreement with rocket-ultraviolet results (~ 15 to 20%; Woods et al. 1986). Eberhardt et al. found that the spatial profile of CO was not consistent with a direct nuclear source alone, but required a second distributed source whose parent scale length was about 1×10^4 km. The nuclear source contributed $\sim 7\%$, consistent with the value retrieved by IUE ($\sim 7\%$; Feldman et al. 1987). The destruction scale length found for H₂CO by Krankowsky (1991) was comparable to that found for the extended source of CO. The production rate for CO from formaldehyde in the combined polymeric and monomeric forms would exceed that from the monomer alone (which was 4.5%, relative to water), so it is plausible that H₂CO was responsible for a significant fraction of the distributed source of CO.

The (1–0) band of CO was tentatively identified in IKS spectra (see Combes et al. 1988, Fig. 8d) near $4.7 \mu\text{m}$, and the P3 line was also detected during an outburst in comet Austin (DiSanti et al. 1990, 1992). Earlier groundbased infrared searches were carried out on comet IRAS-Araki-Alcock (1983 VII) (Weaver et al. 1983, as reported in Chin and Weaver 1984), but the instrumental approach suffered from limited sensitivity. The search in comet Austin was the first to use a modern high-resolution cryogenic echelle spectrometer (IRSHELL; Lacy et al. 1989*a*), however the detector was optimized for longer wavelengths and improved sensitivity is expected with other detectors.

Early attempts to detect CH₄ in comets were unsuccessful (see, e.g., Roche et al. 1975). The upper limits obtained for comet Kohoutek (1973 XII) did not impose useful constraints on the formation models ($\text{CH}_4/\text{CO} < 50$, $\text{CH}_4/\text{H}_2\text{O} < 5$). A search was made in comet Halley from the KAO and an

upper limit of 4% relative to water was obtained (Drapatz et al. 1987). A more restrictive upper limit (0.2–1.2%, the range representing the uncertainty in rotational temperature) was obtained for Halley by Kawara et al. (1988) from groundbased infrared spectroscopy. Taken with the direct source of CO ($\sim 7\%$) measured by the IMS on Giotto (Krankowsky et al. 1986), this suggests a ratio $\text{CH}_4/\text{CO} < 0.03$ to 0.17. Modeling of the Giotto High Intensity Spectrometer data (Balsiger et al. 1986) provided an abundance of 2% for CH_4 relative to water (Allen et al. 1987; Wegmann et al. 1987). However Boice et al. (1990) obtained satisfactory fits to these mass spectra by including the fractionation fragments of polymeric formaldehyde (POM), with no CH_4 , and also reproduced the spatial distribution found for the extended source of CO by the NMS. They did not fit the CH peak ($\text{amu} = 13$) well, however, and so invoked an unidentified source (grains were suggested).

Methane has been detected only in comet Wilson (1987 VII), a dynamically new comet. Larson et al. (1989) found emission at the 5σ level at the expected Doppler-shifted frequencies, and reported it as a possible 3σ detection above the noise level. The rotational temperature was not measured, so the retrieved production rate (1.4–4.5%, relative to water) was presented for two temperatures. The lower value assumes the kinetic temperature (50 K) derived from rotational populations measured for polar molecules (H_2O and HCN), while the higher value represents an upper limit to the kinetic temperature (300 K) for neutral molecules obtained from the NMS spectrometer on Giotto (Lämmerzahl et al. 1987). The production rate (3.3%) was also reported for 215 K. Owing to the curious manner in which these results were reported, all production rates refer to the 3σ level. They would be slightly higher (2.3–7.5%) had the measured level (5σ) been used. IUE observations provided $\text{CO}/\text{H}_2\text{O} < 0.1$ (Roettger 1991), so that $\text{CH}_4/\text{CO} > 0.2$ for this new comet.

This lower limit for comet Wilson exceeds the ratio found for ices in the star-forming region, NGC 7538 IRS 9 (Lacy et al. 1991). Recent observations of another comet (Levy 1990 XX) support a low ratio for CH_4/CO , (< 0.1 , at the 3σ confidence limit) (Brooke et al. 1991*b*). While it is not certain whether comet Levy was dynamically new or was a returning long-period comet (B. Marsden 1991, personal communication), its chemical abundances (e.g., of CH_3OH and CH_4) and the CH_4/CO ratio appear to be consistent with those in P/Halley, but not with comets Austin or Wilson. Still, the upper limits for CH_4/CO in comets P/Halley and Levy are smaller than the ratio found for solid phase CH_4/CO around embedded stars (Lacy et al. 1991).

Bar-Nun and Kleinfeld (1989) studied the condensation properties of laboratory analogs of cometary ices, and compared their findings with the reported (NMS) measurement of $\text{CH}_4/\text{H}_2\text{O} \sim 0.02$ and $\text{CO}/\text{H}_2\text{O} \sim 0.07$ in comet Halley (see Table V). Beginning with gaseous mixtures of H_2O and CO, they found that the ratio of trapped CO in H_2O ice reached 0.07 at a condensation temperature of ~ 50 K, and they argued that the ice in Halley's comet formed at this temperature in the solar nebula. They further argued that a ratio of

$\text{CH}_4/\text{CO} \sim 0.3$ in comet Halley required a gaseous ratio $\text{CH}_4/\text{CO} \sim 0.01$ in the solar nebula, if both ices were condensed from the gas phase at 50 K. This value is consistent with the range of total abundance ratios for CH_4/CO found by Lacy et al. (1991). However, the abundance of CH_4 in comet Halley is now thought to be substantially less than the value of 0.02 reported by Allen et al. (1987).

Prinn and Fegley (1989) and Fegley and Prinn (1989) examined disequilibrium chemistry in the solar nebula and found that the long time scales needed for chemical conversion prevent efficient reduction of CO to CH_4 . Thus, they predict $\text{CH}_4/\text{CO} < 10^{-7}$ for disequilibrium condensation, far lower than the values reported (~ 0.03 – 0.17) for comet Halley. They therefore suggested the giant planet sub-nebulae as a source of pre-cometary material enriched in methane. Chemical reduction is efficient in the giant planet sub-nebulae, owing to higher temperatures and densities, and thus material in them is CH_4 -rich. Lunine (1989b) and Engel et al. (1990) examined radial transport of processed material from the inner solar nebula to the comet-forming zone, and concluded that although this could produce CH_4 with 1 to 4% relative abundance in Halley, an admixture of NH_3 -rich material was needed (however, the NH_3 abundance may be much smaller than originally claimed; see later discussion). They invoked interstellar material as its source, and this of course admits the possibility of delivering the required methane as well. The high ratio of CH_4/CO found in the solid phase in the interstellar medium (Lacy et al. 1991) avoids the need to mix reduced material from the solar nebula into comets, if comets accreted from such grains. In any event, the abundance of reduced material (both carbon and nitrogen) in the nucleus of P/Halley and other short-period comets has been revised downward substantially from the high levels reported initially.

F. Formaldehyde and Methanol

The presence of formaldehyde is expected if the cometary nucleus contains unmodified interstellar material, as formaldehyde is known to be ubiquitous in interstellar clouds. The abundance in the solid phase around the embedded infrared source W33A is $\sim 0.2\%$ (relative to water ice; Table VI). Four independent lines of evidence support its presence in comet Halley at much higher concentrations, but its distribution within the nucleus may be inhomogeneous. Mitchell et al. (1987) and Huebner (1987) interpreted certain ion mass spectra, acquired by the PICCA ion mass spectrometer on the Giotto spacecraft (Korth et al. 1986), as cracking fractions of polymeric formaldehyde (polyoxymethylene or POM). The dissociation of POM also could explain the observed extended source for CO. However, this interpretation may not be unique because temporal variability or other sources of CO could also be significant. Further, Mitchell et al. (1989) challenged the identification of POM as progenitor of the mass spectra, by showing that a blend of compounds of CH_2 , NH , O and N connected to complex hydrocarbons could also produce the observed PICCA mass spectra. Moore and Tanabe (1990) reproduced

the PICCA spectrum by ion sputtering of para formaldehyde, but reported the yield to be 10^3 too small to account for the PICCA results quantitatively. Formaldehyde was also detected by the NMS on Giotto at the production rate of 4.5% (relative to water), and its spatial profile seemed to require a distributed source (Krankowsky et al. 1991; Krankowsky 1991).

TABLE VI
Molecular Abundances in Interstellar Icy Grain Mantles^a

Species	Band Position		Relative Abundance	
	λ (μm)	ν (cm^{-1})	Observed	Calculated ^b
H ₂ O	3.08	3250	—	—
CO	4.68	2135	0–5	0.4
CH ₃ OH	3.5	2830	7	(40) ^c
X-CN	4.61	2167	(4) ^d	—
OCS	4.90	2040	(0.05) ^e	0.4
NH ₃	2.95	3375	< 5	1
H ₂ S	3.94	2540	0.3	0.03
CH ₄	7.70	1300	< 1	0.007
H ₂ CO	3.53	2835	< 0.2	(0) ^c
CO ₂	4.28	2337	—	9

^a Relative abundances refer to number, not mass. Most abundances from Tielens (1989); CH₃OH from Grim et al. (1991); CH₄ from Lacy et al. (1991).

^b Tielens and Hagen (1982).

^c Assuming all H₂CO is converted to CH₃OH by grain surface reactions.

^d Thought to result from ultraviolet photolysis. Abundance estimated from laboratory studies (d'Hendecourt et al. 1986).

^e If the feature is due to OCS.

Snyder et al. (1989) reported a spectral line of monomeric H₂CO in comet Halley (the 110–111 rotational line at 4.8 GHz, detected with S/N~2.5), and found a relative production rate of ~1.5% for late January, 1986. They required an extended source of formaldehyde in the coma to explain their spectrum. However, based on a new model for the rotational spectrum of cometary H₂CO, Bockelée-Morvan and Crovisier (1992) argue that the radio detection in P/Halley must be spurious.

Combes et al. (1988) claimed a tentative detection of the ν_1 and ν_5 bands of formaldehyde, from the 3.6 μm feature detected by IKS. Their retrievals were based on incomplete cometary models and the band shape was not well reproduced by their synthetic models, leading them to label the three channels at band center as spurious. Their synthetic spectrum assumed a rotational temperature of 300 K. They analyzed only the flux which exhibited a cometocentric dependence consistent with that of a parent molecule, and retrieved a production rate of ~4.5% relative to water. Reuter et al. (1989) developed a new fluorescence model for these bands at low rotational temperatures, and Mumma and Reuter (1989) applied it to the IKS spectra, achieving an excel-

lent fit to the band shape and accounting for all spectral channels satisfactorily (Fig. 13). They obtained a production rate of $4.5\% \pm 0.5\%$ relative to water, and found that the formaldehyde was rotationally relaxed ($T \sim 50$ K), in accord with other estimates for the temperature in the intermediate coma.

Mumma and Reuter (1989) also applied their model to the entire set of infrared spectra obtained from March through May 1986 by various observers. This interval spans eight cycles of the 7.37 day period found in the lightcurve for March and April (Millis and Schleicher 1986; Schleicher et al. 1990). When arranged against rotational phase, the production rates relative to water were found to correlate strongly with the lightcurves for C_2 , CN, and other species. The detections occurred over a narrow range of phases in the lightcurve, corresponding to one of the three maxima in activity. This phase range was experienced during both the Giotto and Vega 1 encounters and also for the sole groundbased spectrum in which formaldehyde was marginally present. Upper limits for the production rates at other phases were 5 to 10 times smaller, including phases corresponding to the remaining two maxima in the lightcurves and to the Vega 2 encounter. Reuter and Mumma (1989) suggested that formaldehyde was heterogeneously distributed in the Halley nucleus, relative to water. Robust detections of formaldehyde rotational lines were achieved in two recent comets (Colom et al. 1992; Schloerb and Weiguo 1992). Colom et al. (1992) found H_2CO in comet Austin (1990 V) and comet Levy (1990 XX) at levels of 0.1% and 0.04% relative to water, respectively, assuming that it was produced solely as a parent volatile. Upper limits (3σ) were obtained from infrared spectra of these two comets ($<0.4\%$ and $<0.2\%$, respectively), again assuming a parent distribution (Reuter et al. 1992), however, these were not as sensitive as the millimeter results. The ratios in both cases would be \sim ten times greater, were formaldehyde produced solely from an extended source. Colom et al. (1992) found that an extended source of H_2CO was required in comet Austin, similar to that reported for comet Halley.

Although only one of the groundbased spectra of comet Halley showed (marginally), the $3.6 \mu m$ feature, a feature was nearly always present near $3.52 \mu m$. In their analysis of the IKS spectrum, Mumma and Reuter (1989) found that the entire flux near $3.6 \mu m$ could be attributed to formaldehyde, without requiring any additional flux from the $3.52 \mu m$ feature. The distribution of the two species may therefore be anti-correlated within the nucleus. Brooke et al. (1989) investigated the 3.25 to $3.65 \mu m$ region in comet Wilson at moderate resolving power, and found a high degree of correlation between the spectral intensity profile of the 3.45 to $3.65 \mu m$ region in that comet and the spectrum of comet Halley (Baas et al. 1986). The spectrum could not be explained simply by fluorescence from formaldehyde, however, and following earlier authors (Knacke et al. 1986) they suggested methanol as another possibility.

Cometary methanol was first identified through infrared and millimeter spectroscopy of comet Austin (Bockelée-Morvan et al. 1991; Hoban et al. 1991a). The discovery spectra are shown in Fig. 14. Hoban et al.

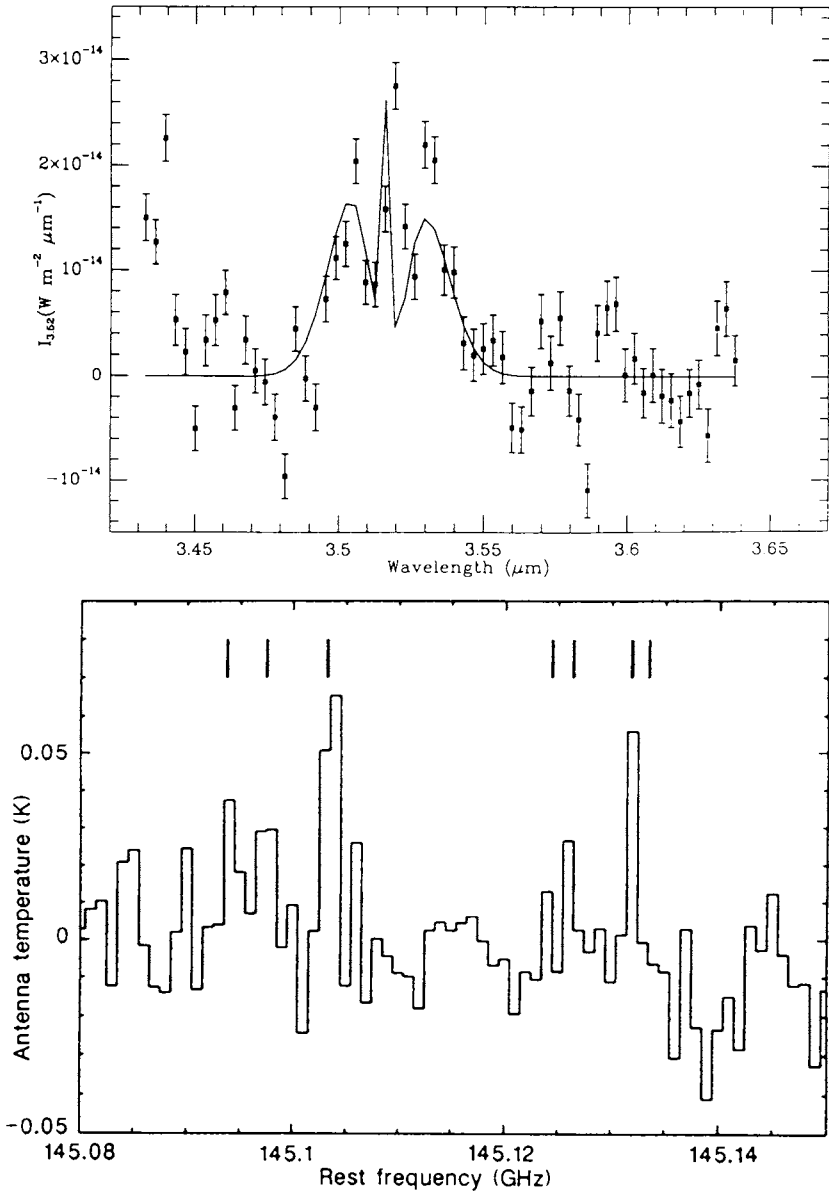

Figure 14. Discovery of methanol in comet Austin (1990 V). Top: vibrational band emission (ν_3) near $3.52 \mu\text{m}$ wavelength on UT May 5–7, 1989 (after Hoban et al. 1991a). Bottom: rotational emission lines near 2.07 mm wavelength on UT 25 May 1990 (after Bockelée-Morvan et al. 1991). Both data sets indicate low rotational temperatures. The synthetic fit for the infrared band is shown for a model with rotational temperature $T = 70 \text{ K}$. The line-by-line mm intensities also indicate a low rotational temperature. The production rates retrieved from these spectra are comparable ($\sim 4\%$ relative to water; see text).

(1991a) studied the spectral shape and spatial profile of the $3.52\text{ }\mu\text{m}$ feature in comets Austin, Brorsen-Metcalf, and Levy (1990 XX) and tentatively identified methanol as its progenitor, based on a new fluorescence model for that molecule. The production rate (relative to water) was 4% in comet Austin on UT 5–7 May 1990. Bockelée-Morvan et al. (1991) detected methanol on UT 24–25 May 1990 at millimeter wavelengths and reported a production rate of 1% relative to water. However, this was subsequently revised upward as a result of improved knowledge of the telescope tracking, and of the application of non-LTE excitation models. The revised value agrees with the infrared result (D. Bockelée-Morvan, personal communication). The infrared production rate for CH_3OH in Austin is not sensitive to rotational excitation models, because the spectral range includes all rotational levels in the molecular band. The integrated band intensity is easily related to the production rate through a fluorescence model. Infrared and millimeter retrievals of methanol in comet Levy (1990 XX) (on the same day) were both $\sim 1\%$ relative to water. In comet Halley, methanol has recently been proposed as a progenitor of the mass 32 and 33 (CH_3OH^+ and CH_3OH_2^+) peaks in the Giotto IMS data, with a relative production rate of 0.3 to 1.5% (Geiss et al. 1991). A relative production rate of 1% was also retrieved from the mass 33 peak in the NMS data (Eberhardt et al. 1991).

The methanol abundance in comet Austin was close to the value in W33A. Recent detections of CH_3OH ice in W33A show it to be present at the level 7% relative to water (Grim et al. 1991), while formaldehyde ice is present at 0.2% abundance (Tielens 1989), so that $\text{CH}_3\text{OH}/\text{H}_2\text{CO} \sim 35$. In comet Austin, the ratio was >40 (taking H_2CO to be a parent species) comparable with the interstellar value. The ratio would be ~ 10 times lower (i.e., 4) were H_2CO produced from an extended source. In comet Halley the ratio was in the range 0.3 to 0.06, significantly lower than the interstellar value. It is interesting that the ratios $\text{CH}_3\text{OH}/\text{H}_2\text{O}$ and $\text{CH}_3\text{OH}/\text{H}_2\text{CO}$ in comet Austin are comparable to those in W33A, as methanol is easily converted to formaldehyde by photo-processing (Allamandola et al. 1988).

It is unknown whether cosmic-ray processing also has this effect, but this line of inquiry seems warranted since Austin was a dynamically new comet and it is not known whether the radiation processed layer had been completely lost by the time of observation (see Sec. III). These results hint that such effects are identifiable from remote observations.

G. Volatile Nitrogen: NH_3 , HCN and N_2

Nitrogen has proven particularly difficult to measure remotely, because neither the atomic nor diatomic forms are easily detected, and the fraction of total N locked in the grains cannot be studied remotely. Of the potential reservoirs of volatile N, only HCN has been detected directly, although the abundances of N_2 and NH_3 have been inferred from measurements of N_2^+ , NH and NH_2 . Wyckoff et al. (1991b) have reviewed the abundance of total nitrogen in comet Halley, retrieved from mass spectrometry of the gas and dust on Giotto

and Vega, and from groundbased spectroscopy of NH, NH₂ and HCN. They argue that total nitrogen is depleted by about two-to-six fold, relative to solar abundance, in agreement with the depletion deduced by Jessberger and Kissel (1991) (see Table IV).

It must be noted that NH₃ has itself not yet been detected in comets. Models based on the ratio of intensities measured for species with mass 18 and mass 19 (taken to be NH₄⁺ and H₃O⁺, respectively) in the Giotto ion mass spectra indicated a relative production rate (NH₃/H₂O) of ~1 to 2% (Allen et al. 1987; Wegmann et al. 1987). However, Ip et al. (1990) pointed out that reactions of H₃O⁺ with HCN influenced the retrieved values for NH₃. They re-analyzed the spectrum, and obtained a value of ~0.5% for NH₃. Boice et al. (1990) developed a model which included the cracking pattern of POM, and reproduced the measured mass spectrum with no CH₄ and only 1% NH₃. Furthermore, the NH₃ production rate (0.1 to 0.3%) retrieved from groundbased spectra of NH and NH₂, taken during the Giotto encounter, was 10 times smaller than the IMS result (Tegler and Wyckoff 1989; Wyckoff et al. 1991a, b; Allen et al. 1989; Magee-Sauer et al. 1989). Krasnopolsky and Tkachuk (1991) found an NH₃ production rate of 0.15% from the TKS spectra of NH and NH₂ on Vega 2. The spatial profiles of NH₂ require a distributed source whose lifetime is consistent with that of NH₃, but the progenitor could be either a grain or a volatile species so long as it has the required destruction scale length. Some fraction of the NH₂ could originate from a source other than NH₃. It is interesting to note that Kim et al. (1989) have argued that NH₃ was not the principal parent of NH in comet Halley. Given the difficulties in extracting unique production rates for NH₃ from mass spectra, greater weight must be extended to the retrievals from NH₂ at this time. The latter provide the most restrictive values for the production rate of NH₃.

When arranged against rotational phase, Mumma et al. (1990) found that the NH₂ production rate was strongly correlated with the lightcurves in C₂ and other radical species (Millis and Schleicher 1986), suggesting that the progenitors of these species are homogeneously mixed within the active regions of the nucleus. Wyckoff et al. (1991a) also argued that NH₃ was uniformly mixed in the nucleus of comet Halley, because its production rate (relative to water) did not change significantly over a span of many months.

Other forms of volatile nitrogen detected in comet Halley include HCN and N₂. Gaseous HCN is a familiar interstellar molecule, and the abundance of X-CN in interstellar ice is ~4% relative to water ice (Table VI). While not all of the X-CN is likely to be HCN, the abundance of HCN predicted by chemical equilibrium models of the outer solar nebula is extremely small (HCN/H₂O ~ 10^{-5.5} (sic) at *T* = 100 K; Lewis 1972). Prinn and Fegley (1989) showed that kinetic inhibition would limit chemical conversion of HCN (to N₂) in the outer solar nebula (HCN/H₂O ~ 10^{-6.8}) and of HCN to NH₃ in the giant planet sub-nebulae (HCN/H₂O ~ 10^{-6.4} at *T* ~ 1220 K). Lightning induced shock chemistry (*T* = 3000–4000 K) could produce significant HCN, and isotopic equilibration at solar values (e.g., of ¹²C/¹³C) would also be

expected. However, only a small dilution factor of shocked gas by unshocked gas could be tolerated to produce the observed value ($\text{HCN}/\text{H}_2\text{O} \sim 1 \times 10^{-3}$) in comet Halley (see Fegley 1992). The abundance of HCN (and the ratios HCN/NH_3 ; HCN/N_2) may prove to be a very significant indicator of the degree of processing experienced by pre-cometary material. HCN was tentatively detected in comet Kohoutek (1973 XII) (Huebner et al. 1974), but it was first securely detected in comet Halley (Despois et al. 1986; Schloerb et al. 1986, 1987; Winnberg et al. 1987). HCN has often been suggested as a likely progenitor of the CN seen at optical wavelengths, however, HCN production rates were found to be significantly smaller than production rates for CN in IRAS-Araki-Alcock (1983 VII). Thus, HCN could not have been the principal volatile source of CN in that older long-period comet (Bockelée-Morvan and Crovisier 1985). Production rates of HCN in comet Halley ($\text{HCN}/\text{H}_2\text{O} \sim 1 \times 10^{-3}$; Schloerb et al. 1986; Bockelée-Morvan et al. 1987) are in approximate agreement with production rates for CN ($\sim 1 \times 10^{-3}$) given by Catalano et al. (1986) and Wyckoff et al. (1988). However, other CN production rates (see Schleicher et al. 1986; Osip et al. 1992) are several times larger. As the retrieved production rates are dependent on assumed model parameters, Bockelée-Morvan et al. (1987) argue that a definitive conclusion on this question will require a reconsideration of the entire data set, accounting for temporal variability and also involving a critical analysis of assumptions in the cometary models. Using a coma model based on ion-molecule chemistry, Ip et al. (1990) reanalyzed the Giotto IMS results for ions with 28 and 29 amu/e⁻, identifying them with H_2CN^+ , and concluded that the production rate ratio $\text{HCN}/\text{H}_2\text{O}$ was $< 2 \times 10^{-4}$.

Disregarding model sensitivities to coma physical parameters, the IMS and millimeter results can only be reconciled if the production rate for HCN varies by a factor of 5, relative to water. Millimeter production rates for HCN did show significant day-to-day variability, and CN emission showed both jets and shells (Schloerb et al. 1986; A'Hearn et al. 1986a; Cosmovici et al. 1988; Schlosser et al. 1986).

A'Hearn et al. (1986a, b) argued that ~ 20 to 50% of the CN was produced from dust, and this is consistent with the retrieved HCN and CN production rates at the accuracy of the retrievals. While it is clear that HCN is present in the nucleus at $\sim 0.1\%$, relative to water, it seems that CN is produced from both gaseous and refractory sources; for an alternative view, see Combi (1987). The millimeter and optical observations represent many observations on a wide range of dates (hence rotational phases), while the IMS retrieval represents the rotational phase at the time of the Giotto encounter. It is not yet clear whether the measurements of Giotto are representative of other rotational phases or not.

N_2 itself has not been detectable spectroscopically in comets, having no allowed vibrational or rotational transitions, and with its first allowed electronic transition ($b^1\Pi_u - X^1\Sigma_g^+$) at 99.5–85.5 nm, below the short wavelength cut-off of IUE and the High Resolution Spectrograph and Faint Object Spec-

trograph instruments of the Hubble Space Telescope (HST). The production rate ratio ($\text{N}_2/\text{H}_2\text{O}$) was found to be <0.15 , based on the mass 14 amu/e^- peak in the IMS spectra on Giotto (Balsiger et al. 1986), and was <0.1 from the mass 28 peak in the NMS (Eberhardt et al. 1987*b*). N_2 was also retrieved from observations of N_2^+ (Wyckoff et al. 1991*b*). The ratio N_2^+/CO^+ was measured in the tail of comet Halley, and the production rate of N_2 was retrieved from the CO production rate using a model in which photo-ionization was the dominant production mechanism for both ions, while the main loss mechanism was dissociative recombination (Wyckoff et al. 1991*b*). The abundance ratio $\text{CO}/\text{H}_2\text{O} = 0.1$ was used to obtain the $\text{N}_2/\text{H}_2\text{O}$ production rate ratio $\sim 2 \times 10^{-4}$. This approach is the most direct one available for N_2 ; however, its accuracy is difficult to assess because the rates for dissociative recombination are sensitive to electron temperatures, and these are not well known.

H. Sulfur Chemistry

Sulfur has relatively high cosmic abundance ($\text{S}/\text{O} \sim 0.02$) and is well represented in dense clouds in both oxidized and reduced forms, but investigation of its chemistry in the cometary nucleus has only recently become tractable. Production rates for S and CS have been retrieved from ultraviolet spectra of several dozen comets since 1976 (see below). S_2 was observed for the first time in any astrophysical source during an outburst in comet IRAS-Araki-Alcock (1983 VII), and its short decay length (~ 300 km) suggested that it sublimated directly from the cometary nucleus (A'Hearn et al. 1983). Its production rate has recently been revised downward to 2.5×10^{-4} , relative to water, based on an improved fluorescence model (Kim et al. 1990).

A'Hearn and Feldman (1985) argued that the S_2 may have been produced by irradiation of ices on interstellar grains, then incorporated into the cometary nucleus. While laboratory simulation experiments for sulfur compounds in an oxygen-free matrix do produce S_2 , those conducted with an oxygen rich matrix (e.g., H_2O ice) often produce more SO than S_2 (Grim and Greenberg 1987*b*). Moore et al. (1988) demonstrated that synthesis of S_2 in oxygen-rich ices also produced significant SO_2 . Kim and A'Hearn (1991) established upper limits for SO and SO_2 in recent comets, including IRAS-Araki-Alcock (1983 VII), for which they found $\text{SO}/\text{S}_2 < 2 \times 10^{-2}$ (<0.6), if SO is treated as a parent (daughter), and $\text{SO}_2/\text{H}_2\text{O} < 8 \times 10^{-7}$. For other comets, $\text{SO}_2/\text{H}_2\text{O}$ is typically $<10^{-4}$ and was $<2 \times 10^{-5}$ in P/Halley. The absence of SO in IRAS-Araki-Alcock appears to rule out models for production of S_2 by irradiation of sulfur-bearing icy mantles on pre-cometary interstellar grains (Kim and A'Hearn 1991). S_2 has not been observed in any other comet, either before or after Iras-Araki-Alcock (the detection in P/Halley reported by Wallis and Krishna-Swamy [1987] has been challenged by Feldman 1991*a*). Russell et al. (1987) suggested that the detection of S_2 in comet I-A-A may have been related to an unusual, nearly radial alignment of the interplanetary magnetic field, permitting solar-wind particles to penetrate much deeper than usual

into the coma. If so, additional sources and excitation mechanisms might be created. The origin and significance of S_2 in comets is still highly uncertain at present.

Cometary H_2S was first detected in comets Austin (1990 V) and Levy (1990 XX) and its abundance was found to be 0.2% relative to water (Crovisier et al. 1991). The discovery spectrum and a partial energy level diagram are shown in Fig. 15. The production rate for H_2S in comet Halley had been obtained from the Giotto Positive Ion Cluster Composition Analyzer (PICCA) ion spectra and was found to be impossibly large (Marconi et al. 1990); however Crovisier et al. (1991) found that an incorrect lifetime was used. With the correct lifetime of 4000 s, the revised abundance is consistent with the values found for Austin and Levy. The abundance of H_2S is about ten times less than the abundance of total volatile sulfur, estimated to be $S/H_2O \sim 0.02$ (Azoulay and Festou 1986). However, the retrieval of total sulfur from IUE observations of atomic sulfur depends on the assumed parent lifetime. Roettger (1991) has established an upper limit (5×10^{-3}) for the sum of measured (H_2S , OCS) and inferred (CS, S_2 upper limit, CS_2 , SO_2) parent species. Because it is not clear that all S-bearing species were counted, the abundance of volatile sulfur is still open to question. Upper limits have been established at millimeter wavelengths for OCS and H_2CS at 0.2% and 0.1% in comet Levy, thus they remain possible significant contributors to the total sulfur budget. CS_2 is a prime candidate, and is likely to be present at the 0.1% level if it is the principal parent of CS (Jackson et al. 1982). However, being linear and symmetric, CS_2 has no allowed pure rotational transitions, so is undetectable at millimeter and far-infrared wavelengths. It is detectable at infrared wavelengths but only from airborne altitudes or higher, as its strong ν_3 fundamental overlaps the ν_2 band of water (near $6.5 \mu m$). The ν_2 band occurs near $25 \mu m$ and might be accessible at favorable sites but the fluorescence efficiency is very small.

Sulfur was detected in grains in comet Halley by the PIA and PUMA instruments on Vega 1 and Giotto with $S/O \sim 0.08$. The bulk ratio in dust and ice in comet Halley was estimated to be ~ 0.035 (Table IV), somewhat higher than the solar abundance ratio (0.02). Jessberger and Kissel (1991) did not include any volatile sulfur compounds in arriving at the bulk S/O ratio, so the S/O discrepancy will be made worse when compounds such as H_2S and CS_2 are included (see Table IV). There is at present no clear approach for detecting sulfur in condensed phase matter in comets, other than by direct sampling.

I. Noble Gases

Owing to their low polarizability, the frosts of noble gases are extremely volatile. They are therefore sensitive "thermometers" of the formation temperature and subsequent thermal history of comets. Although other low temperature thermometers exist (e.g., CO, CH_4 , H_2CO), noble gas abundances are easier to interpret because they are less affected by chemistry. In principle, the maximum temperature experienced by cometary ices can be determined

Figure 15. Discovery of H_2S in comets. Top: Partial energy level diagram for H_2S showing ortho and para levels, and the two rotational transitions observed in comets Austin (1990 V) and Levy (1990 XX). Bottom: Spectra of the $1_{10}-1_{01}$ line measured in comet Austin on UT 24–25 May 1990 (after Crovisier et al. 1991).

from the relative abundances of these temperature sensitive gases. However, the inferred temperature depends also on poorly known physical factors, such as the trapping efficiency of gases in the ice matrix (Bar-Nun and Kleinfeld 1989). The change in relative abundances of noble gases in ices formed at different temperatures has been described (with applications to comets) by Owen et al. (1991).

Noble gases were not identified from *in-situ* measurements of comet Halley. However, searches for noble gases in recent comets were conducted using EUV spectroscopy. Stern et al. (1992) observed the dynamically new comet Austin (1990 V) with a sounding rocket payload in April 1990. Based on the upper limit for the He I resonance line at 58.4 nm, they concluded that the He/O ratio in this comet was a factor of 1.5×10^4 smaller than the solar value. Feldman et al. (1991) observed comet Levy (1990 XX) with the ASTRO-1 Spacelab observatory during December 1990. Unfortunately, the ASTRO-1 observations took place in daylight, and geocoronal emission prevented detection of cometary He I. Also, the instrumental spectral resolution was too low to separate the Ne I 73.6 nm line (observed in second order) from the S I 147 nm line. Weak upper limits were obtained for the cometary Ar and Ne abundances (<5 – 10 times their solar abundances), using O as a standard. As noted by both reports, the interpretation of these results remains open given the ease with which noble gases sublime from the surface and (possibly) diffuse from the interior when the nucleus is warmed, for example, either during its residence time in the Oort cloud or after entering the planetary region (see earlier discussion). The uncertainty in the predicted de-volatilization is due in part to our poor knowledge of the thermal conductivity and microscopic pore structure of the cometary nucleus.

Future abundance determinations for temperature sensitive noble gases (e.g., Ne, Xe, Ar; cf. Table II) may provide useful constraints on the condensation temperature and processing history of cometary ices, and may assist in interpreting the abundances of species that are strongly affected by both chemistry and by temperature dependent fractionation during condensation (e.g., S_2 , N_2 , CH_4 , CO , NH_3 , H_2CO , CH_3OH ; cf. Table I).

J. Nuclear Spin Temperatures

Infrared spectroscopic studies of water vapor in comets Halley (1986 III) and Wilson (1987 VII), were conducted with sufficient spectral resolution to reveal the intensities of individual ro-vibrational lines, and even to measure their velocity profiles (Mumma et al. 1986; Larson et al. 1987; Weaver et al. 1987; Larson et al. 1989). An especially surprising finding was that cosmogonic information may have been preserved in the relative abundances of the nuclear spin species of cometary water (Mumma et al. 1987, 1988a, b; Mumma 1989).

The energy levels for water are organized into two ladders, according to the total value of the nuclear spin ($I = 1$ or 0), corresponding to the ortho- and para- H_2O nuclear spin species (note: "nuclear" in this context refers

Figure 16. Right: Water consists of two noncombining nuclear spin species, ortho and para, with the value of the total nuclear spin $I = 1$ or 0 , respectively. Left: Partial energy level diagram of the water molecule. Ro-vibrational transitions measured in comet Halley are shown by solid lines, while those which must have been present but which were obscured by terrestrial CO_2 are shown as dashed lines (after Mumma et al. 1986).

to sub-atomic structure, not the cometary nucleus). Ortho- and para-water may be regarded as independent and noninteracting species, under normal conditions (see below). The physical orientation of the proton spins is shown schematically in Fig. 16. The measured water lines (Fig. 12) represent the major part of the $(001-000)$ ν_3 water band in comets, but a few additional lines are obscured by CO_2 atmospheric extinction. Transitions observed in comet Halley are represented by solid lines and the inferred transitions by broken ones in Fig. 16. The latter intensities can be inferred from the measured lines using known branching ratios, if the coma is assumed to be optically thin. Infrared optical trapping is not too important for the KAO observations, owing to the large beam diameters used (34,000 km and 20,000 km in Dec. 1985 and March 1986, respectively) (cf. Mumma et al. 1986; Bockelée-Morvan and Crovisier 1987). Some 81% (70% for March 1986) of the sampled molecules lie more than 5000 km from the nucleus, and fewer than 4% (10% for March 1986) lie within the zone where infrared optical depths are significant ($R < 1000$ km).

The abundance ratio of the ortho and para spin species (the OPR) is readily modeled for the equilibrium case, using the defining relation for rotational distribution (Mumma et al. 1987). An ortho-para ratio may be obtained from the measured cometary line intensities by summing the total line intensities for each spin species separately. The ratio of summed intensities is the observed ortho-para ratio, and the nuclear spin temperature may be determined by comparison with the equilibrium case (cf. Mumma et al. 1988a, b). Summing over the intensities is equivalent to summing over the rotational population if all levels are sampled and all lines are measured. Mumma et al. (1987)

summed only over levels sampled directly in the KAO spectra, while Mumma et al. (1988*b*) corrected for several levels whose lines were obscured by terrestrial extinction, by assuming that a single temperature characterized the rotational distribution. The ortho-para ratio and rotational temperature were then retrieved from a nonlinear least-squares analysis of the measured line intensities. A discussion of the approach and its uncertainties is given by Mumma et al. (1988*b*).

The results for comet P/Halley clustered near OPR of 2.5 ± 0.1 , equivalent to a spin temperature of 29 K, even though the conditions of observation were very different and the measurements were separated in time by four months (W. E. Blass and M. J. Mumma, personal communication). Over this time interval, active regions of the nucleus likely eroded by ~ 5 to 10 m (assuming 30% active surface area), and thus the measured values are characteristic of the ensemble average spin temperature for a range of depths and surface areas of Halley's nucleus. Comet Wilson, however, showed an OPR of $\sim 3.2 \pm 0.2$, which is consistent with thermal equilibrium at temperatures > 50 K (Mumma et al. 1988*b*).

Bockelée-Morvan and Crovisier (1990) applied a much more sophisticated model for formation of cometary water lines, and were able to fit the KAO line intensities for P/Halley with OPR of 3 when opacity effects were included, indicating thermal equilibrium at > 50 K. However, the same model applied to comet Wilson returned OPR of 3.9. The meaning of the latter result is not clear, because there is no known mechanism for producing a ratio > 3 (technically, this would be a spin "maser"). The retrieved ortho-para ratios for both comets were substantially lower when opacity effects were neglected, and the value for Halley post-perihelion (2.5) then agreed with the result of Mumma et al. (1988*b*), and the line-by-line intensities were satisfactorily reproduced. However, although the pre-perihelion result (OPR = 2.5) also agreed with Mumma et al. (1988*a*), the retrieved rotational temperature was lower than that demonstrated by the KAO spectra and the modeled line-by-line intensities were not in good agreement with the KAO spectra. The ortho-para ratio for Wilson (3.65) still substantially exceeded that of Halley. As the water production rates for comet Wilson were comparable to those for comet Halley pre-perihelion, and both were much smaller than for comet Halley post-perihelion, it is unlikely that opacity effects can explain the large difference found for the ortho-para ratios, which is evident even in the individual spectra.

Several aspects of the optically thick model may need further development; for example, the use of the escape-to-space approximation has not yet been verified for cometary comae, and electron collisions should be included. Xie and Mumma (1992) showed that electron collisions dominate rotational excitation of water in the intermediate coma of comet Halley (the region sampled most efficiently by the KAO spectra), increasing the distance for which the rotational states are in equilibrium and lending additional strength to the LTE assumption. In any event, both groups find that the ortho-para ratio for

comet Wilson differs significantly from that of comet Halley, and the fact that they differ is not dependent on model assumptions. A possible interpretation of this difference is discussed below.

Conversion between the spin species is an exceedingly unlikely process, requiring a strong nonuniform magnetic field, such as might be experienced by collisions with a paramagnetic species. Although spin species conversion is poorly studied for water, the data that do exist suggest very long conversion times (see Mumma et al. 1988*b*). Better data exist for molecular hydrogen, and we may employ this as an analog. Theoretical studies of gaseous molecular hydrogen demonstrate a radiative conversion time ($\sim 10^{20}$ s) exceeding the age of the universe, and laboratory studies confirm a collisional half-life of 3 yr at STP ($\sim 2 \times 10^{17}$ collisions) (Dodelson 1986; Farkas 1935). The conversion time is reduced significantly if a paramagnetic collision partner is introduced (e.g., O₂, NO, Pt), and this approach has been used to prepare laboratory samples of pure para-hydrogen. Once prepared, however, the para-hydrogen may be stored separately, and will retain its relaxed spin temperature for an indefinite period. In laboratory ices, spin conversion proceeds slowly for H₂ (even at temperatures as low as 10 K) because migration of ortho-H₂ enables ortho-ortho collisions, thus providing the required asymmetric magnetic field (cf. Silvera 1980). Amorphous water ice is weakly hydrogen bonded, however, and this will likely prevent migration of ortho-water molecules, thus inhibiting spin conversion in low temperature cometary ice.

Spin relaxation has now been found in astrophysical systems for several phases related to formation of planetary systems. In regions of bi-polar outflow from young stellar objects, the spin temperature for H₂ is typically ~ 100 K (corresponding to formation on grains at a temperature ~ 65 K (cf. Takayanagi et al. 1987; Hoban et al. 1991*b*). Minh et al. (1991) found relaxed ortho-para ratios for H₂CS in several dense cloud cores (e.g., TMC-1, where $T_{\text{spin}} \sim 15$ K, comparable to the kinetic temperature), while Madden (1990) found cyclopropenylidene (C₃H₂) to be relaxed in Orion KL. However, ketene (CH₂:CO) is not relaxed (W. M. Irvine, personal communication). The mechanism responsible for relaxation is not yet certain, and the different behavior exhibited by ketene is not understood.

Mumma et al. (1988*b*) have suggested that the spin temperatures found for Halley and Wilson may be cosmogonic. The water now released by the active regions in comet Halley may have been last processed as an ice on grains at a temperature of ~ 29 K, then incorporated into cometesimals and buried deep within the original nucleus, where the overburden protected it from cosmic-ray damage. The outer layers of the nucleus experience significant processing while in the Oort cloud, as discussed earlier in this chapter, and this (particularly radiation processing) would reset the ortho-para ratio to the high temperature limit. Thus, a dynamically new comet (e.g., Wilson) might be expected to show a statistically equilibrated ortho-para ratio (i.e., 3 for H₂O). Johnson (1991) has modeled radiation damage for the outer layer of new comets, and estimates that more than 30% of the chemical bonds have

been altered in this way. He argues that hydrogen atom exchange could be an efficient mechanism for spin-species alteration in new comets.

K. Elemental and Isotopic Abundances

Elemental abundances can be deduced by summing the contributions identified in gaseous and refractory progenitors. For example, Wyckoff et al. (1991*b*) examined the abundance of volatile nitrogen and argued that it is deficient in Halley, relative to solar abundance. The heavy elements in grains were discussed by Jessberger et al. (1988) and Jessberger and Kissel (1991). With the exception of H (deficient by ~ 650 fold), N (deficient by ~ 3 fold), and Fe (deficient by ~ 2 fold), all total elemental abundances appear to be solar, to within model and measurement accuracy (Table IV, see Jessberger and Kissel 1991; Wyckoff et al. 1991*b*; cf. the discussion of total sulfur in Sec. IV.H).

However, extrapolations of cometary ensemble averages are subject to uncertainties, such as: (1) the use of unverified models to retrieve a parent abundance from the observed species (e.g., N_2 from N_2^+ , CO from CO^+); (2) the assumption that all significant reservoirs have been tallied; and (3) the inability to measure directly production rates for certain key atoms (e.g., the resonance line of N near 120 nm is difficult to separate from H Lyman α at 121.6 nm with moderate resolution spectrometers, such as that on IUE). Further discussion exceeds the scope of this chapter, and the reader is referred to the excellent reviews which already exist on this topic (cf. Delsemme 1991) and to the sources already cited.

Along with the gross chemical identities of the cometary volatiles, the abundances of their isomeric and isotopic variations should provide key information on the conditions of volatile formation and subsequent processing. Isomeric and isotopomeric studies are well advanced for interstellar molecular clouds, and recent reviews of cloud observations and cloud chemistry have been provided by Irvine and Knacke (1989) and Turner (1989*c*) (see also Chapter by van Dishoeck et al.). Considering that detections of most cometary parent volatile species post-date 1985, it is perhaps not surprising that their isomers (e.g., HNC) have yet to be detected. Swade et al. (1986) reported $HNC/HCN < 0.3$ in comet Halley. As detection capabilities improve, this may well become a fruitful line of investigation.

Isotopic ratios have been regarded as relatively less subject to interpretational difficulties, but measurements require both very high sensitivity and very high resolution. The only ratio measured in comets prior to comet P/Halley was $^{12}C/^{13}C$ in C_2 . The derived cometary ratios were consistent with a solar system value of 89, except for comet West (1976 VI), for which Lambert and Danks (1983) found somewhat lower values (50 ± 15 , 60 ± 15). The value of $^{12}C/^{13}C$ was measured in CN and was found to be 89 ± 17 in comet Halley (Jaworski and Tatum 1991). The lower value for Halley reported originally by Wyckoff et al. (1989) (65 ± 9) has been revised recently (100 ± 15)

as a result of improved analytical procedures (S. Wyckoff 1991, personal communication). Thus, $^{12}\text{C}/^{13}\text{C}$ in CN is consistent with solar abundance.

The interpretation of isotopic ratios in molecular fragments like CN and C_2 must be approached with care. About 20 to 50% of the CN in the coma was produced in jets (A'Hearn et al. 1986a). These jets are not congruent with the jets seen in the optical continuum (A'Hearn et al. 1986b), and are possibly associated with the CHON carbonaceous grains discovered in comet Halley (Krueger and Kissel 1987; Kissel and Krueger 1987). The CHON grains show a wide range of $^{12}\text{C}/^{13}\text{C}$ ratios, although some uncertainty in the ^{13}C retrieval is introduced by the coincidence with CH at mass 13 (Jessberger et al. 1988). Wyckoff et al. (1989) discounted the refractory source of CN and suggested that their earlier value (65 ± 9) was inconsistent with formation of cometary nuclei in the Uranus-Neptune region. However, Krankowsky and Eberhardt (1991) demonstrated that the claimed enrichment (note: since revised, see above) in ^{13}C in CN could originate entirely from the refractory source. A solar $^{12}\text{CN}/^{13}\text{CN}$ ratio can be accommodated by reducing the fraction of ^{13}CN contributed by grains, however, this only emphasizes the lack of uniqueness in the interpretation. Thus, even with a solar ratio for $^{12}\text{CN}/^{13}\text{CN}$, the isotopic ratio in the volatile source of CN is unresolved at present. As the volatile parent of CN is a minor constituent (e.g., HCN is $<0.1\%$, relative to water), the interpretation of $^{12}\text{C}/^{13}\text{C}$ in volatile carbon in comets also requires measurements on the major carriers (CO , CO_2 , CH_3OH , H_2CO , etc.).

More definitive results were obtained for D/H, in the form of the following: $\text{H}_2\text{DO}^+/\text{H}_3\text{O}^+$. Eberhardt et al. (1987b) found the number ratio for D/H to be within the range 0.6 to 4.8×10^{-4} , which exceeds the local interstellar value significantly but agrees with the values found in molecular cloud "hot cores," as discussed in Sec. V (Fig. 17). It is larger than the values for the proto-Sun, Jupiter and Saturn (all bodies that received their hydrogen in the form of nebular H_2), while it is comparable to values for Uranus, Neptune, Titan and the Earth (seawater is 1.6×10^{-4}), bodies that are believed to have acquired their hydrogen in the form of water ice and/or hydrated silicates (for the Earth). The D/H ratio found in comet Halley thus supports the idea that Earth's ocean water may have been contributed by cometary impact. The cometary D/H value also suggests that the water in comet Halley did not re-equilibrate with H_2 , the principal reservoir of hydrogen in the solar nebula. Grinspoon and Lewis (1987) argued that the time scale for such equilibration exceeds the estimated lifetime of the solar nebula. It would therefore appear that the D/H ratio in cometary water was established in the natal dense cloud core (see later discussion). The value retrieved for isotopic oxygen was $^{18}\text{O}/^{16}\text{O} = 0.0023 \pm 0.0006$, in agreement with the terrestrial value (0.00205). The ratio $^{15}\text{N}/^{14}\text{N}$ in CN in comet Halley is also typical of solar system values (Wyckoff et al. 1989). A good review of isotopic compositions appears in Vanysek (1991).

At this writing, the isotopic measurements support a common origin for

Figure 17. A comparison of the D/H ratios for solar system bodies. The value found for comet Halley significantly exceeds values in the diffuse interstellar medium (ISM) and solar nebula, but is consistent with values found for water in molecular cloud "hot cores" (see Sec. V), and with values measured for solar system bodies that acquired their volatile inventory in the form of ices. The x's superimposed on the Uranus and Neptune results are the predictions of an accretion model in which pre-planetary ices are assumed to be enriched in deuterium to the SMOW level by condensation fractionation, and nebular H_2 is disproportionately captured by the growing protoplanets (Hubbard and MacFarlane 1980b) (adapted from de Bergh et al. 1990).

the ices in comet Halley, and for solar system bodies that acquired their hydrogen in the form of ices.

V. SYNTHESIS

From a chemical perspective, there are three important questions regarding the composition of cometary nuclei. First, are the mean chemical abundances consistent with interstellar composition, or do they require some degree of processing (e.g., reduction or isotopic exchange) either in the solar nebula or after incorporation into the final cometary nucleus? Second, is the nucleus chemically homogeneous or heterogeneous, and if the latter, is that heterogeneity natal or derived? Third, are there important differences between comets that result from their mode and site of origin? We have reviewed the chemistry of cometary nuclei, and have assembled a typical cometary composition in Table I (see also Tables IV, V). However, an impressive array of evidence is accumulating in support of the idea that comets exhibit both intra- and inter-nuclear heterogeneity. The ratio of total production rates for dust and gas varies strongly from comet to comet, as do the production rates of some trace volatiles relative to water. The variability in the dust/gas ratio may also be related to surface processing and to received insolation, however, and must be evaluated at a uniform heliocentric distance to remove temperature dependence. These effects must be considered along with cosmogonic differences. CO may vary strongly from comet to comet, and measurements of H_2CO and of CH_3OH in recent comets suggest that they also exhibit intra- and inter-nuclear variability. The former (CO) may be related to variation in the condensation temperature of pre-cometary ices or its thermal history after formation, while the latter (H_2CO , CH_3OH) may reflect varying degrees of processing prior to incorporation into the nucleus.

Several lines of evidence indicate the presence of macroscopic internal heterogeneity in comet Halley (Table VII). The relative production rate for formaldehyde varied more than ten fold in March and April 1986, and the positive detections corresponded with only one of the three peaks revealed in the lightcurves for the species CN, C_2 and NH. This region was active during both the Vega 1 and Giotto encounters (but not during Vega 2), suggesting that the spacecraft data should be re-examined from the perspective of revealing macroscopic chemical heterogeneity in the nucleus. Other notable evidence includes the CO_2 -rich outburst observed by Feldman et al. (1986), and the unusual outburst of March 20 observed in H_2O and other species (cf. Larson et al. 1990). The latter outburst occurred during direct measurements of water at infrared wavelengths, and it more than doubled the water content of the inner coma. Larson et al. (1990) suggested that the latent heat released by conversion of amorphous ice to the crystalline form may have provided the required energy. This is consistent with the view that the ices in comet Halley formed at low temperatures, perhaps in the outer reaches of the solar nebula (beyond the orbit of Jupiter) or in the interstellar medium, and that

TABLE VII
Evidence Supporting Macroscopic Heterogeneity
in the Nucleus of Comet Halley

Short-Term Variability	
Diurnal Activity	
H ₂ CO	Mumma and Reuter 1989
Outbursts	
Dust	e.g., Russell et al. 1986
H ₂ O (Amorphous?)	Larson et al. 1990
CO ₂	Feldman et al. 1986
Pre-Post Perihelion Asymmetry	
Organics Feature	e.g., Danks et al. 1987
Possible Explanations:	
Cosmogony:	
Chemically distinct icy planetesimals, (some) 50 to 70 m diameter	
Formed in different regions of solar nebula or interstellar medium	
Gravitational diffusion in solar nebula	
Agglomeration into final nucleus	
Post-Accretional Processing:	
Thermal migration of chemical species within nucleus	

the pre-cometary ices in comet Halley were not later processed at elevated temperatures during infall in the solar nebula. Further, comet Halley could not have spent significant time in an orbit with insolation high enough to trigger amorphous-to-crystalline conversion throughout the nucleus. The exothermic conversion of amorphous ice to the crystalline form may expel excess trapped gas, whose accumulation in pockets could drive some outbursts (Prialdnik and Bar-Nun 1987), but comet Wilson did not show such outbursts. However, the repetitive production of formaldehyde from only one of several active regions on the nucleus of comet Halley would appear to require macroscopic heterogeneity.

The "mean" chemical abundances may also be examined in the context of either a solar nebula or interstellar origin for cometary material. Table VIII summarizes certain key indicators, discussed in detail earlier. The evidence at present supports the presence of pre-solar volatiles, as found in dense molecular cloud cores, and of low-temperature refractory organics in cometary nuclei. Thus, it appears that any successful model for cometary formation must account for the absence of significant processing of pre-cometary material in the

TABLE VIII
Some Key Indicators of the Nature of Cometary Material

CO:	Variable abundance consistent with condensation near 25–50 K.
H ₂ O:	Enriched D/H consistent with unmodified interstellar material (UIM) ^a . Low spin temperature in Halley consistent with UIM. High spin temperature in Wilson consistent with cosmic ray damage.
HCN:	Abundance much higher than expected for inner solar nebula or giant planet sub-nebulae; consistent with UIM.
H ₂ CO:	Abundance much higher than expected for inner solar nebula or giant planet sub-nebulae, but near that for UIM. Polymer not expected for solar nebula origin.
¹² C/ ¹³ C:	Value in CN is consistent with solar abundance ratio. The ratio in CHON grains is highly variable, as in primitive meteorites, and demonstrates that the grains are chemically disequilibrated. Consistent with stellar and interstellar origin for the grains. It is not known whether the solar nebula could produce similar effects.
NH ₃ :	Low abundance (0.2% or less) consistent with UIM.
CH ₄ :	Low abundance (0.2% or less) consistent with UIM.
CH ₃ OH:	Abundance consistent with UIM, but not with processed material from the solar nebula.
N ₂ /NH ₃ :	Ratio consistent with UIM.
CO/CH ₄ :	Ratio consistent with UIM.
S ₂ :	Inconclusive. Detected in only one comet, but not certain whether S ₂ is native to the nucleus or is a secondary product.
CHON:	Easily destroyed, unique chemistry favors UIM.
Outbursts:	Significance not yet clear. Could represent either heterogeneous accretion, or thermal processing of nucleus.

^a By "unmodified interstellar material" (UIM) we mean that the observed quantity is consistent with values found in dense molecular clouds, implying little or no subsequent processing in the solar nebula prior to incorporation into the cometary nucleus. For example, an abundance would be similar to those found in interstellar ice, and a temperature would be similar to those found in dense cloud cores.

solar nebula and giant planet sub-nebulae. Several key indicators point to an interstellar composition, unmodified by processing in the solar nebula. These include evidence for the low nuclear spin temperature for water in Halley, the presence of easily destroyed CHON particles and of HCN, the presence of

both H_2CO and CH_3OH , the presence of substantial CO but of virtually no CH_4 , and the virtual absence of NH_3 . However, the heterogeneity (in H_2CO) revealed by comet Halley may indicate the presence of chemically distinct bodies within the nucleus, and this could be the signature of heterogeneous aggregation. Gravitational scattering by the giant protoplanets will cause radial diffusion of cometesimals formed in different regions of the solar nebula, possibly resulting in aggregation of chemically distinct icy bodies into a single final cometary nucleus.

The D/H ratio (in $\text{H}_2\text{DO}^+/\text{H}_3\text{O}^+$) is distinctly higher in comet Halley than it is in solar system bodies that acquired their hydrogen mainly in the form of nebular H_2 (e.g., Jupiter, Saturn, the Sun), and it significantly exceeds the value in the local interstellar medium. However, D/H is often enriched in trace species in dense molecular cloud cores (Irvine and Knacke 1989), and so the value in comet Halley could reflect fractionation through ion molecule processes in the natal cloud. The high D/H value in Halley demonstrates that its water was never re-equilibrated with the principal reservoir of hydrogen (H_2 , HD) in the solar nebula. Re-equilibration with H_2 in the solar nebula is kinetically inhibited though, so the D/H ratio does not test the question of vaporization of icy mantles from infalling grains.

The gas phase abundances in “hot cores” of giant molecular clouds are quite different from those found in cold dense clouds (where volatile species reside in both vapor and condensed phases), and are thought to reflect evaporation of icy mantles from interstellar grains (cf. Brown and Charnley 1990; Chapter by van Dishoeck et al.). Abundances in hot cores may thus be directly comparable to cometary ices. Jacq et al. (1990) measured the $\text{HDO}/\text{H}_2\text{O}$ ratio in the hot cores of several giant molecular clouds. Using the standard rotation diagram approach for estimating column abundances in four clouds having the best quality data, they obtained values ($\text{HDO}/\text{H}_2\text{O}$) of 3 to 6×10^{-4} . However, it is not certain that the measured lines are optically thin, and so Jacq et al. also presented abundance ratios obtained from lines having similar excitation energies and frequencies. In this case, the abundance ratios ($\text{HDO}/\text{H}_2\text{O}$) were larger by factors of 2 to 3.

The D/H ratios in hot cores, as retrieved from the first method (1.5 to 3×10^{-4}) are consistent with the value found in comet Halley (0.6 to 4.8×10^{-4}) and are about ten times larger than the values found for the local interstellar medium. A rigorous comparison must await more accurate analysis of the Halley NMS data (in progress, P. Eberhardt, personal communication) and further evaluation of the question of spectral line formation in hot molecular cloud cores. We cannot exclude the possibility that the D/H ratio in comet Halley may be a typical value for condensed phase water in dense molecular cloud cores, and may not be unique to our solar system. Given that, we cannot absolutely conclude that Halley is of “solar system” origin, as compared with the capture scenario, though capture remains a very low probability event and cannot yield the population of the Oort cloud. However, all isotopic evidence

(including D/H) in comet Halley is consistent with an origin as a member of our solar system.

The presence of H₂S and CO in cometary nuclei is consistent with formation of cometary ices at temperatures likely <60 K (cf. Table I). The low spin temperature for water in comet Halley (if Mumma et al. [1988*b*] are interpreting it correctly) suggests that water was last processed at ~29 K, and this low temperature would also be consistent with direct condensation of CO (~25 K). However, CO can also be trapped at ~7% relative abundance by condensation from a vapor-phase mixture of CO and water at ~50 K. The presence of N₂, the presumed parent of N₂⁺, also supports a low condensation temperature (~22 K) if it condensed directly. However, it is not known whether N₂ can be trapped at higher temperatures, as CO is. Thus, the present evidence supports the formation of cometary ices at temperatures below ~60 K, and possibly as low as 20 to 30 K. If these represent physical temperatures in the solar nebula, they imply that cometary ices formed at distances greater than ~20 AU from the Sun.

Our understanding of the formation of comets in the Uranus-Neptune zone is complicated by our poor knowledge of the formation of icy planetesimals in that region, and poor understanding of the formation of Uranus and Neptune themselves. Solar-system formation studies have tended to focus on the formation of the terrestrial planets and the problem of forming Jupiter and Saturn prior to dispersal of the nebular gas. However, if we allow that icy planetesimals of cometary dimensions did form in the Uranus-Neptune zone, and that some accreted to form those two outer planets, then the ejection of comets to the Oort cloud follows as a natural dynamical consequence of this process. Furthermore, several researchers (see, e.g., Safronov 1972) have argued that an initially much larger mass of icy planetesimals was necessary in the Uranus-Neptune zone to provide sufficient initial surface density to decrease the formation times for those planets to a value less than the age of the solar system. The extra material was dynamically ejected, either to the Oort cloud or to interstellar space. Estimates of the total mass and angular momentum of comets in the Oort cloud are fully consistent with ejection from the outer planet zone. The failure to observe interstellar comets passing through the solar system raises questions about the ubiquity of cometary formation around other stars, but the uncertainties in the calculations are too great to make any definitive conclusions in this regard.

If the long-period comets originated in the Uranus-Neptune zone, and if the short-period comets also originated there, or in the Kuiper belt region just beyond, then what conclusions can be drawn about processes in that region of the solar nebula? Given the close identity of cometary materials with their expected pre-solar state in dense molecular cloud cores, it would seem that very little reprocessing went on in the solar nebula at distances of ~20 AU or greater. Infalling material was apparently decelerated gently, perhaps across only a weak shock, with little heating, and icy mantles on interstellar grains may have been preserved. Temperatures may have been even lower than

predicted by Hayashi (1981) or Cameron (1978a) (Fig. 2). Compared with most models for the inner nebula, the solar nebula at 20 AU was a fairly benign environment.

Formation of comets at much larger distances in the solar nebula, on the order of several thousand AU or more, is also consistent with the compositional evidence presented in this chapter. However, the detailed dynamics of that formation are so poorly defined that it is difficult to give much credence to such hypotheses. If detailed examination of cometary materials continues to argue for an unprocessed pre-solar composition, then this may provide sufficient impetus to better quantify the details of possible cometary formation at larger heliocentric distances.

Figure 18. Four suggested models for the structure of cometary nuclei. Top left: the icy conglomerate model (Whipple 1950; drawing from Weissman and Kieffer 1981); top right: the fractal model (Donn et al. 1985); bottom left: the primordial rubble pile (Weissman 1986a); and bottom right: the icy-glue model (Gombosi and Houpis 1986). All but the icy-glue model were suggested prior to the Halley spacecraft encounters in 1986.

The internal structure of cometary nuclei is very uncertain (see reviews by Keller 1990 and Rickman 1991). A variety of models have been suggested (Whipple 1950; Donn et al. 1985; Weissman 1986a; Gombosi and Houpis 1986) and several of these are illustrated in Fig. 18 (from Weissman 1986b). The current consensus is that nuclei are weakly bonded, fractal assemblages of smaller icy-conglomerate planetesimals, possibly “welded” into

a single nucleus by thermal processing and sintering. Dynamical scattering of planetesimals by the outer planets may have resulted in mixing of bodies formed at different heliocentric distances in the solar nebula, and hence, in different temperature regimes. These different regimes may be reflected in compositional differences between the fragments making up each cometary nucleus.

Figure 19. A schematic view of the various processes that cause comets to evolve. Effects shown on the left are driven by thermal- and photo-processing during perihelion passages in the planetary region. Effects shown on the right are due to processes which take place in the Oort cloud (after McSween and Weissman 1989).

Several processes are thought to cause cometary evolution in the Oort cloud (Fig. 19). How do these various evolutionary processes interrelate? Clearly, collisions with Oort cloud debris and erosion by interstellar grains compete with irradiation and heating damage. One expects irradiation and impact processes to make cometary surfaces more dense, in turn enhancing the efficiency of erosion and thermal wave penetration. One also expects the most severely heat- and radiation-damaged crust to be removed by interstellar grains. The erosion mechanism could be tested by obtaining cosmic-ray exposure ages for surface material from a new comet. Because radiation damage is a continual process while erosion is episodic, an anomalously young exposure age is expected. The record of earlier supernova damage should also be missing, unless the most recent nearby supernova heating pulse came since the last erosional encounter with a dense galactic cloud (i.e., within the past 300 Myr). However, because the heat wave from encounters

with passing O-type stars would likely penetrate to much greater depths than can be removed by interstellar grain erosion, some thermal damage is expected in all comets (unless the actual surface diffusivity is so low as to limit the heating to a very thin layer near the surface).

No detailed, quantitative model has been attempted for a cometary surface undergoing the full suite of Oort cloud processing mechanisms. Although such a model would be instructive, the present lack of knowledge about the physical properties and conditions on and under cometary surfaces prevents such a detailed description from being profitably carried out. Perhaps a more useful route would be to perform laboratory experiments simulating irradiation, interstellar grain bombardment, and stellar heating on the same cometary surface analog. Among the most interesting results anticipated from such an experiment would be the degree of interactive effects between the various processes. One wishes to know, for example, if hypervelocity impacts of interstellar grains result in a net *erosion*, or instead in a net *accretion* of material on the nuclear surface. Similarly, one wishes to know the penetration depth of a simulated supernova or O-star thermal wave after irradiation and interstellar grain bombardment has reworked the surface. Although we now know that comets are evolved from their formation state, it is important to stress the comparative subtlety and low rate of evolution experienced by objects in the Oort cloud. By obtaining an understanding of the processes which serve to modify cometary surfaces in the Oort cloud, we are better equipped to interpret both cometary behavior and cometary samples. Still, comets are almost certainly the best preserved samples from the epoch of planetary formation. In comparison to evolutionary time scales on planetary surfaces, cometary modification is slow and modest, indeed. Owing to the cold and rarefied environment of the Oort cloud, the cometary reservoir is a very quiet (though not silent) place. At least while the Sun remains on the main sequence, the Oort cloud will likely remain the most benign evolutionary environment in the solar system.

Future remote sensing of comets can be employed both to determine the degree of processing by radiation and by heating, and to refine model predictions. For example, CO, N₂, CH₄, Ar, S₂, and Ne should be depleted in the outer layers of new comets, due to thermal processing in the Oort cloud, while the ratios of less volatile species (e.g., CH₃OH, H₂CO) may be influenced more strongly by radiation processing than by thermal effects. From abundance ratios, it should be possible to estimate the maximum processing temperatures experienced. However, the provisional detection of CH₄ in the dynamically new comet Wilson, coupled with much lower abundances in one short-period comet (P/Halley) and one returning long-period comet (Levy 1990 XX), is consistent with enhancement of CH₄ in the outer layers of Oort cloud comets.

The spin temperatures of ices in the surface layer of new comets may also be related to radiation processing in the Oort cloud. The results for Halley and Wilson are most easily explained by the reset of spin temperatures

in radiation-processed material in new comets while their interiors remain protected, preserving the spin temperature at which the ice was last processed (prior to accretion into the nucleus). The low spin temperatures in P/Halley are consistent with temperatures in dense cloud cores, suggesting that the H_2O ice in comets was last processed in the interstellar medium. The hypothesis of the ortho-para ratio as a cosmogonic indicator is testable. Measurements are needed on other comets, and observations from space would permit access to the entire ν_3 band, thereby reducing the sensitivity of the retrieved ortho-para ratio to modeling uncertainties. Extension to other molecules with nuclear symmetry (e.g., H_2S , CH_4 , NH_3 , H_2CO and H_2CS) is an obvious objective.

Our capabilities for remote characterization of cometary composition are still expanding rapidly. Infrared searches of comets Austin and Levy in 1990 were carried out with cryogenic grating and Fabry-Perot spectrometers and these provided detections of CH_3OH and possibly CO , and sensitive upper limits for H_2CO and CH_4 . Instrumental sensitivities are improving rapidly, and detections should become routine now that higher-resolution echelle spectrometers equipped with large format array detectors have become available. Similar advances at millimeter wavelengths led to the detections of HCN , H_2S , H_2CO and CH_3OH , and to sensitive upper limits for OCS , SO_2 , H_2CS and HC_3N . Detections of additional molecular species are likely.

The two approaches provide complementary information. Infrared observations permit spatial mapping at high spatial and temporal resolution, of both polar and nonpolar molecules. Their relatively broad spectral grasp permits measurement of the entire ro-vibrational band simultaneously, thereby retrieving the rotational distribution. This complements the intensity measurements of individual spectral lines obtained at millimeter wavelengths (albeit with larger beam sizes). The millimeter range is useful for polar species, and is less subject to spectral confusion for C-H bearing compounds as compared with infrared measurements. Ultra-high velocity resolution is easily achieved at millimeter wavelengths, permitting measurement of intensity profiles of individual spectral lines and thus providing direct measurements of the kinematics of the coma. These velocity fields are crucial to the retrieval of production rates from observations made with small beams in other spectral domains.

Similar major advances are expected when the sub-millimeter wavelength range becomes available for cometary studies, and indeed that field was recently opened with the detection of H_2CO in comet Levy at sub-millimeter wavelengths. Already the most sensitive probe of SO and of noble gases, ultraviolet observations can be expected to play an increasingly important role in direct detection of parent volatiles, as higher spectral resolution (e.g., with HST) and observations at extreme ultraviolet wavelengths become routine. Future remote sensing should provide new insights into the composition and processing history of individual comets, and will permit the development of a taxonomy for comets.

However, many key questions can only be addressed definitively by mea-

surements made *in situ*. For the cometary nucleus, these include fundamental properties such as the porosity, tortuosity, and mean density; the surface thermal conductivity and its variation with depth; the degree of compositional differentiation with depth and with lateral position; the nature of the inactive surface material; and the detailed physical, thermal, chemical and mineralogical structure of the nucleus. Once these properties are known, the nature of the cometary accretion process and of subsequent evolutionary processes can then be inferred more clearly.

Microscopic investigations of individual cometary grains are required for many key investigations and these can best be accomplished from spacecraft near the cometary nucleus, or in terrestrial laboratories after return of cometary samples to the Earth. These studies would provide the relative abundances of pristine interstellar dust and of refractories processed in the inner solar nebula, key indicators of the history of cometary material prior to accretion of the cometary nucleus. Such direct studies could also establish the identities and abundances of pre-biotic chemicals, including (possibly) the simple amino acids, which are critical for understanding the role of comets in delivering these materials to the early Earth. In comets, most of these organics are locked in the grains, and cannot be identified remotely. The need for direct sampling and analysis can be appreciated by noting that more than 500 distinct organic compounds have been isolated from the Murchison meteorite alone. Direct sampling and analysis of cometary volatiles are also needed. Production rates for some of the more abundant volatile species can be obtained from remote sensing, but several of the more important ones are inaccessible (e.g., N_2) and many trace species will be missed entirely because of inadequate sensitivity of Earth-based instruments. While Earth-based studies may identify macroscopic chemical heterogeneities of the nucleus, their detailed spatial distribution on the nucleus can only be accomplished from a close-orbiting spacecraft which can sample and analyze the outflows from individual activity sites, and can supplement these with maps of surface composition.

There is also considerable interest in the physical processes that affect cometary material as it flows outward in the coma. The complex processes that occur there are still poorly understood. Direct measurements of parent molecules and their destruction products will help to clarify our understanding of the chemical kinetics and hydrodynamics of the coma, while measurements of plasma properties will lead to improved understanding of the interaction between the coma and the solar wind. This understanding can then be extended to remote observations of comets, leading to an improved ability to interpret the cosmochemical record encoded in them.

In-situ analyses will provide a major advance for both refractory and volatile material, but ultimately cometary material must be returned to Earth and subjected to a full suite of diagnostic investigations in terrestrial laboratories. These will provide an unbiased inventory of all significant constituents and will permit direct investigations of minor volatile and refractory components, including abundance measurements for isotopomers. Other key

parameters will then be open to study, too. For example, radiation exposure ages of bulk samples may be compared with formation ages of processed refractories (obtained by rhenium-osmium dating, for example). In this way, it may be possible to date the epoch of nucleus formation, and to constrain accretion times for cometary nuclei during the formative phase of the solar system.

Several *in-situ* investigations of comets are planned. The Giotto spacecraft (Reinhard 1987) is scheduled to fly by a second short-period comet Grigg-Skjellerup on 10 July 1992. The surviving instrument complement (which does not include the multicolor camera) will emphasize characterization of the solar wind interaction with the cometary coma. The Comet Rendezvous Asteroid Flyby (CRAF) mission would place a spacecraft in orbit about a short-period comet and would conduct detailed investigations of the nucleus and coma over a period of three years, from its dormant phase near aphelion throughout its most active phase near perihelion (Weissman and Neugebauer 1992). CRAF was approved for a New Start by NASA in 1989, but it was terminated in 1992 for budgetary reasons. Given the potential benefits to studies of solar system origin, the loss of the cometary science results from the CRAF mission is a significant setback. Attention now is focusing on the Rosetta mission, in which an intact sample of cometary material would be returned to Earth for detailed analysis (Schwehm and Langevin 1991). Rosetta will seek to obtain a core sample from a cometary nucleus, along with samples of crustal material and perhaps a pristine sample from deep within the nucleus. Rosetta is now being studied jointly by NASA and ESA.

Future physical and dynamical studies will continue to test the various hypotheses of cometary formation. At present, the weight of evidence and physical plausibility favors cometary formation from relatively unmodified interstellar material, and the low temperatures inferred would place the region of accumulation in or just beyond the Uranus-Neptune zone of the solar nebula. However, it would be imprudent to extrapolate the findings obtained for a few comets to sweeping conclusions on the general cometary population. Remote compositional studies of many comets, combined with detailed direct examination (both *in situ* and through sample return) of cometary materials from a few, are needed to clarify the true formation site(s) and mechanisms of cometary nuclei, and to identify the evolutionary processes that affected this material before and after its incorporation into the cometary nucleus.

MAIN-SEQUENCE STARS WITH CIRCUMSTELLAR SOLID MATERIAL: THE VEGA PHENOMENON

DANA E. BACKMAN

NASA Ames Research Center

and

FRANCESCO PARESCÉ

Space Telescope Science Institute

Solid grains with temperatures of 50 to 125 K and fractional bolometric luminosities (L_{grains}/L_*) in the range 10^{-5} to 10^{-3} were found early in the IRAS mission around three nearby A main-sequence stars, α Lyrae (Vega), α Piscis Austrinus (Fomalhaut), and β Pictoris. Spatial resolution of the emission indicates that: (1) the grains are larger than interstellar grains; (2) the material probably lies in disks in the stellar equatorial planes; (3) the disks extend to distances of 100 to 1000 AU from the stars; and (4) zones a few tens of AU in radius around the central stars are relatively empty. The total mass included in the small grains in each case is only 10^{-3} to $10^{-2} M_{\oplus}$ although more mass could be in undetectable larger bodies. Subsequent surveys of IRAS data reveal more than 100 main-sequence stars of all spectral classes having unresolved excesses with similar temperatures and fractional luminosities to the three prototypes. Some stars with excesses have estimated ages of 1 to 5 Gyr. Thus, main-sequence far-infrared excesses appear to be widespread and are present in systems old enough to be probably past the stage of active planet formation. The sizes of these disks correspond most closely to the hypothetical Kuiper disk reservoir of short-period comets that is supposed to lie in the ecliptic plane just outside the planetary region of our solar system.

I. INTRODUCTION

Expecting to obtain routine calibration observations of α Lyrae during the first months of 1983, IRAS science team members instead found a powerful source of far-infrared radiation an order of magnitude brighter than the emission from the star's photosphere at wavelengths of 60 and 100 μm . Turning to other stars, they discovered several more with similarly strong excesses. Initial studies of the infrared sources around α Lyrae (Vega) (Aumann et al. 1984), α Piscis Austrinus (Fomalhaut), and β Pictoris (Gillett 1986) resulted in the exciting realization that these objects were the first main-sequence stars apart from our Sun known to have attendant solid material in the absence of significant mass loss. Those studies made it clear that the emission was

caused by thermal radiation from grains warmed by the respective stars to temperatures of about 50 to 125 K.

As a result of the IRAS announcements Smith and Terrile (1984) observed β Pic with a coronagraph also constructed for investigations of planetary rings and satellites (Vilas and Smith 1987). Their images revealed that the grains lie in an edge-on disk, considered strong evidence of a relationship between this object and a planetary system. It was initially thought that the material detected by IRAS might represent ongoing planet formation because these three stars are in spectral class A and have lifetimes of order 10^9 years or less, roughly corresponding to the era of planet formation and subsequent heavy bombardment in our solar system. However, investigators continuing to survey the IRAS data have found more than 100 additional examples of similar far-infrared excesses around main-sequence stars of all types and ages.

This review will cover relevant physics and astronomy background information in Sec. II, observations and models of the three spatially resolved examples in Sec. III, search methods and general properties revealed by surveys in Sec. IV, time scales and evolution in Sec. V, and plausibility of a connection between these objects and our solar system in Sec. VI. The latter section includes a comparison between the characteristics of the Vega phenomenon and possible properties of the Kuiper disk.

Several notes of caution are necessary:

1. Almost all the information about these systems comes from IRAS, supplemented in a few cases by groundbased infrared and sub-millimeter observations and in only one case (β Pic) by visual wavelength images. Thus, the available data are limited.
2. It is not clear whether the sources of far-infrared excess in the 100+ candidate systems are the same as in the three resolved prototypes despite similar excess color temperatures and fractional luminosities (L_e/L_\star). Until the candidates are resolved by present or future telescopes such as HST, ISO, SOFIA, or SIRTf, the physical mechanism remains uncertain. However, for the purposes of this review these numerous candidates will be considered as examples of the Vega phenomenon.
3. The properties of the three resolved examples which suggest planetary systems are inferred with varying degrees of certainty but are not directly observed. Those properties are: (a) grains larger than interstellar grains; (b) material orbiting rather than falling into or flowing away from the stars; (c) material arranged in disks in the stellar equatorial planes rather than, e.g., in spherical clouds; (d) central regions similar in size to the planetary region of our solar system which are relatively lacking in small grains; (e) a necessary reservoir of larger undetected parent bodies to resupply the presently observed small grain population against various rapid removal processes; (f) transient spectral absorption line events attributed to comets impacting β Pic. These inferences will be examined in later sections.

II. INFRARED EMISSION FROM STARS AND GRAINS

A. Expectations for Stellar Photospheres in the Infrared

The peak emission of even the coolest stars, $T_{\text{eff}} \sim 2500$ K, occurs at wavelengths shorter than $2.5 \mu\text{m}$. The continuum flux densities of stars follow a Rayleigh-Jeans (RJ) slope ($F_\nu \propto \lambda^{-2}$) to about 10% accuracy from wavelengths of 3 to $30 \mu\text{m}$ and greater, with real stellar infrared continua generally being slightly steeper than RJ (see, e.g., Dreiling and Bell 1980; Engelke 1990 and references therein). Thus, it is relatively easy to estimate the far-infrared flux from a star given its flux at shorter wavelengths and to distinguish excess flux which is not photospheric. An excess with a given luminosity which itself has a spectrum like a Planck function will be more easily detected the cooler it is with respect to the star.

Determination of far-infrared photospheric and excess flux requires a choice of wavelengths at which a star's photosphere can be confidently considered the sole source of significant flux. Figures 1 and 2 compare the observed spectral energy distributions of four systems having strong far-infrared excesses with those of four stars which have little or no far-infrared excess but similar spectral types and similar near-infrared ($1\text{--}5 \mu\text{m}$) colors (see, e.g., Johnson 1966; Koornneef 1983*a, b*).

B. Thermal Emission from Grains

Temperatures of spherical grains warmed by stellar radiation can be calculated from equilibrium between absorbed and emitted energy:

$$g_1 \pi a^2 \left(\frac{R_\star}{r} \right)^2 \int_0^\infty \pi \epsilon_\nu B_\nu(T_\star) d\nu = 4 g_2 \pi a^2 \int_0^\infty \pi \epsilon_\nu B_\nu(T_g) d\nu \quad (1)$$

where a is the grain radius, r is the distance of the grain from the illuminating star, g_1 and g_2 are geometric factors depending on grain shape, conductivity, and rotation, and ϵ is the grain radiative efficiency. The spectrum of the star is assumed to be a Planck distribution with T_\star equal to the effective temperature T_{eff} . If a grain is small or thermally conductive or rapidly rotating such that its entire surface is at the temperature T_g , then $g_1 = g_2$.

The efficiency parameter ϵ is crucial to consideration of the thermal equilibrium of solid material. Particles efficiently absorb and emit radiation with wavelengths smaller than the grain size, but not with wavelengths much larger than the grain size. For a given grain size a and ignoring spectral features of the grain material, ϵ can be considered roughly constant, $\epsilon \sim (1 - \text{albedo}) \sim 1$, for absorption and emission of radiation of wavelengths shorter than a critical wavelength $\lambda_o \sim a$. Efficiency ϵ decreases for interaction with radiation of wavelength longer than λ_o .

The ratio between critical wavelength λ_o and grain radius, $\xi \equiv \lambda_o/a$, can vary widely depending on the grain optical properties. For example, $\xi \sim 2\pi$ for strongly absorbing material, while $\xi \sim 1/2\pi$ for weakly absorbing

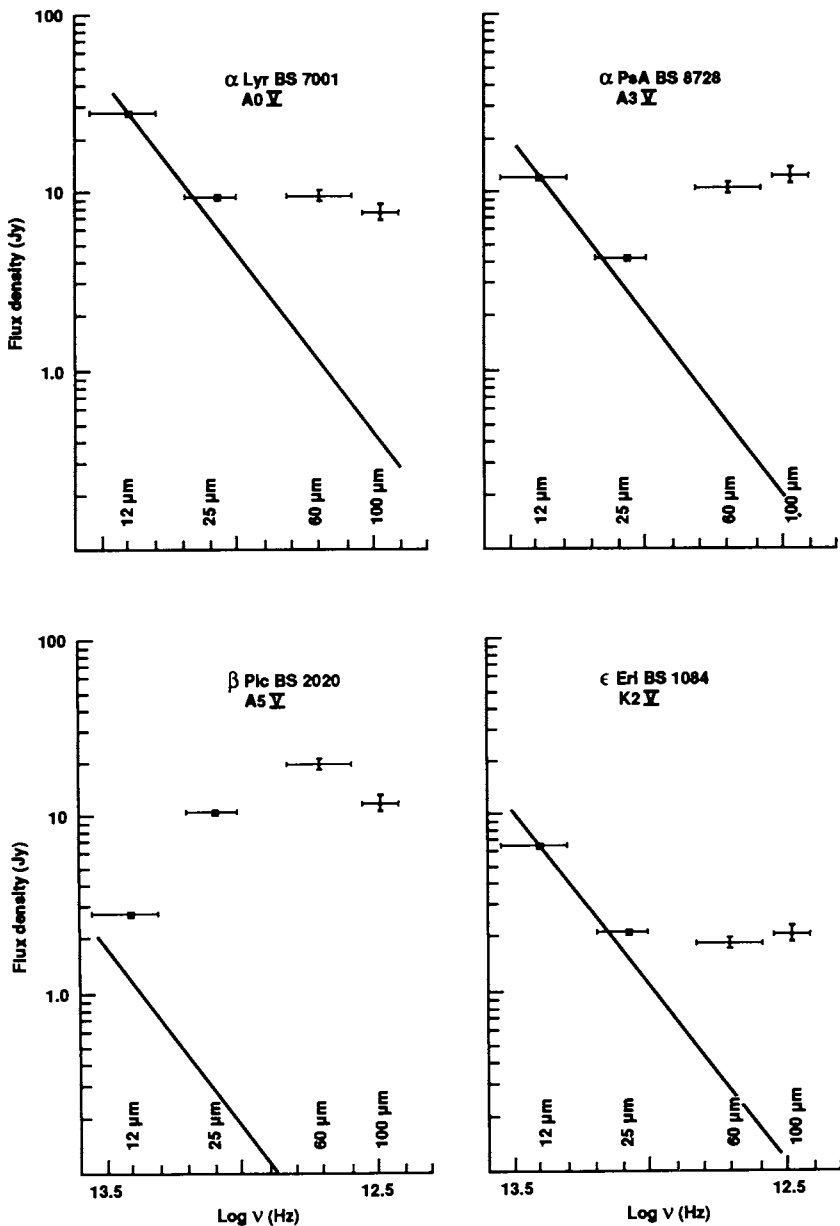

Figure 1. Spectral energy distribution of four nearby main-sequence stars with strong far-infrared excesses detected by IRAS. The diagonal lines show Rayleigh-Jeans extrapolations of the 3.5 μm (L -band) photospheric flux densities. The four excesses have 25–100 μm color temperatures which imply flux densities at 3.5 μm of less than 10^{-10} of the photosphere. The flux density uncertainties include uncertainties in the absolute calibration (figure courtesy of F. C. Gillett 1986).

material. A value of $\xi \sim 1$ may correspond roughly to moderately absorbing dielectrics like "dirty ice" (see, e.g., Greenberg 1978).

The decrease in radiative efficiency for $\lambda > \lambda_o$ can be described by a power law in λ with exponent controlled by the grain properties. A slope $\epsilon \sim (\lambda_o/\lambda)^1$ is appropriate for amorphous materials whereas a steeper decrease $\epsilon \sim (\lambda_o/\lambda)^2$ corresponds to crystalline dielectrics and metals (see, e.g., review by Witt 1989). Grains in the interstellar medium (ISM) may be characterized by an exponent value of about 1.5 (see, e.g., review by Helou 1989).

Assumption of power law absorptive and emissive efficiencies allows an analytic solution to Eq. (1). Specifically, if, ϵ (absorp) is $\epsilon_o(\lambda_o/\lambda)^p$ and ϵ (emiss) is $\epsilon_o(\lambda_o/\lambda)^q$, then for simple geometry ($g_1 = g_2$) the grain temperature is:

$$T_g = \left[\frac{\gamma(4+p) \sum_{n=1}^{\infty} n^{-(4+p)}}{\gamma(4+q) \sum_{n=1}^{\infty} n^{-(4+p)}} \left(\frac{hc}{k\lambda_o} \right)^{q-p} \frac{L_*}{16\pi\sigma_{SB}r^2} T_*^p \right]^{\frac{1}{4+q}} \quad (2)$$

where σ_{SB} is the Stefan-Boltzmann constant.

Grain size has a strong effect on the grain temperature. Arbitrarily large (blackbody) grains with efficient emission at all wavelengths will have the lowest temperature at a given location, while very small grains (like interstellar grains) with inefficient emission at all relevant wavelengths will have the highest temperature.

The most important consequences of this regarding the "Vega phenomenon" are: (1) infrared emission can be proven to be due to grains illuminated by the star in question if the temperature and spatial scale of the emission are consistent, and (2) an estimate of the typical grain size can be made from measurements of the emission temperature and scale. For example, if the grains are much larger than the peak wavelengths of both the absorbed and emitted spectra (blackbody grains), then $p=q=0$ and Eq. (2) reduces to:

$$T_g = 278 L_*^{\frac{1}{4}} r_{AU}^{-\frac{1}{2}} K \quad (3)$$

where L_* is in units of L_{\odot} , 3.9×10^{33} erg s⁻¹. The temperature can also be calculated using the source *angular* scale and the *apparent* brightness of the central star. For example, Eq. (3) for blackbody grains can be rewritten as:

$$T_g = 88 \theta^{-\frac{1}{2}} 10^{0.10(4.75-m_v-B.C.)} K \quad (4)$$

where θ is the grain distance from the star in arcsec, m_v is the star's visual magnitude, and B.C. is the bolometric correction in magnitudes for the star's type (see, e.g., Allen 1976).

A grain much larger than the peak wavelength of the incoming stellar radiation but much smaller than the peak wavelength of the grain thermal emission would have efficient absorption ($p = 0$) but inefficient emission ($q > 0$). If $p = 0$ and $q = 1$, one obtains:

$$T_g = 468 L_*^{\frac{1}{5}} r_{AU}^{-\frac{2}{5}} \lambda_o^{-\frac{1}{5}} K = 186 \theta^{-\frac{2}{5}} 10^{0.08(4.75-m_v-B.C.)} \lambda_o^{-\frac{1}{5}} K \quad (5)$$

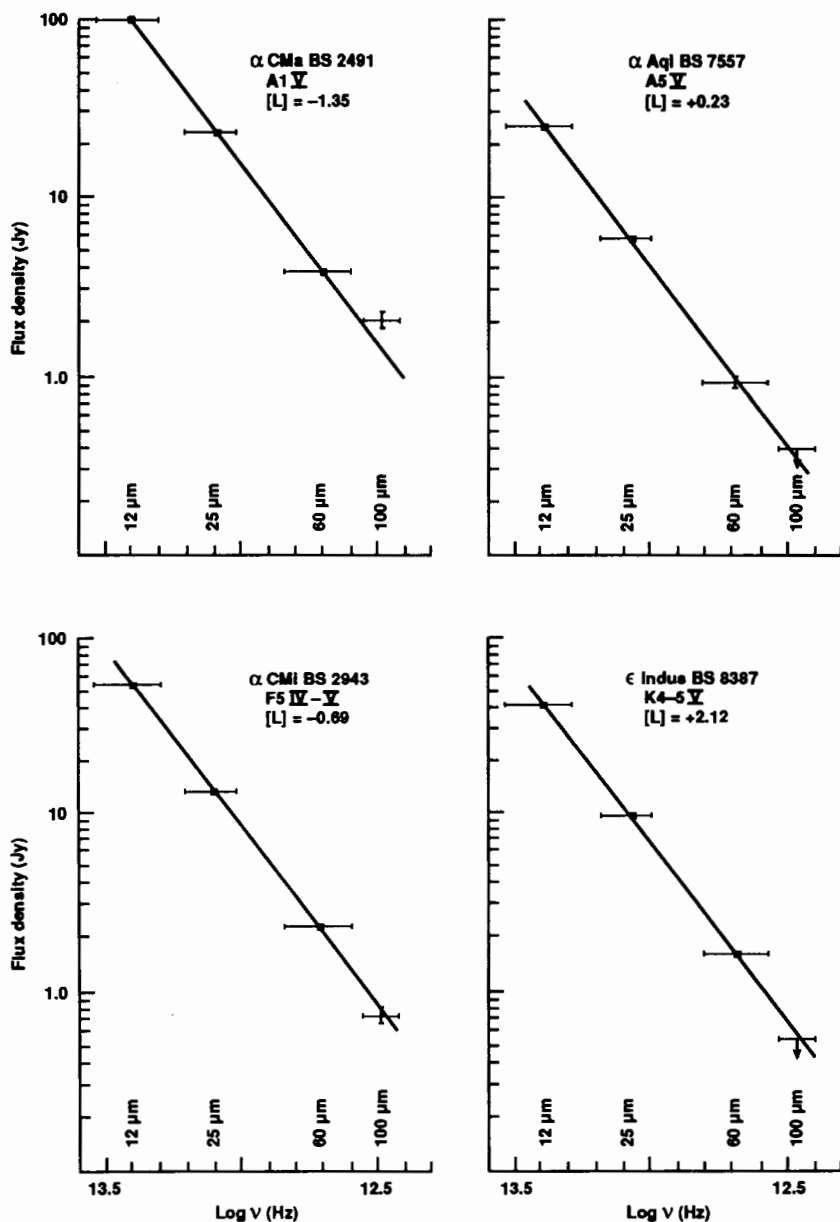

Figure 2. Comparison of spectral energy distributions of four stars of similar spectral types to those in Fig. 1, but with little or no far-infrared excess emission.

where λ_o is in μm .

ISM grains are small enough that they both absorb and emit stellar radiation inefficiently as well as emit inefficiently. Assuming $p=q=1.5$, one obtains:

$$\begin{aligned} T_g &= 636 L_*^{\frac{2}{11}} r_{\text{AU}}^{-\frac{4}{11}} \left(\frac{T_*}{T_\odot} \right)^{\frac{3}{11}} \text{ K} \\ &= 275 \theta^{-\frac{4}{11}} 10^{(0.80/11)(4.75-m_v-B.C.)} \left(\frac{T_*}{T_\odot} \right)^{\frac{3}{11}} \text{ K} \end{aligned} \quad (6)$$

where T_\odot is 5770 K.

The temperatures described in Eqs. (1)–(6) are physical temperatures of the grain material. The received grain emission spectrum will be affected by the radiative efficiency for $\lambda > \lambda_o$ such that:

$$F_\nu = \epsilon_\nu B_\nu [T_g(r, a)] \Omega = \left(\frac{\xi a \nu}{c} \right)^q B_\nu [T_g(r, a)] \Omega \quad (7)$$

where ξa represents the critical wavelength λ_o and Ω is the solid angle subtended by the total of the geometric cross sections of the grains.

Assuming an optically thin disk and single-size grains, the flux density received at the Earth from a system of grains is:

$$F_\nu = 2\pi \times 10^{23} \int_{r_1}^{r_2} \sigma_o \left(\frac{r}{r_o} \right)^\gamma \left(\frac{\xi a \nu}{c} \right)^q B_\nu [T_g(r, a)] \frac{r dr}{D^2} \text{ Jy} \quad (8)$$

in Janskys [$= 10^{-26} \text{ W m}^{-2} (\text{Hz bandwidth})^{-1}$], where $B_\nu [T_g(r, a)]$ is in cgs units, D is the distance to the system, and the amount of material in the disk is expressed as a face-on fractional geometric surface density $\sigma(r)$, cm^2/cm^2 , following a power law in radius with exponent γ . The face-on optical depth for such a disk would be $\tau_\perp(r, \nu) = \sigma(r)(\xi a \nu/c)^q$. The volume density distribution producing a spectrum would be $n(r) \propto r^{\gamma-1}$.

Equation (8) can be converted to an expression which allows integration over temperature rather than radius, concentrating most of the “modeling power” in those regions where the temperature and thus the thermal emission is largest (Artymowicz et al. 1989):

$$F_\nu \propto \int_{T_{\min}}^{T_{\max}} \epsilon_\nu B_\nu(T_g) y(T) T^{-\kappa} \frac{dT}{D^2} \quad (9)$$

where $\kappa = 4$ for blackbody grains (Eq. 3) or $\kappa = 3$ for “intermediate” sized grains (Eq. 5), and $y(T(r)) \propto r \sigma(r)$.

A spectrum falling more steeply than an RJ slope at long wavelengths may indicate the grain spatial distribution rather than a limit on grain size. Conversely, for some spatial distributions an RJ slope can be produced by an ensemble of grains substantially smaller than the wavelengths of observation.

Combining Eq. (3) for blackbody grains with Eq. (8), assuming $r_1 = 0$ and $r_2 = \infty$ but also assuming that total optical depth along the disk plane is small, there are exact solutions for the spectral energy distribution if $\gamma > -2$. These have the form:

$$F_\nu \propto \lambda^{2\gamma+1}. \quad (10)$$

A spectrum declining faster than an RJ slope results from a disk spatial distribution with $\gamma < -1.5$ even if the grains are assumed arbitrarily large. Note that this is an idealization since total grain area, mass, and optical depth actually diverge for an infinite distribution with $\gamma > -2$. A realistic spatial distribution would have finite inner and outer radii (the inner radius perhaps fixed by the temperature of grain evaporation) and would therefore emit a spectrum falling below the simple power law at both short and long wavelengths.

III. RESOLVED EXAMPLES: α LYR, α PSA, AND β PIC

Examples of the "Vega phenomenon" which have been definitely spatially resolved are the regions around the three stars α Lyr, α PsA and β Pic, although Aumann (1991) may have found a measurable extent for ϵ Eri as well. The three resolved systems deserve special attention because resolution allows structural models and discussion of origins and evolution. This section will discuss observational data, models and interpretations of these systems.

Characteristics of the stars are shown in Table I. All three systems are well within the range of accurate trigonometric parallax distance determinations. A comparison of the visual/near-infrared colors of these stars ("obs": Koornneef 1983a; Campins et al. 1985) to the average colors for main sequence stars of their spectral types ("std": Koornneef 1983b) in columns 7 and 8 demonstrates that these three have no significant near-infrared excesses. The expected main sequence lifetimes in the last column corresponding to the estimated masses are interpolated from Iben (1967).

A. General Analyses of the "Big 3"

1. *IRAS Discovery.* Table II presents the photospheric and excess flux densities in the IRAS bands from "pointed" observations (Gillett 1986). The uncertainties include estimates of absolute calibration uncertainty; the relative photometric uncertainties are only a few percent. The $12\ \mu\text{m}$ IRAS measurements are close to photospheric for α Lyr and α PsA but β Pic has a significant excess even at that wavelength.

The possibility that the observed excesses include substantial line emission can be rejected. The infrared continuum of α Lyr is smooth across the range of wavelengths ($\leq 13\ \mu\text{m}$) over which it has been carefully compared to standards with no far-infrared excess (Witteborn and Cohen, personal communication). Reports of weak visual wavelength emission lines and variability of α Lyr (Johnson and Wisniewski 1978, and references therein) have not been confirmed and are likely due to difficulties in observing such a bright object

TABLE I
Stellar Characteristics

	BS #	Spectral Type	T_e	m_v	B.C.	obs $V-L$	std $V-L$	dist	L_*	M_*	Expected Lifetime
α Lyr	7001	A0V	9700 K	+0.02	-0.40	0.00	0.00	8.1 pc	60 L_\odot	2.5 M_\odot	4×10^8 yr
α PsA	8728	A3V	8800	+1.15	-0.23	+0.15	+0.21	7.0	13	2.0	7×10^8
β Pic	2020	A5V	8200	+3.85	-0.12	+0.38	+0.36	16.4	6	1.5	2×10^9

TABLE II
Photometric Characteristics

	IRAS Flux Densities, Janskys				Single temperature Fit to Spectrum		
	12 μ m excess (photosphere)	25 μ m excess (photosphere)	60 μ m excess (photosphere)	100 μ m excess (photosphere)	$T_{B.B.}$	$f \equiv L_e/L_*$	Bolometric
α Lyr	0.0 ± 0.8 (28.0)	2.75 ± 0.5 (6.45)	8.2 ± 0.5 (1.1)	7.1 ± 0.8 (0.4)	89 K	2×10^{-5}	
α PsA	0.3 ± 0.8 (11.3)	1.4 ± 0.2 (2.6)	9.35 ± 0.5 (0.45)	11.1 ± 1.1 (0.2)	72	8×10^{-5}	
β Pic	1.6 ± 0.1 (1.2)	10.1 ± 0.5 (0.3)	18.8 ± 0.9 (0.05)	11.2 ± 1.0 (0.02)	108	3×10^{-3}	

optically and finding suitable reference standards. Recent 1- μm -resolution spectrophotometry of β Pic near 10 μm shows that a small amount of silicate line emission is present (Telesco and Knacke 1991).

The excess flux densities at 25 to 100 μm can be fit fairly well in all three cases by Planck distributions with single temperatures listed in column 6 of Table II. A single-temperature fit implying a single radial location for the material is of course only schematic. As discussed previously, many combinations of radial density and grain size distributions can produce a spectrum which resembles portions of a Planck distribution. In the case of β Pic, accounting for all of the 12 μm excess (excluding the weak line emission) in the simplest way requires addition of a second hotter component.

Fractional luminosities f of the excesses relative to the stars are presented in the last column of Table II. The optical depth of grains along a radial line from the star to infinity is $\tau \sim f/\sin i$ if the grains are in a "wedge" or "flaring" disk with thickness proportional to radius and opening angle $2i$. The range of fractional luminosities for these three stars is surprising: f for β Pic is more than 1 order of magnitude larger than for α PsA and 2 orders larger than for α Lyr. Note that the fractional luminosity of the material around β Pic is 4 orders of magnitude larger than for the zodiacal dust in our solar system (Sec. VI).

IRAS profiles of these three sources show widths that are significantly wider than profiles of point sources. Figure 3 compares the average of 12 scans at 60 μm across α PsA, the largest of the three resolved sources, with a point source profile which is a combination of 24 scans of α Boo and β Gru.

Table III presents intrinsic 60 μm source sizes for the three resolved cases estimated from simple deconvolution (Gillett 1986). Note that these are characteristic scales of the strongly emitting regions but are not limiting outer diameters of the sources; substantial amounts of cooler material may lie at larger distances. In the cases of α Lyr and α PsA the sizes given are the largest of values measured along several scan position angles. These can be used to estimate diameters of circular figures seen in projection as ellipses (Sec. III.A.6). In the case of β Pic the infrared source sizes along two orthogonal directions have been de-projected using the disk orientation angle seen in optical images (Sec. III.B.1).

2. α Lyr as Prototype: Large Grains In Orbit. Explanations for infrared excesses other than an optically thin collection of orbiting grains can be eliminated by arguments from the first α Lyr IRAS paper (Aumann et al. 1984), *which also should be considered for all candidate analogs to α Lyr found in IRAS data.* Note that points (c), (d) and (e) depend on successful spatial resolution of the infrared emitting region.

(a) Plasma (free-free) emission, e.g., from a hot wind: the excess is well fit by a Planck function and rises in flux density between 12 and 60 μm , inconsistent with a thin or partially thick free-free spectrum which would have $f_\nu \propto \lambda^{-2}$ to λ^0 ;

(b) Chance alignment with background interstellar cirrus: the source

Figure 3. Comparison of IRAS 60 μm scan profiles of α PsA, the most extended of the "Big 3," with a composite of several point sources. The scans were made at 1/2 the all-sky-survey scan rate with a sampling interval of 3.6 arcsec. Scan widths represent a combination of detector FOV, detector response time, telescope diffraction and intrinsic source width; the FWHM is equal to the 90 arcsec detector width parallel to the scan direction ("in-scan"). The profiles are normalized to 1 at their peaks, which makes the broader source appear narrower above the FWHM points. Irregularities in the α PsA profile wings indicate the noise level (data provided courtesy of F. Low, F. Gillett, G. Neugebauer, J. Good and H. Aumann).

temperature of 89 K is much warmer than even unusually warm cirrus knots (Low et al. 1984);

(c) Chance alignment with an 89 K infrared object: the 60 μm source scale of 29 arcsec is quite consistent with heating of grains many μm in size by the star (Eqs. 4 and 5) and the centroid of the far-infrared source is found to be within 2 to 3 arcsec of the star's position, strongly indicating that the emission must be from grains around α Lyr;

(d) A single optically thick blackbody, either a cool self-luminous companion or a single object heated by Vega: its diameter from the flux and temperature would be 0.2 arcsec, much smaller than the observed diameter of the source;

(e) Emission from ordinary circumstellar/ISM grains around α Lyr with efficiencies approximately proportional to $\lambda^{-1.5}$: the diameter of such a shell with the observed color temperature would be almost 2000 arcsec (Eq. 6);

(f) Emission from ordinary grains in a shell around a low-luminosity companion close to the line of sight to the primary star: based on normal ISM grain efficiencies, the shell optical depth would be 4×10^{-3} and the luminosity

TABLE III
Source Sizes, Estimated Grain Sizes, Total Area, and Mass

	Source Diameters, Arcsec		Single-Size Grain Models				
	Observed 60 μm	Hypothetical B.B. Grains	ISM Grains	Grain Size, $\lambda_o, \mu\text{m}$	Total Grain Area, cm^2	Minimum Mass, M_{\oplus}	“Maximum” Mass, M_{\oplus}
α Lyr	29	21	1800	80	1×10^{27}	2×10^{-3}	9×10^2
α PsA	36	17	1300	27	3×10^{27}	2×10^{-3}	2×10^3
β Pic	26	1	180	1	3×10^{29}	7×10^{-3}	4×10^4

of the companion would be $0.4 L_{\odot}$. Such a companion would be detectable as a close optical double, but none is observed (see, e.g., Hanbury Brown et al. 1974);

(g) Large grains condensing in a stellar wind flowing from Vega: a mass-loss limit of $\dot{M} < 3.4 \times 10^{-10} M_{\odot} \text{ yr}^{-1}$ was obtained for α Lyr from radio and ultraviolet measurements (Hollis et al. 1985, and references therein). Even with optimistic assumptions about the carrying capacity of a wind with α Lyr's metallicity, i.e., all the elements except H and He condensed into grains and a wind speed just above escape velocity, this upper limit on mass loss precludes enough mass in a continuous spherically symmetric wind to be carrying the minimum grain mass of $10^{-8} M_{\odot}$ (Table III) across the indicated range of radii. The crucial conclusion that the grains must be in orbit around the star rests on (1) the impossibility of interstellar grains being found at the observed radii and temperatures, and (2) inconsistency of mass loss limits with the amount of solid material observed.

Regarding mass loss from the other prototypes: β Pic's shell is like typical A-F shells in showing no overt signs of mass loss like asymmetric or violet-displaced lines (Slettebak and Carpenter 1983), but precise evaluation of mass-loss limits for β Pic is complicated by transient absorption line events (Sec. III.B.5). α PsA has ultraviolet absorption lines which may be from circumstellar gas (Kondo and Bruhweiler 1985) although an analysis of optical Na I and Ca II lines (Hobbs et al. 1985) indicates otherwise. Assuming for a limit that all of the column density tabulated in Bruhweiler and Kondo (1982) represents material in a spherically symmetric wind with solar abundance, fractional ionization $X(\text{Mg}^+) = 0.01$, v_{∞} of 15 km s^{-1} , and purely gravitational deceleration, then the mass-loss rate from α PsA is less than $10^{-9} M_{\odot} \text{ yr}^{-1}$.

3. *Grain Sizes and Total Grain Mass.* Columns 3 and 4 in Table III show the source sizes expected from the source temperatures if the grains are blackbody grains (Eq. 4) or ISM grains (Eq. 6). The actual grains in all three cases can be judged to be smaller in size than $100 \mu\text{m}$ but also clearly larger than ISM grains because the observed source sizes lie between these extremes. The grains around α Lyr appear to be the largest, approaching blackbody size, while the grains around β Pic appear to be relatively small.

Typical grain sizes can be estimated by assuming the grains are intermediate-sized ($\epsilon < 1$ across the IRAS bands) and calculating a best fit to the observed source size and 25 to $100 \mu\text{m}$ flux densities. Resulting grain size parameters ($\lambda_o \sim a$) are presented in column 5 of Table III. The total grain areas in column 6 of Table III are geometric cross sections. The values of grain size and total area depend on the assumed value of emissivity exponent q but the relative ranking of the three systems is preserved if the same q is used for each. Note that the amount of material is anti-correlated with the mass and luminosity of the central stars.

The quality of the fits of these single-size grain models to the observed spectra are not great. It is more likely that the grains have a range of locations and sizes, but this exercise gives some indication of effective or typical grain

sizes. The calculated grain size for α Lyr for $q = 1$ appears to be nearly large enough to violate the assumption implicit in Eq. (5) that most of the emission takes place at wavelengths larger than λ_o . A solution for α Lyr with blackbody grains yields nearly the same grain area.

The mass associated with the circumstellar grains is of primary importance and unfortunately is also uncertain. The grain size distribution slope and maximum sizes are not constrained by the IRAS observations. Minimum total masses derived with the assumptions that all the grains have size $a = \lambda_o$ and density 1 g cm^{-3} are presented in column 7 of Table III ($1 \text{ M}_\oplus = 3 \times 10^{-6} \text{ M}_\odot = 6 \times 10^{27} \text{ g}$). These masses are quite small; note especially in the case of α Lyr that $2 \times 10^{-3} \text{ M}_\oplus$ of $80 \mu\text{m}$ grains can produce a far-infrared signal which overpowers the star's flux and is easily detectable at stellar distances. In the case of β Pic the lower limit to the grain mass is approximately consistent with solar composition and an upper limit on neutral gas mass (Sec. III.B.4).

A maximum grain mass presented in the last column of Table III can be estimated by assuming: (1) collision fragmentation equilibrium size distribution $n(a) \propto a^{-3.5}$ (Dohnanyi 1969); (2) minimum size $a_{\min} = \lambda_o$; (3) maximum size $a_{\max} = 1000 \text{ km}$ estimated from the gravitational instability in a thin dust disk at 100 AU (Goldreich and Ward 1973; Greenberg et al. 1984); and (4) density of 5 g cm^{-3} . These values are larger than the total mass of the planets in our solar system (450 M_\oplus) and scale with the assumed maximum size as $a_{\max}^{1/2}$. The grain upper mass limit for β Pic is 0.1 M_\odot . The grain population that contains most of the surface area and is most easily detected does not represent the population containing most of the mass in this distribution: half of the total area is contained in grains smaller than 4 times the minimum size, while half the mass is contained in grains larger than 1/4 the maximum size.

Note that the deduced maximum mass is quite sensitive to the size distribution exponent: assuming a power law a^{-4} rather than $a^{-3.5}$ produces "maximum" mass estimates smaller by a factor of 10^4 . Grain size distributions caused by mechanisms differing from collisions, such as sublimation of icy bodies, seem to give size distributions differing from $a^{-3.5}$ in our solar system (see, e.g., Kyte and Wasson 1986).

4. *Inner and Outer Boundaries.* An important fact provided by the spectral energy distributions of these objects is that they have relatively empty central regions (Gillett 1986). This conclusion is based on consideration of maximum grain temperature determined by minimum wavelength of excess flux. If in Eq. (8) the outer boundary radius $r_2 \rightarrow \infty$, then the entire disk emission can be characterized by the value of the inner boundary radius r_1 . Table IV presents estimates of inner boundary radii for each of the three systems constrained by the hottest IRAS color temperature and assuming grain sizes from Table III. The solutions differ significantly depending on whether a flat or steep spatial distribution is assumed. Only in the case of β Pic is there independent information about the actual spatial gradient ($\gamma \sim -1.7$ at r greater than about 65 AU; Sec. III.B.1).

TABLE IV
Inner Boundary Radii

	γ	r_1	$T_g(\text{max})$
α Lyr	0.0	—	—
	-1.7	26	119
α PsA	0.0	30	104
	-1.7	67	75
β Pic	0.0	20	199
	-1.7	38	154

These calculations show that the grain number density in these three systems cannot increase monotonically toward the stars or even be constant with radius. Instead, there must be central regions of relatively low density. These central "voids" have sizes similar to each other and also similar to the planetary region of our solar system. Note that this analysis finds that the amount of material at $r < r_1$ was undetectable with IRAS but it may not be zero, and there is not necessarily a sharp boundary at r_1 . One conclusion of Aumann et al. (1984) was that a hypothetical hot grain component around α Lyr with $T = 500$ K could have up to 10^{-3} of the grain area in the 90 K component and not violate the limit on excess at $12 \mu\text{m}$. Because PR radiation drag (Sec. V.B.2) would act quickly to fill in the voids, grain removal mechanisms such as ice sublimation, radiation pressure expulsion of small collision fragments, or gravitational perturbations are probably required to prevent a warm dust signature. Better photometry at infrared wavelengths much shorter than the emission peaks would further define the inner structure of these systems and the processes controlling the location of the grains.

The ability of infinite spatial distributions to yield positive or negative spectral slopes has been discussed. The IRAS data therefore do not allow specification of *outer* boundary radii for these systems. IRAS sensitivity to outlying material would have been limited by detector field of view and grain temperature. The IRAS field of view at $100 \mu\text{m}$ corresponds to roughly 1500 by 2500 AU at the distance of α Lyr and 3000 by 5000 AU at β Pic. Material colder than about 30 K has an emission peak beyond the long wavelength cutoff of the IRAS $100 \mu\text{m}$ band and would be difficult to detect without substantial optical depth. That temperature corresponds to distances of about 1000 AU from α Lyr and 2300 AU from β Pic for the model grain characteristics in Table III.

5. *Is the β Pic System Really a Disk?* We are likely to be viewing the β Pic system from near the star's equatorial plane because the star's projected rotation velocity is above the mean for main-sequence stars of its spectral type (Table V). Is it possible that the linear structure seen in the coronagraph images is not a disk of orbiting grains? Could it instead

TABLE V
Stellar Rotation and IRAS Source Orientation

	Mean $v \sin i$ for Spectral Type, km s^{-1}	Observed $v \sin i$, km s^{-1}	Apparent Grain Disk Inclination, i , degrees
α Lyr	145	15	30^{+15}_{-30}
α PsA	135	100	>70
β Pic	125	139	>80

represent equatorial mass loss or even bi-polar jets emanating from a post-main-sequence star as Herbig (1989*b*) speculated based on the disk optical appearance and Slettebak's (1975) classification of the central star as a sub-giant? The argument that the observed system must actually be a disk of orbiting material is provided by Paresce and Artymowicz (1989), which we summarize:

(a) An equatorial flow capable of reaching the great distances of the observed disk can be rejected because the escape velocity from the β Pic atmosphere is about 500 km s^{-1} but the observed rotation rate is 139 km s^{-1} ;

(b) The bipolar jet hypothesis can be rejected because there is little resemblance between bipolar nebulae and the β Pic disk in terms of scale, mass, grain temperature, expansion velocity, lifetime, or molecular content;

(c) The central "void" would require that the grains condense at much colder temperatures than in all other known examples of grain condensation in stellar winds;

(d) Such a jet would need to be directed by another substantial disk that would necessarily also lie close to our line of sight to the star, yet no such disk is observed;

(e) There are no obvious spectroscopic signs of mass loss (Slettebak and Carpenter 1983);

(f) The surface brightness declines rapidly as r^{-4} or steeper, but material on an escape trajectory decelerating gravitationally and presenting a "wedge" in projection (Sec. III.B.1) would instead have scattering surface brightness following $r^{-2.5}$ (r^1 increasing viewing path length $\times r^{-1.5}$ volume density decrease $\times r^{-2}$ decrease of input photons).

6. *Source Morphologies and Stellar Rotation.* Previously described analyses by Gillett (1986) of IRAS $60 \mu\text{m}$ in-scan and cross-scan profiles of α Lyr yields minimum and maximum source scales of 25 and 29 arcsec, interpreted as roughly FWHM of the surface brightness distribution. Because these scans were made along a number of position angles, it appears that this source is nearly circular in projection. The same analysis for α PsA yields a scale of 36 ± 2 arcsec along position angle 29° W of N, but less than 13 arcsec perpendicular to that direction. In this case there is only one scan axis and therefore size estimates only along two position angles. The actual source shape for α PsA could be between two extremes: (1) elliptical, with axial

ratio less than 13/36 and major axis along the IRAS scan direction, or (2) a one-dimensional source lying along a position angle 10° E of N.

The IRAS spatial information on β Pic is of lower quality but is consistent with a one-dimensional source oriented like the optical disk. A careful analysis of the scattered light isophotes (Artymowicz et al. 1989) shows that the disk inclination to the plane of the sky is greater than 80° (Sec. III.B.1).

These source shapes provide crucial information about the true location of the grain material relative to the rotation axes of these stars. Table V compares the observed (projected) stellar rotation velocities (Uesugi and Fukuda 1970) with the average (projected) rotation velocities for stars of the same spectral types (Schmidt-Kaler 1982, and references therein). This is statistical evidence that the star α Lyr is nearly pole-on to us, that β Pic is nearly equator-on to us, and that α PsA lies between those extremes. There is also independent evidence from detailed spectral line analysis (Gray 1986) that what we see in the case of α Lyr is the pole of a rapidly rotating star.

The inclination angles of disks which would result in elliptical projections with the observed aspect ratios are in the last column of Table V. This comparison of the rotational orientation of the three stars with the projected shapes of the regions containing the grains is the basis for concluding that the material is probably arranged as disks in the stellar equatorial planes.

7. IRAS Followup. A number of investigators have extended the original IRAS results on source sizes and spectral energy distributions for the three resolved systems. Harvey et al. (1984) confirmed the α Lyr excess from the Kuiper Airborne Observatory (KAO) and measured a source size at 47 and $95\ \mu\text{m}$ consistent with, but marginally larger than, the IRAS values. Lester et al.'s (1990) KAO $100\ \mu\text{m}$ characteristic size for α PsA is in agreement with Gillett (1986) along the major axis, and they find evidence for some emission at least 240 AU (35 arcsec) from the star. Aumann (1991) re-analyzed IRAS slow-scan observations of α Lyr, α PsA, β Pic, and other stars assuming Gaussian intrinsic source profiles and found sizes like Gillett's (1986) except an upper limit twice as large as Gillett's for α PsA's minor axis. Early KAO photometry by Harper et al. (1984) showed flux density from α Lyr at $193\ \mu\text{m}$ well below an extrapolation of the IRAS 25 to $100\ \mu\text{m}$ color temperature. Becklin and Zuckerman (1990) found a similar result for α Lyr and β Pic (but not α PsA) at 450 and $800\ \mu\text{m}$ using the 15 m James Clerk Maxwell Telescope (JCMT). They also noted that the excess flux from α PsA was stronger at an offset of 16 arcsec (one beamwidth) from the star than in a beam centered on the star, which they interpreted as direct confirmation of the central "void" inferred from the spectrum. Becklin and Zuckerman modeled the emission from the three systems as due to emission from material at one temperature (i.e., no spatial distribution) and thus interpreted their and Harper et al.'s flux-density shortfalls relative to IRAS extrapolations as evidence of: (1) smaller grain sizes ($a < \lambda_{\text{obs}}$); and (2) lower total dust masses, than previously published. However, rapidly declining long-wavelength spectra can also be produced by some spatial distributions (Sec. II.B). Chini et al. (1990) used the

30 m Instituto de Radioastronomia Millimetrica (IRAM) telescope and found excesses relative to the stellar photospheres which decrease as $\lambda \rightarrow 1$ mm, but claim an inconsistency exists between their beamsize/flux density/source size information and that of Becklin and Zuckerman (1990). Chini et al. find their results in agreement with the IRAS source sizes.

Figure 4. Red ($0.89\ \mu\text{m}$) CCD coronagraph image of the β Pic disk from the 100-inch telescope at Las Campanas. The extent of each wing of the disk is roughly 25 arcsec or 400 AU. Processing involved use of comparison images of α Pic to remove the profile of light scattered in the atmosphere and instrument (figure from Smith and Terrile 1984).

B. Detailed Analyses of β Pic

It has already been noted that β Pic possesses the warmest and proportionately most luminous infrared excess of the “Big 3”. Following the IRAS discovery Smith and Terrile (1984) used a CCD coronagraph to detect $0.89\ \mu\text{m}$ (I-band) light scattered by grains in a nearly edge-on disk around the star (Fig. 4). β Pic is the only example which has been so far detected optically because it is by a wide margin the densest main-sequence grain disk within 20 pc (Sec. IV.A.4) and is fortuitously inclined so as to enhance the surface brightness by

roughly an extra factor of 10. β Pic is also nearly unique among these systems in that it exhibits substantial excess emission at wavelengths as short as 10 to $20\ \mu\text{m}$ (Aumann and Probst 1991). β Pic is therefore the object in this class about which most is known and considerable discussion of its properties is warranted.

Figure 5. Radial surface brightness distribution in V band of the β Pic disk midplane, both wings plotted together. (Smith and Terrile, unpublished data.)

1. Disk Structure: Optical. The disk was visible beyond the edge of Smith and Terrile's coronagraph mask at $r \geq 6$ arcsec (100 AU) extending about 25 arcsec (450 AU) to the north-east and 20 arcsec to the southwest along a position angle of 30° (Fig. 4). The disk is resolved along its short dimension, with a seeing-deconvolved thickness of 3 arcsec (50 AU) at $r = 350$ AU. The I-band surface brightness is 16th magnitude per square arcsec at 100 AU, decreasing approximately as $r^{-4.3}$.

Subsequent images (Smith and Terrile 1987) show the disk apparently extending inward to radii of a few arcsec and outward to 60 arcsec (1100 AU). The most complete surface brightness profile combining the two "wings" is shown in Fig. 5. The surface brightness fades below present detectability beyond 1100 AU but the disk may well extend farther.

Smith and Terrile's (1984) Fig. 2 implies that there is an asymmetry of the disk involving truncation of the southwest wing and increasing thickness of that wing near its outer terminus. A brown dwarf companion for β Pic was suggested (Whitmire et al. 1988) as a possible cause for such a disturbance of the disk. However, Paresce and Burrows (1987) found no systematic asymmetry in the disk structure in their optical coronagraph images. In fact, asymmetries with both the same *and opposite* sense of that originally proposed

Figure 6. Contour plot of the β Pic disk surface brightness at $0.79\ \mu\text{m}$. The isophotes are most easily modeled as a “wedge” disk (thickness increasing with radius) convolved with atmospheric seeing (figure from Artymowicz et al. 1989).

can be easily produced by small registration errors in the nontrivial process of reducing coronagraph images using reference star images.

Model pertaining to the specific radii range of 6–15 arcsec (100–250 AU) show that the likeliest structure capable of producing the observed elliptical isophotes (Fig. 6) is a “wedge” disk having an opening angle of about 14° and a presentation angle (versus exactly edge-on) of 10° or less, convolved with terrestrial seeing (Artymowicz et al. 1989). Those model calculations show that the isophotes for a constant thickness disk would be quite different and easily distinguished from a wedge and that the symmetry of the surface brightness distribution is consistent with a scattering phase function similar to that for zodiacal dust (see especially Artymowicz et al. Figs. 1 and 3–7). It is more difficult to distinguish between model isophotes of a wedge versus a very thin, inclined disk. However, the latter hypothesis is rejected because it would require an unlikely scattering phase function more isotropic than Lambert’s law.

Given a slightly inclined wedge geometry, the optical depth *perpendicular to the disk plane* is deduced to follow approximately $r^{-1.7}$ for $r \geq 65$ –100 AU (Artymowicz et al. 1989, 1990). This corresponds to a mid-plane grain volume number density declining approximately as $r^{-2.7}$.

2. Models Combining Optical and Infrared Data. The area corresponding to the infrared luminosity of the entire disk is within a factor of two of the scattering area observed outside coronagraph masks (Artymowicz et al. 1989; Backman et al. 1992). The total grain surface cross-sectional area is related to the scattering area σ_s , the infrared (absorption/emission) area σ_i , and the

albedo \mathcal{A} via:

$$\sigma_{total} = \sigma_s + \sigma_i = \sigma_s / \mathcal{A}. \quad (11)$$

Plausible albedos imply there cannot be much more grain area hiding within the regions obscured in coronagraph images.

The grain temperature in 4 and 8 arcsec fields of view centered on the star is 180 K from observations at 10 and 20 μm if radiative efficiency is assumed to be $\epsilon \propto \lambda^{-1}$ (Telesco et al. 1988; Backman et al. 1992). Because the temperature on these scales is not growing rapidly with decreasing aperture size, one can estimate that the maximum temperature of detectable material is $T_{max} \sim 200$ K, which corresponds quite well to the limits in Table IV based on IRAS data.

Models attempting to match both infrared data and results of analyses of optical observations have been calculated by Diner and Appleby (1986), Nakano (1988), Artymowicz et al. (1989) and Backman et al. (1992). All combined optical-infrared models agree on a relatively flat spatial distribution for the grains producing the bulk of the grain thermal luminosity. These models in general show:

1. An outer component corresponding to the disk visible in coronagraph images, extending from $r \leq 100$ AU to $r \geq 1000$ AU with mid-plane grain number density decreasing steeply as $n \sim r^{-3}$; this component emits most of the radiation detected at $\lambda > 20 \mu\text{m}$;
2. A transition region extending approximately from $r = 10$ –100 AU as yet hidden from easy view in coronagraph images, with a lower density and either smaller grains or a less steep spatial gradient than the outer component; most of the radiation at $\lambda < 20 \mu\text{m}$ originates from this region;
3. An innermost region with grain area below present detection limits.

Details of the structure in the region hidden by coronagraph masks such as the sizes and properties of the transition region and innermost “void” are not uniquely determined by the available infrared observations (see, e.g., Diner and Appleby 1986). The grain cross-section area in these regions is as little as 1% of the amount there would be if the outer component gradient continued to $r = 0$. The face-on optical depth in the inner component is of order 10^{-4} in contrast to a maximum in the outer disk of a few times 10^{-3} . The physical mechanisms that may contribute to the relatively low density of material in the inner regions of the β Pic disk are discussed in Secs. V.B and C.

The midplane visual extinction Δm based on assumption of a “wedge” structure and following the definitions in equation (8) is:

$$\Delta m_\lambda \sim 1.1 \tau_\lambda \sim 1.1 \int_{r_1}^{\infty} \frac{\sigma_o}{\theta r} \left(\frac{r}{r_o} \right)^\gamma dr = \frac{1.1 \sigma_o}{-\gamma \theta} \left(\frac{r_1}{r_o} \right)^\gamma \text{ mag} \quad (12)$$

where r_o is a reference radius of 100 AU, r_1 is the radius of the disk inner edge, and θ is the wedge angle ~ 0.1 rad (Artymowicz et al. 1989). Models with

small grains (Sec. III.B.3) predict the correct infrared spectrum and source size if $r_1 \sim 30$ to 100 AU for the main outer disk component containing most of the optical depth and if $\sigma_o \sim 1-5 \times 10^{-3}$, yielding $\Delta m \leq 0.04$ mag. This agrees with careful analysis (Paresce 1991; see Sec. V.A below) of β Pic photometry versus new metallicity indices and isochrones showing that the star lies on the zero age main sequence (ZAMS) within the uncertainties involved. Thus, our line of sight through the disk does not suffer significant extinction. The conclusion by Smith and Terrile (1984) that there must be a central cavity of roughly 30 AU radius is therefore only fortuitously correct because their argument was based on an assumption that substantial gray extinction is observed toward β Pic.

3. *Grain Properties.* The composition and size of the grains around β Pic are significant in comparing this system to our solar system. Grain sizes are necessary input to calculations of grain lifetimes against removal processes discussed in Sec. V.A such as direct radiation pressure expulsion, mutual collisions, collisions with interstellar grains, PR radiation drag, and ice sublimation. Grain lifetimes in turn are crucial to hypotheses of the source and evolution of the grains.

One complication is that the grains are unlikely to have a single size. A steady-state size distribution $n(a) \propto a^{-3.5}$ has been derived from theoretical studies of inelastic collisions and fragmentation processes and compared to observations of asteroids and micrometeoroids (Dohnanyi 1969). This distribution has been adopted in some discussions of the β Pic system (see, e.g., Smith and Terrile 1984; Matese et al. 1987). Model calculations based on observations usually yield a single size parameter, but the relation between such a size and the properties of a realistic size distribution are quite uncertain (see, e.g., Backman et al. 1992).

Scattering properties of the grains will be set in part by their size. Smith and Terrile (1987) and Paresce and Burrows (1987) find that the color of the scattered light is the same as the color of the star within observational uncertainty across the range 0.4 to 0.9 μm . This would indicate grains 1 μm or larger in size. Gradie et al. (1987) have found very red colors for the disk, $V-I \sim 0.6$ magnitudes redder than the star, also implying a grain size larger than 1 μm . Gledhill et al.'s (1991) optical polarization measurements yield a (model-dependent) size of about 0.25 μm .

As previously discussed, the grain size can be characterized by a comparison of the run of temperatures represented by the thermal spectrum to measurements of the size of the infrared emitting region. Telesco et al. (1988) determined the size of the warmest grains radiating at 10 μm to be 0.1 to 0.4 μm ; Backman et al. (1992) find typical sizes of 2 to 20 μm or minimum sizes of 0.05 to 3 μm for the infrared emitters depending on choice of emissivity exponent and spatial gradient.

Artymowicz (1988) has calculated the ratio of radiation pressure forces to gravitational forces acting on small grains in the β Pic system, similar to the work of Burns et al. (1979) for grains of various types in our solar system (Sec.

V.B.1). The deduced minimum stable size for a wide variety of compositions is of order $1\text{ }\mu\text{m}$, and could be larger if the grains are porous, delicate, or icy. There may also be a size regime (perhaps smaller than $\leq 0.1\text{ }\mu\text{m}$, depending on composition) below which grains would couple inefficiently to the β Pic radiation field and also be stable. Grains in the range 0.1 to $1\text{ }\mu\text{m}$ should be subject to rapid ejection from the system.

Various groups have thus reported substantially different grain size results, and the disagreements are difficult to interpret. Comparison of the radiation pressure calculation with the optical and infrared observations indicates that the β Pic grain size distribution may not be continuous but may consist of one population smaller and one larger than the size range excluded by direct radiation pressure.

Artymowicz et al. (1989) concluded that the β Pic disk has $9 \times 10^{28}\text{ cm}^2$ of optical scattering cross-section area in the region $100\text{ AU} < r < 500\text{ AU}$, yielding an albedo of $\mathcal{A} = 0.6$ (Artymowicz et al. 1989) or 0.35 (Backman et al. 1992) for the grains at $r > 100\text{ AU}$ depending on the amount of thermal radiating area attributed to the same region. These albedos are very high compared to small grains found in various parts of our solar system such as zodiacal dust grains ($\mathcal{A} \leq 0.1$; Hauser and Houck 1986) or grains in comet comae ($\mathcal{A} \sim 0.2$; Ney 1982). Even material which is nearly pure ice by mass with carbon added at solar abundance has albedo generally below 0.1 (Clark and Lucey 1984).

4. *Spectroscopy of the Classical Shell Gas Component.* β Pic has been classified as a shell star because of the presence of strong narrow circumstellar absorption features superimposed on the cores of some of the broad photospheric lines at ultraviolet wavelengths (Slettebak and Carpenter 1983; Kondo and Bruhweiler 1985; Lagrange et al. 1987; Lagrange-Henri et al. 1988) and at visible wavelengths (Slettebak 1975; Hobbs et al. 1985; Vidal-Madjar et al. 1986; Ferlet et al. 1987; Hobbs et al. 1988). The lines involved are listed in Table VI and are transitions from resonance ($=$ ground) or metastable states, signifying gas with low density and temperature relative to the stellar atmosphere. 'I' signifies a neutral species, 'II' singly ionized, and 'III' doubly ionized.

The shell absorption lines in the β Pic spectrum themselves have complex multi-component structures. In general this structure can be decomposed into a strong stable component at the star's 21 km s^{-1} heliocentric radial velocity, plus additional components especially noticeable in the Al III and Mg II lines which are extremely variable in strength and velocity on time scales of days and months and are always redshifted with respect to the stable component (Sec. III.B.5). Both the stable and variable components were recently observed with the Goddard High-Resolution Spectrograph on the Hubble Space Telescope (Boggess et al. 1991).

The stable component may correspond to a "classical" A-F star shell. Detectability of the Ca II 3d and Fe II metastable transitions indicates that the radiation dilution (solid angle subtended by the star) must be $W > 10^{-5}$ in

TABLE VI
Shell Lines in the β Pic Spectrum

Line	λ , Å
UV	
Al III resonance	1854
Fe II resonance multiplet	~2600
Fe II metastable	2750
Mg II resonance doublet	2795, 2802
Mg I resonance	2852
VISUAL/FAR-RED	
Ca II K resonance	3934
Na I D2 resonance doublet	5890, 5896
Ca II 3d metastable	8542

order that the rate of depopulation of the lower levels via spontaneous decay be negligible compared to radiative absorption (see, e.g., Viotti 1976). This in turn indicates that the stable lines from ionized gas originate in material at $r \leq 1$ AU. Thus, the presence of β Pic's "classical" shell may be unconnected to the infrared/optical grain disk lying at roughly 10 to 1000 AU. There is no correlation between strength of far-infrared excess and strength of spectroscopic A-F shell indicators (Hobbs 1986; Jaschek et al. 1986), and contrary to Jaschek et al. (1986), the frequency of far-infrared excess in A shell stars is not anomalously high compared to ordinary A stars (Sec. IV.A.3).

Velocity dispersion parameters of $b = 1.8 \text{ km s}^{-1}$ for Na I versus 3.7 km s^{-1} for Ca II K are evidence that the material producing the neutral sodium absorption is connected to the grain disk because it seems to lie farther from the star than the ionized material in the shell. Most of the gas mass around β Pic would be expected to lie in this outer component considering the relative volumes and densities, and would distinguish β Pic from "classical" A-F shell stars. Estimates of the total gas mass (including hydrogen) indicate that it is less than $2 M_{\oplus}$, ($<0.5\%$ of the mass in our planetary system) (Vidal-Madjar et al. 1986; Hobbs et al. 1988). Model results indicate that the gas near the star is roughly solar-composition but the line strengths imply that the region where the Na is located must be extremely depleted in Ca relative to Na, possibly because the Ca is trapped in grains (Vidal-Madjar et al. 1986). A recent search (Lagrange-Henri et al. 1990) for spectroscopic analogs to β Pic is discussed in Sec. IV.B.

5. Transient Spectroscopic Events: Comet Impacts? Although spectral variability is also found in other shell stars, the unique occasional highly red-shifted absorption events at β Pic have been claimed as evidence of impact of comet-like bodies onto the star (see, e.g., Ferlet et al. 1987; Lagrange-Henri et al. 1988; Beust et al. 1990; Beust et al. 1991). The most dramatic changes occur on time scales as short as an hour for the Al III line and 6 to 8 hours for

the Ca II line. Individual components of the Al III and Mg II lines can reach equivalent widths of 400 and 900 mÅ and velocities of 350 and 300 km s⁻¹, respectively. These velocities are comparable to free-fall speeds at 2–3 R_* . In contrast, the Ca II K variable components never exceed about 40 km s⁻¹ red shift. Estimated frequencies of redshifted events for the Ca II K line are 10 to 100 yr⁻¹ and 100 to 200 yr⁻¹ for the Al III line depending on red shift. Typical velocities and frequencies appear to vary somewhat over the course of years.

A highly developed but not unique explanation for these phenomena is described by Beust et al. (1990,1991). In their model the transient events in the metallic lines are attributed to the passage through the observer's line of sight of infalling asteroids or comets producing clouds of dust grains that are sublimating or evaporating as they approach the star. The amount of absorbing material is equivalent to the complete vaporization of cometary objects several kilometers in diameter. The observed multi-component structure of the time-variable features can be plausibly explained in this scenario as resulting from objects breaking into pieces due to tidal disruption or extreme heating. The ratio of radiation pressure to gravity is a factor of 10 larger for Ca II ions than for Al III and Mg II ions, which is crucial to explaining the large differences in their observed behavior. Their model also includes a planetary mass in the β Pic system that sends the infalling bodies on the inferred trajectories. A complete dynamical simulation described in Beust et al. (1991) is able to fit the spectroscopic data well with only a few free parameters.

A cometary hypothesis is not as far-fetched as it might seem since small Sun-grazing comets that are totally disrupted in the ensuing collision are known to occur in our own solar system as often as 10 times per year (Michels et al. 1982). It is therefore an interesting possibility that the younger and perhaps more crowded β Pic system is host to many active comets.

IV. SEARCHES FOR VEGA-LIKE SYSTEMS: SURVEYS AND INTERPRETATION

A. Infrared Searches

The statistical properties of the IRAS Point Source Catalog (PSC) including detectability and characteristic far-infrared properties of various types of objects are discussed by Chester (1985). The IRAS Faint Source Survey (FSS) released in September 1990 consists of coadded survey data and is thus 2 to 3 times as sensitive as the PSC, but avoids the galactic plane and does not contain sources detected only at 100 μ m.

1. *IRAS Limitations in Observations of Stars.* Normal main-sequence photospheres are difficult targets of study in IRAS data for the following reasons:

(a) Stellar photospheres of different types all have approximately RJ spectra and are nearly indistinguishable in the IRAS data, with [12]–[25], etc.

colors close to 0.0 mag. As a corollary, cool main-sequence *physical* companion stars are essentially undetectable with IRAS—the maximum possible color excess $E(V-[12])$ due to a main sequence binary companion to any main sequence primary is roughly 0.2 magnitudes.

(b) IRAS was only slightly more sensitive than the human eye to sources with stellar temperatures; the PSC $12\ \mu\text{m}$ completeness limit of ~ 0.4 Jy corresponds to visual magnitude +5.0 for A and +7.5 for G main-sequence stars ($d < 30$ pc!).

(c) Most stars cooler than the Sun detected by IRAS are giants; the dividing line between detection of mostly dwarfs versus mostly giants is at $B-V \sim 0.75$ (approximately spectral type G5) (Waters et al. 1987).

In the absence of circumstellar material one would therefore expect that only a few nearby and bright main-sequence stars would be found in the IRAS data and that even these would not be detected beyond $12\ \mu\text{m}$.

Unlike binary companions, *background* stars are capable of producing substantial excesses in IRAS observations of nearby stars in measures of $V-[12]$, $V-[25]$, etc. In a groundbased $2.2\ \mu\text{m}$ photometric study of the IRAS fields of view around approximately 60 candidate stars with substantial $V-[12]$ excesses, Aumann and Probst (1991) found that only 2 (β Pic and ζ Lep) had true intrinsic $12\ \mu\text{m}$ excess and the rest were caused by red background stars. This implies that the phenomenon of far-infrared excesses around main-sequence stars is usually limited to temperatures below about 200 K.

IRAS discovered that the sky is covered with low-temperature emission from the general ISM, now called infrared “cirrus,” which is concentrated toward the galactic plane. The usually extended cirrus emission includes concentrations which sometimes mimicked the characteristics of a point source in IRAS data processing. One of the warmest such sources found at high galactic latitude and discussed by Low et al. (1984) has a color temperature of 34 K. A source with color temperature less than 40 K is most significantly detected in the $100\ \mu\text{m}$ band in IRAS data. Thus, sources associated by position with nearby stars but having $T_c < 40$ K, and also excesses detected only in the $100\ \mu\text{m}$ band, are possibly due to background cirrus. This is more likely statistically at low galactic latitudes. One way to eliminate candidate Vega-like sources caused by background cirrus would be improved spatial resolution in future infrared instruments which might show a cold source to be an extension of a larger structure or not centered on the star in question.

The far-infrared color typical for galaxies and infrared galactic components (HII regions, planetary nebulae, parts of molecular clouds and star forming regions) of $f_v(25) < f_v(60)$ (Chester 1985) also describes the prototype main-sequence circumstellar sources. However, infrared galactic components are strongly concentrated toward the galactic plane and thus would likely produce only a few spurious candidates. External galaxies, especially starburst galaxies, can have spectra and fluxes similar to the Vega-like sources (Helou and Beichman 1991) and far-infrared sizes of order 10 arcsec, so it is at least possible that some Vega-like candidates could be produced by a galaxy lying

in the background of a star, although the number density of sufficiently bright galaxies versus IRAS 60/100 μm detector field of views of 7 to 15 square arcmin makes for agreement with subject. Again, future comparison of source centroids with star positions can help eliminate this possibility.

Finally, reflection nebulae have been found to emit in all 4 IRAS bands, generally with $f_{\nu}(12) < f_{\nu}(25) < f_{\nu}(60) < f_{\nu}(100)$ after removal of direct flux from the illuminating star (Sellgren et al. 1990). Some of the 60/100 μm ratios are not far from 1 and thus are similar to the circumstellar disk prototypes. This similarity should not be surprising because the β Pic disk is in a sense a reflection nebula. Characteristics which might distinguish orbiting material from ISM grains warmed by a luminous star might be: symmetric versus asymmetric source shape and/or angular scale too small for emission involving small ISM grains. Once again, spatial resolution superior to that available with IRAS may be needed to distinguish normal reflection nebulae from Vega-like systems.

2. *IRAS Data on Typical Main-Sequence Stars.* Waters et al. (1987) and Cohen et al. (1987) summarize PSC data on objects in the Bright Star Catalog (BSC) (Hoffleit and Jaschek 1982). Both papers present typical V-[12], V-[25], etc. colors for a range of spectral types and luminosity classes and confirm the expectation that there are no significant flux *deficits* relative to expectations of RJ or slightly steeper slopes; disturbances to photospheric colors are exclusively *excesses*. An independent check by Graps (personal communication) confined to luminosity class V found V-[12] colors similar to Waters et al.'s means for all spectral types. These colors are about 0.1 mag redder than predicted by stellar atmosphere models.

Figure 7 presents the median IRAS 12/25 μm flux density ratios versus spectral type for the 670 BSC stars of luminosity classes IV, IV-V, and V detected in both bands (Graps, personal communication). These continuum slopes are quite similar to those found for Gliese catalog (nearby) stars (Backman and Gillett 1987) and for SAO stars (Stencel and Backman 1991).

Among A and early F stars, even typical stars have modest 25 μm excesses with median T_c cooler than T_{eff} by several thousand degrees. Note that the ratio for α Lyr is exactly at the median for types B9-A1, yet approximately 25% of the 25 μm flux density in that case is known to be excess from grains. For these types, 50th percentile falls closer to the blue end of the distribution, because the population includes only a few stars with substantial excesses. Median (50th percentile) late F, G and early K stars fall near the average of the range, and the range is consistent with IRAS photometric uncertainty, implying that few of these stars have detectable excess at 25 μm compared to 12 μm . Typical B IV-V stars have substantially redder colors than stars of later types and 50th percentile falls nearer the red end of the ranges, approaching the colors of a free-free plasma emission spectrum. This is consistent with the typical B star having a free-free excess but with a blue tail in the population toward stars with more nearly photospheric colors.

3. *Published Surveys and Present "Master List."* A number of searches

Figure 7. Median IRAS 12/25 μm flux density ratios (raw, i.e., without bandwidth color corrections) vs spectral type for main-sequence stars in the Yale Bright Star Catalog detected in both bands. Stars with giant or supergiant companions were excluded. There were few enough main-sequence stars later than K4 that they were also excluded. The type bins represent combinations of groups of 3 subtypes, i.e., the median labelled A0 is for B9, A0, and A1 stars considered together. The error bars represent the range from 25th percentile to 75th percentile. The R-J line at the top represents the color of a blackbody of infinite temperature. The F-F line at the bottom represents the color of pure free-free (plasma) emission.

have been conducted for examples of stellar far-infrared excesses. Aumann (1985) examined PSC data on stars with $d < 25$ pc and found 12 stars with galactic latitude $|b_{ll}| > 10$ deg having $[12] - [60] > 1.0$ mag, defined there as Vega-like, including the three resolved prototypes. The fact that the ones with excess are mostly A–F stars was recognized as probably due to a luminosity selection effect. Sadakane and Nishida (1986) examined PSC data on BSC members and found 12 more Vega-like stars using criteria identical with Aumann's (1985), again mostly A–F stars with *no lack of excesses in binary systems*, which may be very significant information about the mechanisms for forming these grain clouds. One of the stars, λ Boo, is known to be metal deficient, which is interesting in light of the low metallicity of β Pic (Sec. V.A), and raises the issue of composition of the circumstellar grains. Coté (1987) examined PSC data on BSC B and A stars and found 24 examples of infrared excess, some of which were also noted in the previous studies. Twenty-one of these cases are attributed by the author to dust emission, 3 to free-free emission.

Odenwald (1986a, b) examined PSC data on G stars of all luminosity

^a References: Au = Aumann 1985 (Gliese+Woolley catalogs; PSC+coadds); B1 = Backman et al. 1986 ($d < 5$ pc stars; survey coadds + pointed obs.); B2 = Backman and Gillett 1987 (Gliese subset; survey coadds); Co = Cote 1987 (BS catalog B+A stars; PSC); Ho = Hobbs 1986 (shell stars; PSC); Ja = Jaschek et al. 1986 (shell stars; PSC); SN = Sadakane and Nishida 1986 PASP 86, 685 (BS catalog; PSC); WW = Walker and Wolstencroft 1988 (HD catalog; PSC-extended sources).

classes and found strong infrared excesses mostly from dusty shells around supergiants, but also at least one case of a main sequence excess. Johnson (1986) found warm excesses around some K dwarfs, most of which are classified as T Tauri stars. Jaschek et al. (1986) examined PSC data on 19 Ae/A shell stars comparable in optical spectral qualities to β Pic and found 8 with strong far-infrared excess. This is similar to the frequency of excesses among normal A stars in samples of nearby stars (Sec. IV.A.4). There appears to be no clear correlation between the optical and infrared properties of shell and emission line stars.

Walker and Wolstencroft (1988) selected HD stars ($m_v > 10$) with PSC 60/100 μm flux density ratios similar to the prototypes. In addition, they examined evidence of the extent of the emission via the IRAS data "confusion" flag, which was set when a source was seen by 3 detectors in one waveband, nominally requiring a size of at least 20 arcsec. The data were then analyzable in terms of grain size and total mass. Some of the objects discovered in this survey have stronger far-infrared fluxes than the prototypes, and since these HD stars are in general dim the fractional luminosities (optical depths) in some cases approach 1, substantially different from the prototypes. A search for CO emission (Walker and Butner 1991) from some of these stars did not detect any molecular material other than probable background emission.

Backman et al. (1986) combined groundbased near-infrared photometry

with IRAS pointed observation ("AO") data on stars within 5 pc and found several examples of weak excess which had been missed at the sensitivity level of the PSC. One of those stars, Ross 128, is the only M dwarf so far known to have a Vega-like excess. α CMa (Sirius) was found to have a weak $100\ \mu\text{m}$ excess, but the characteristics seem to exclude emission from orbiting grains, as confirmed by Chini et al. (1990) with mm-wave measurements.

Table VII is a "master list", a union of lists of main-sequence (luminosity class IV, IV–V, and V) stars found to have far-infrared excesses. Because the selection criteria and procedures were not uniform and the IRAS data used had various sensitivities, this list is of somewhat mixed quality.

Backman and Gillett (1987) and Aumann (1988) showed by examining coadded survey photometry of nearby stars that the phenomenon of far-infrared excesses (a) may be the rule rather than the exception for main-sequence stars, (b) appears in all spectral types, and (c) is not restricted to stars of young age. The implication that our solar system might also have a cool excess when viewed from outside is considered in Sec. VI.D.3.

4. Bright Star Catalog and Gliese Catalog Surveys. Table VIII presents a complete list of BSC main-sequence stars found to have Vega-like far-infrared excesses, as defined below. There is some overlap between this list and the "master list" in Table VII. The original sample consisted of all BSC stars in luminosity class V with detected flux at $12\ \mu\text{m}$ and having no higher-luminosity class companion. In case of dimmer companions, the system is listed by the primary's spectral type. IRAS PSC2 data were used and all infrared sources within 60 arcsec of the star position corrected for proper motion to 1983.5 were accepted.

It was found in a plot of $f_v(25)/f_v(60)$ versus $f_v(12)/f_v(25)$ (Fig. 8) that the three prototypes α Lyr, α PsA, and β Pic spanned a broad stretch of the diagram, and a number of objects were found to lie in the same stretch. Stars of spectral class O or Be were found to lie often in a region with $f_v(25)/f_v(60) > 1$ and $f_v(12)/f_v(25) < 2.5$ which contains the locus of a purely free-free spectrum and were rejected as having excesses likely due to plasma emission. Stars with detected flux at $100\ \mu\text{m}$ but with $f_v(60)/f_v(100) < 0.2$, i.e., $T_c < 30\ \text{K}$, were excluded as being likely due to background cirrus. Finally, stars with $f_v(25)/f_v(60) > 4.0$, i.e., $T_c > 500\ \text{K}$, were excluded; over that wavelength range, those colors do not differ significantly from photospheric colors. These criteria in combination are essentially equivalent to a search for excesses most prominent at $60\ \mu\text{m}$.

Note the two trajectories in Fig. 8 which show the loci of points corresponding to: (a) a system like β Pic if the disk luminosity is decreased relative to the star from its actual value of 2×10^{-3} toward 1×10^{-5} , approaching the upper right of the diagram where the colors of a pure stellar photosphere lie; and (b) a system like α PsA if the disk luminosity is increased relative to the star from its actual value of 8×10^{-5} toward 1×10^{-2} , approaching the locus of β Pic. This indicates that the different loci of β Pic and α PsA in this color-color plot simply represent different fractional grain luminosities but

not fundamental differences in disk structure or the mechanism of far-infrared emission. The region of the diagram these trajectories cross is interpreted as the region of Vega-like excesses.

A study made by Backman and Gillett (1987) examined coadded IRAS photometry of 134 stellar systems from the Gliese Catalog (Gliese 1969; Gliese and Jahreiss 1979). The sample was limited to stars of spectral types A–K, luminosity classes V and IV–V, trigonometric parallax $\pi_t \geq 0.045$ ($d < 22$ pc), and color temperatures above 35 K. This study contrasts with the aforementioned Bright Star survey in that the sample was defined by a flux density limit at $12\ \mu\text{m}$, with the result that a greater proportion of later-type stars were included.

Those stars with significant excesses at 25, 60, or $100\ \mu\text{m}$ with color temperatures above 35 K are listed in Table X. Significance was defined as greater than 3 times the rms noise in the off-source scan baseline. The summed luminosity of components listed by Gliese (1969) was used in calculating the fractional cloud luminosities in column 11. Table IX lists as a function of spectral type an estimate of the sample distance limit (reciprocal of 25th percentile trigonometric parallax), the number of stars in the sample, the fraction of sample stars with significant excesses, and the fraction of sample stars with significant excesses stronger than a fractional luminosity of 2×10^{-5} , approximately equivalent to α Lyr.

The possible meaning of the statistics in Table IX is that there is no strong dependence on spectral type when frequencies of far-infrared excesses

Figure 8. IRAS color-color diagram for main-sequence stars in the Yale Bright Star Catalog. The colors of the three prototype objects are indicated. The two trajectories respectively show the range of colors which the β Pic and α PsA disks would have if all other disk parameters were kept constant while the optical depth was varied. The "excluded" region contains the color of pure free-free emission.

TABLE IX
Far-Infrared Excesses in Gliese Catalog Subsets

Spectral Type	N	Excess $>3\sigma$	Excess $\tau \geq 2 \times 10^{-5}$	Approx. limit (pc)
A	22	41%	18%	20
F	51	10%	10%	18
G	39	10%	8%	15
K	22	14%	14%	7

are compared by fractional luminosity rather than by significance of IRAS detection. Similar results are reported by Aumann (1988). The frequency of far-infrared excesses around A stars at this sensitivity limit is near 50%; it may be that a more sensitive instrument than IRAS will find that fraction approaching 100%. Note also in column 12 of Table X that there are several stars with ages approaching the age of our Sun determined from photometric isochrones (Varsik 1987), lithium abundances (Simon et al. 1985), or emission-line strengths (Duncan 1981). This implies that the Vega phenomenon is not limited to proto-stellar or proto-planetary contexts.

B. Optical Spectroscopic and Coronagraph Searches

Lagrange-Henri et al. (1990) have undertaken a comprehensive spectroscopic survey for β Pic analogs. Since β Pic has both an infrared excess and a

shell spectrum, they searched 57 candidates that had at least one of those two attributes for the telltale signature of narrow, mostly redshifted and possibly variable circumstellar absorption lines of Ca II and Na I. Although a few (especially HR 10, 2174, 8519 and 9043) had some similarities or were remarkable in some way, none in the sample were found to resemble β Pic in detail.

Coronagraph surveys based on lists of IRAS excesses and/or shell spectra have been made separately by Brahic, Smith and Terrile, and Burrows and Paresce. The latter team examined 20 of the objects in Lagrange-Henri's list mentioned above, and found no disk detectable at radii of 6 arcsec from the stars to an I-band surface brightness limit of about 18 mag arcsec⁻². This limit is roughly 2 mag fainter than the β Pic disk, but null results are not surprising considering that β Pic's grain optical depth and orientation are so exceptional.

V. TIME SCALES, DYNAMICS, AND EVOLUTION

A. Ages of The "Big 3"

The metallicities of α Lyr and α PsA are close to solar. Their ages on the Green et al. (1987) revised Yale isochrones are 4×10^8 and 2×10^8 yr, respectively, with uncertainties of roughly 30%. The derived age for α Lyr is near the end of the stage of core hydrogen burning for its mass, and in fact that star is a factor of 3 to 4 times brighter than its ZAMS luminosity.

The indicated metal abundance for β Pic from a new calibration of Geneva photometry (Kobi and North 1990) is $\log_{10}[\text{M}/\text{H}] = -0.6 \pm 0.3$, or 1/4 of solar, rather depleted with respect to normal nearby stars of early spectral class. Fundamental parameters of $R_\star = 1.2 R_\odot$ and $M_\star = 1.5 M_\odot$ are found, both slightly lower than typical A5 dwarfs but within a plausible range. The ZAMS bolometric magnitude from the Green et al. isochrones for $Z = 0.004$, $Y = 0.2$, $T_e = 8200$ K is $M_{\text{bol}} = 2.80 \pm 0.15$ mag (1 σ) versus an observed value from its parallax, V magnitude, and bolometric correction of 2.63. β Pic's age can be estimated to be about 100 Myr, above but close to the ZAMS. The most evolved position on the Yale isochrones allowable (considering the range in possible helium and metal abundances) corresponds to an age of 200 Myr, about 10% of the main sequence lifetime of a $1.5 M_\odot$ star (Paresce 1991).

B. Intrinsic Grain Removal Processes

Radiation pressure, particle collisions, and ice sublimation are processes which can remove or destroy grains orbiting stars. Their time scales offer clues to the source and evolution of the grain material. Individual processes will be discussed separately in the next sections, followed by discussion and comparison of their rates at inner and outer radii in the three prototype systems.

1. Radiation Pressure Expulsion. A simple derivation of the overpressure ratio δ of radiation to gravitational forces acting on a grain near a star assuming

spherical black ($A = 0$) grains of radius a is:

$$\delta \equiv \frac{F_{\text{rad}}}{F_{\text{grav}}} = \left(\frac{3}{16\pi cG} \right) \left(\frac{L_{\star}}{M_{\star}} \right) \left(\frac{1}{a\rho} \right) = \left(\frac{0.57}{a_{\mu\text{m}}\rho} \right) \left(\frac{L_{\star}}{L_{\odot}} \right) \left(\frac{M_{\odot}}{M_{\star}} \right). \quad (13)$$

The value of δ is inversely proportional to grain size in this simple treatment. For a given value of grain density there will be one size for which $\delta = 1$, defining a minimum stable or “blowout” size for grains released at rest which depends only on the central star’s luminosity and mass. Both forces depend on r^{-2} so their ratio δ has the same value at all locations for a given grain and all regions will be cleared equally well. Grains are propelled beyond radii of 10^3 AU on free-fall time scales of order 10^4 yr by this means. Column 2 of Table XI presents the “blowout” size for each of the three systems. It is interesting that this size is comparable to the typical or abundant grain sizes estimated in Table III, as if this process provides lower limits to grain size distributions weighted toward the smallest grains.

A more careful treatment of radiation pressure effects (Burns et al. 1979) including grain albedo and radiative efficiency shows that there is a maximum value in our solar system of $\delta \sim 0.5$ at a grain size of about $0.5 \mu\text{m}$ (close to the peak wavelength of the Sun’s radiation) for most realistic grain materials. Grains smaller and larger than that size are more stable against ejection, meaning there is no unstable size for grains released at rest in our system. One can approximately scale Burns et al.’s results to other stellar systems with an increase of overpressure by a factor of $(L_{\star}/L_{\odot})(M_{\odot}/M_{\star})$ and a shift of the grain size of maximum overpressure to smaller sizes by a factor of T_{\star}/T_{\odot} . Artymowicz (1988) employed a similar analysis for the case of β Pic. The general expectation for stars with the luminosities of the three A stars is an excluded grain size range between about $1/30$ and $1/2$ times the simply calculated “blowout” size.

2. Poynting-Robertson Radiation Drag. Particles stable against radiation pressure ejection are subject to the PR effect in which incoming radiation in the moving frame of the grain has a component that always opposes the grain velocity. This causes grains orbiting in a radiation field to spiral toward their orbit center even if the orbit center and the radiation source are not the same. The orbit decay time due to PR drag (see, e.g., Burns et al. 1979) is:

$$t_{PR} = \left(\frac{4\pi a\rho}{3} \right) \left(\frac{c^2 r^2}{L_{\star}} \right)_{\text{cgs}} = 7.1 \times 10^2 a_{\mu\text{m}} \rho r_{\text{AU}}^2 \left(\frac{L_{\odot}}{L_{\star}} \right) \text{yr}. \quad (14)$$

An important characteristic of PR drag is that it is guaranteed to apply to all stably orbiting grains of any composition in any optically thin situation whereas other processes such as mutual collisions or ice sublimation may not apply in some cases.

3. Grain Collisions. The mutual collision time scale is approximately:

$$t_{\text{coll}} \sim \frac{t_{\text{orb}}}{8\sigma(r)} \sim \frac{r_{\text{AU}}^{\frac{3}{2}}}{8\sigma(r)} \left(\frac{M_{\odot}}{M_{\star}} \right)^{\frac{1}{2}} \text{yr} \quad (15)$$

where $\sigma(r)$ is the fractional surface density as in Eq. (8). This expression assumes that each orbiting grain encounters the full surface density roughly twice per orbit as it oscillates perpendicular to the disk plane and that the collision cross section is 4 times the cross-sectional area of individual grains to include tangential collisions.

Collisions can be assumed to result in destruction rather than accretion because even tangential collisions at relative speeds greater than 0.1 km s^{-1} (10^8 erg g^{-1}) should result in catastrophic fragmentation (see, e.g., references in Lissauer and Griffith 1989). The relative velocity of grains due to their motion perpendicular to the plane of a disk is approximately $V_z \sim iV_{\text{orb}}$, where $2i$ is the opening angle of the disk subtended at the star. For example, for β Pic with an opening angle of about 0.1 rad and $M_* = 1.5 M_{\odot}$, $V_z > 0.1 \text{ km s}^{-1}$ at $r < 1000 \text{ AU}$. Most fragments from such high-speed collisions involving small grains would likely be smaller than the “blowout” size and be rapidly ejected from the system.

Grains of various sizes will move at different orbital speeds for the same orbit because the radiation force reduces the effective potential. The range of orbital speeds resulting from this effect for grains between 1 and 10 times the “blowout” size would also imply relative speeds greater than the collisional destruction threshold of 0.1 km s^{-1} throughout the relevant radii ranges even if motions perpendicular to the disks are unexpectedly small.

4. *Ice Sublimation.* The time scale for sublimation of pure water ice grains can be estimated from expressions in Isobe (1970):

$$t_{\text{subl}} = 1.5 \times 10^{-12} a \rho \frac{10^{2480/T_g}}{T_g^{7/2}} \text{ yr} \quad (16)$$

where T_g is the grain temperature. This rate is an extremely powerful function of temperature; i.e., for temperatures of 90 to 120 K, Eq. (16) can be approximated by:

$$t_{\text{subl}} \sim 10^6 a_{\mu\text{m}} \left(\frac{T_g}{100\text{K}} \right)^{-55} \text{ yr}. \quad (17)$$

A more complete treatment can be found in Lien (1990), including the result that “dirty ice” grains have a much shorter sublimation time scale than pure ice at a given location.

5. *Comparison of Grain Removal Time Scales, and Mass-Loss Rates.* Columns 4–6 of Table XI contain the time scales for each process at inner boundaries and outer locations in the models of the three systems using grain sizes from Table III and assuming grain density of 1 g cm^{-3} . The PR decay time would increase linearly with increased density. The inner boundary radii are for the $\gamma = -1.6$ case. The outer positions considered correspond roughly to the optically traced extent of the β Pic disk. The face-on optical depths $\sigma(r_1)$ for Eq. (15) can be approximated by the fractional luminosity f in Table III. Time scales labelled ∞ are much greater than 10^{10} yr .

TABLE XI
Grain Removal Processes

	Blowout Size, μm	r_1 , AU	Removal Time Scales, yr		
		r_2 , AU	t_{PR}	t_{coll}	t_{subl}
α Lyr	14	26	2×10^5	5×10^5	9×10^5
		1000	3×10^8	5×10^{10}	∞
α PsA	4	67	6×10^6	6×10^5	∞
		1000	1×10^9	3×10^9	∞
β Pic	2	38	2×10^5	8×10^3	4×10^{-4}
		1000	1×10^8	2×10^8	∞

A number of conclusions can be drawn from this information and a comparison with the stellar lifetimes and ages in Table I and Sec. V.A:

1. The grain lifetimes are shorter than the stellar main sequence lifetimes throughout the systems to $r \sim 1000$ AU.
2. The grain lifetimes are so short at the inner boundaries that the grains must be either continually replenished from some reservoir or else the inner boundaries move rapidly compared to stellar time scales.
3. Icy grains could persist for the lifetimes of the stars throughout the α PsA system and in the outer regions of the α Lyr and β Pic systems.
4. The ice sublimation time is only a few hours in the inner zone of the β Pic disk, so the grains there must be refractory, apparently confirmed by the detection of silicate emission close to the star (Telesco and Knacke 1991).
5. The maximum temperatures in the three systems are so different in terms of implied ice lifetimes that it seems unlikely the inner boundaries are all defined by a phase transition from icy to refractory grains unless the grain composition differs significantly from system to system.
6. Within uncertainties of grain density and radial structure the PR process is competitive with the collision process throughout these systems, although collisions appear to be generally dominant. If PR drag were in fact dominant, the existence of inner voids would require some additional mechanism to prevent grains from moving toward the stars and erasing the voids.

The time scales in Table XI clearly indicate that most of the small grains detected by IRAS are short-lived and must be replenished somehow. Detection statistics for analogs to the prototypes show that these systems are too common to represent chance detection of events as brief as the grain lifetimes.

Collisions can be a mechanism for production as well as destruction of small grains via destruction of larger bodies. Collisional or thermal fragmentation of undetected parent bodies to balance loss of the detectable grains were originally discussed by Weissman (1984), Harper et al. (1984), and Matese et al. (1987).

The grain lifetimes do not seem to offer a general explanation for the

inner boundary locations, temperatures, and surface densities of the three prototypes. It is possible that the inner boundaries reflect original structural features such as orbits of major planets. Planets orbiting the stars at the inner boundaries of the infrared-emitting regions and consuming or perturbing grains inbound under the influence of the PR effect could explain the central voids. On the other hand, in analogy with our solar system a large planet might result in an asteroid belt interior to its orbit which would be a source of extra dust, especially in a young planetary system. Surface photometry of the disks at $\lambda = 10$ to $20\ \mu\text{m}$ with spatial resolution of 1 arcsec or better would be extremely valuable in constraining the sizes of the central voids and determining which processes are responsible for their creation and maintenance.

Minimum mass loss rates from collisions alone can be estimated by integrating Eq. (15) over radii, assuming that all the surface area is in grains with sizes as in Table III and density $1\ \text{g cm}^{-3}$. If this rate were to remain constant over the main sequence lifetime of the stars, a mass in small grains of at least $1 \times 10^{-2}\ M_{\oplus}$ for α Lyr and $1 \times 10^1\ M_{\oplus}$ for β Pic would be destroyed.

C. Speculation on History and Evolution

1. Protostellar and Protoplanetary Stages. The broad context of the study of protostellar and protoplanetary evolution tends towards elaboration of a basic planetesimal theory. This proceeds from the gravitational collapse of a rotating molecular cloud core to the formation of an optically thick circumstellar gas and dust accretion disk, which could be the precursor to optically thin grain disks like the ones under consideration here.

The choice between minimum-mass (see, e.g., Cassen and Summers 1983) and massive (see, e.g., Lin and Pringle 1990) protoplanetary disk scenarios is presently a basic controversy in the field of planetary formation. The relevance to this review is the question of origin of material at radii of 10^3 AU like the grains in the disk around β Pic, and by inference the other main-sequence far-infrared excess stars. In the minimum-mass scenario, material could reach that position via (1) the process of angular momentum distribution which dumps much of the initial disk into the star but greatly expands the scale of the remainder, and/or (2) orbital perturbation from the inner solar system; for example, many Uranus-Neptune zone planetesimals could be tossed outward by encounters with the nearly completed planets and found at intermediate semimajor axes of 10^2 – 10^3 AU, falling short of the Oort cloud. In contrast, in the massive-disk scenario planetesimals can form *in situ* at radii of 10^3 AU.

Calculations (Lin and Pringle 1990) of the evolution of massive disks show that the operation of some viscosity mechanisms makes any original surface distribution produced by infall eventually approach $\sigma_m(r) \propto r^{-1.5}$. This may indicate that the β Pic optical disk with $\sigma \propto r^{-1.7}$ from 100 AU to 1000 AU is a fossil remnant of an original disk rather than material sorted into that region by planetary perturbations.

At later development stages there is ample observational evidence that a

significant fraction of young main-sequence stars are surrounded by optically thick circumstellar disks of solar-system size with masses $\sim 0.01 M_{\odot}$ (Strom et al. 1989d; Beckwith et al. 1990) which corresponds to the entire disk in a low-mass scenario or the central portions of a more massive disk. Recent near- and mid-infrared (Skrutskie et al. 1990) and mm-continuum (Beckwith et al. 1990) studies of a large sample of pre-main-sequence stars in the Taurus-Auriga complex suggest that half of the known very young ($t < 3$ Myr) solar-type stars have excess emission arising from heated dust embedded within such optically thick disks (see also Walter et al. 1988). At ages $t \geq 10$ Myr, fewer than 10% of the Taurus-Auriga sample show the infrared signatures of optically thick disks. Hence, disks apparently evolve from optically thick to optically thin structures. If all solar-type pre-main-sequence stars are initially surrounded by disks, then roughly half have either fully accreted their initial disk material or have begun to assemble grains into planetesimals by an age of 3 Myr and few optically thick disks survive for more than 10 Myr.

In a series of papers Nakano (1987a, b, 1988) has attempted to extend a detailed theory of planetesimal and planet formation to explain the observations of β Pic and α Lyr in a self-contained way. This ambitious model is at odds in some ways with other planetesimal scenarios for the formation of our planetary system in having low initial disk mass and long time scales. Nakano (1987a) "finishes" Neptune in 3 Gyr, more than 1/2 the age of our solar system, whereas models of "runaway" accretion which begin with disks an order of magnitude more massive than the minimum mass produce planets much faster (Lissauer 1987) and put leftover material into substantial inner and outer Oort clouds. The most troubling disagreement between Nakano's model and observations of β Pic is that the model implies that we are viewing the star nearly in the disk midplane through significant optical depth ($\tau \sim 0.5$), but as discussed in Sec. V.A, the metallicity of β Pic explains the star's apparent low luminosity without extinction. Despite this and other problems, the value of these papers lies in the profound importance of the general issues raised by connecting the β Pic and α Lyr systems with theories of planet formation.

Nakano (1988) models the scattered light from the β Pic disk as due to small grains released by planetesimal collisions. He predicts an edge-on surface brightness of the disk following $r^{-4.375}$, quite close to the observed value $r^{-4.3}$, and also an approximately constant disk opening angle in the outer parts of the disk, agreeing with analyses of coronagraph observations. Nakano's model in addition predicts that there should be three regions in the β Pic disk, $r < 4.7$ AU in which the planets are finished, $4.7 < r < 23$ AU in which the planetesimals have had at least one encounter and an equilibrium thickness has been reached, and $23 \text{ AU} < r < \infty$, a realm of colliding ice planetesimals which corresponds to the region visible in coronagraph images. The innermost region in the model represents a striking theoretical prediction of a central zone of the appropriate size which might be empty of small grains to the IRAS sensitivity limit. It is interesting that the outer region would not

be full of small grains but instead because of low planetesimal collision rates would contain discontinuous regions of relatively high density resulting from individual recent collisions, analogous to the asteroidal dust bands discovered in our solar system in IRAS data (Low et al. 1984; Sykes and Greenberg 1986). If this is true the surface brightness of a face-on disk would not be uniform but instead would be composed of myriad discrete and incomplete bands and streaks.

Planetesimal models of planet formation in general predict a progression of the planet formation process with time to greater radii, reducing the number of planetesimals and therefore the infrared luminosity from small grains. There would also be a decrease in the color temperature of the emission as the boundary between regions containing finished planets (no planetesimals) and unfinished planets (plus planetesimals and plentiful small grains) moves to greater radii. Nakano's models imply that a disk originally of β Pic's particle density and fractional luminosity would be more than an order of magnitude less prominent by an age of 5 Gyr.

2. *Encounters with the Interstellar Medium.* Lissauer and Griffith (1989) pointed out that erosion by dust grains in the ISM could be a significant destruction process for small grains orbiting far from a star like β Pic. This is true only if ISM grains can reach the circumstellar grains in the face of repulsion by the stellar luminosity; the work of Burns et al. (1979) and Artymowicz (1988) imply that very small grains may be relatively unaffected by radiation forces. The steady erosion of grains around stars with lifetimes of several times 10^8 yr or more would be mostly due to encounters with ISM grains in atomic clouds. The fragments would likely leave the circumstellar disk due to ISM gas drag, or radiation pressure, or ejection velocity above escape velocity.

Over a 100 Myr period in which no molecular clouds are encountered, erosion during the nominal 3% of the time spent in atomic clouds with $n_H \sim 20 \text{ cm}^{-3}$ would decrease a grain's radius by an average of $\Delta a = 50 (v/10 \text{ km s}^{-1})^3 \mu\text{m}$. Note the dependence on v^3 ; that plus the fact that stellar random velocities are larger than cloud random velocities means that case-by-case stellar velocity will be important. The main point of the Lissauer and Griffith paper is that β Pic has a surprisingly low velocity relative to the "local standard of rest" (LSR), defined as the galactic circular orbital velocity vector for the solar neighborhood. The average motion of interstellar Ca II is within 3 km s^{-1} of the LSR (Mihalas and Binney 1981), indicating the LSR is a reasonable choice for the velocity frame of atomic clouds.

Lissauer and Griffith's conclusion is that β Pic's grains should be suffering markedly less ISM erosion than grains around other stars. This may provide an explanation as to why β Pic's disk density is so high and also why the typical grain size is so small compared to other examples. As further evidence, they find a weak correlation between grain luminosity L_g/L_* and stellar velocity for 10 nearby stars which have Vega/ β Pic analog far-infrared excesses.

Whitmire et al. (1992) propose instead that passage through a dense re-

gion of the ISM would act to temporarily *increase* the total grain area around stars via multiple-impact fragmentation of large grains in pre-existing disks. The grains in our inner solar system which have been produced by asteroid collisions or released from active comets have typical sizes of $100\ \mu\text{m}$ (Grün et al. 1985). This is roughly the same size as the grains in the α Lyr disk. Whitmire et al. argue that multiple collisions during passage through an atomic cloud could result in destructive fragmentation even of large grains. In this scenario most circumstellar disks are in quiescent states of low detectability during which large grains are produced by parent body collisions or sputtering. This alternates with brief periods during which the large grains suffer fragmentation so that detectability is greatly enhanced until the various internal removal mechanisms clear out the small grains.

Whitmire et al. (1992) show that five A stars with the most luminous circumstellar disks or candidate disks (α Lyr, α PsA, β Pic, β Leo and ζ Lep) have space motions which are highly correlated. The trajectories of all 5 of these stars passed through or near the Lupus-Centaurus (also called Sco-Cen) ISM concentration ($d = 100\text{--}200$ pc) between 5 and 10 Myr ago. Although groups of stars with small dispersion velocities in at least two components are usually young stars of common origin which can often be associated with a known concentration, this is unlikely to be the explanation for this group of 5 stars because their mean velocity is not close to that of objects in the Lupus-Cen concentration or any other known concentrations. Also, evidence in Sec. V.A indicates that the ages at least of α Lyr and β Pic are discordant, and both stars are much too old to have formed in Lupus-Cen. Another explanation would be a selection effect whereby stars which independently passed through the nearest concentrations of the ISM call attention to themselves by their newly enhanced small-grain far-infrared excesses. Such stars which are currently in our vicinity would necessarily have similar velocity vectors.

The essential differences between the Lissauer and Griffith and the Whitmire et al. scenarios is that the former group imagines an initial population of grains of a range of sizes down to $1\ \mu\text{m}$ which is not replenished but is eroded progressively except in special cases of low stellar velocity. The latter group imagines continual replacement of large grains which are episodically converted into smaller grains.

3. Post-Main-Sequence Evolution. Matese et al. (1989) investigated the question of the fate of circumstellar disk material when the parent star leaves the main sequence and progresses through red giant and asymptotic giant branch (AGB) stages. The luminosity of 1 to $2\ M_{\odot}$ stars increase by factors of $10^3\text{--}10^4$ during these stages over periods of $10^7\text{--}10^8$ yr, with corresponding increases of circumstellar grain temperatures by factors up to 10. For example, small water ice grains located anywhere within 10^4 AU of β Pic would be heated to above sublimation temperature and be rapidly destroyed. Larger icy parent bodies would become active and release gas and grains as comets do in our inner solar system.

Matese et al. conclude that the grain release rate from activated comets is

probably not sufficient to supply the grain mass observed in AGB star winds usually interpreted as condensing directly from the wind material. However, small grains from the comets could provide the necessary cores on which the AGB stellar mass loss would condense into larger grains. The source of those nucleation cores has been somewhat of a puzzle in ISM grain and AGB star research especially given the fact that other types of stars (e.g., hot supergiants and most Wolf-Rayet stars) have significant mass loss but negligible grain condensation. Their model of the environment of AGB stars yields testable predictions of grain condensation location and morphology of the grain flow (flat rather than spherical) which differ significantly from the predictions of classical nucleation theory. Jura (1990) (see also Judge et al. 1987) finds that less than 5% of G–K *giants* have far-infrared excesses in IRAS PSC data. G giants are mostly descendants of A–F main-sequence stars, do not generally show signs of mass loss, and precede the AGB evolutionary stage. If giants had disks with optical depths like those seen around at least 20% of nearby main-sequence stars, they would have had detectable excesses (a G giant has about 3 times the luminosity of its A main-sequence progenitor). Jura concluded that either main-sequence circumstellar grains are destroyed by PR drag without resupply, or the grains are icy such that grains originally near 100 K are quickly destroyed by small temperature increases at the beginning of post-main-sequence evolution.

VI. RELATIONSHIP TO OUR SOLAR SYSTEM

The crucial question of the relation of these Vega/ β Pic systems to our solar system and to planetary systems in general needs to be addressed. If the examples of cool debris around main-sequence stars detailed in Sec. IV are each sign of a planetary system, then the Drake equation factor expressing the fraction of stars with planets f_p can be estimated to be greater than 0.15 based on these IRAS investigations.

A. Planetary Systems Around The “Big 3” Prototypes?

As previously discussed, there is evidence that the infrared radiating material in all three prototypes probably lies in a disk in the stellar equatorial planes. Central clearings of solar system scale have been found in these examples because flux densities are high enough to allow a plausible determination at IRAS sensitivity of a maximum grain temperature. This has been interpreted as evidence that planets have accreted and removed an original small grain population from detectability (Diner and Appleby 1986). On the other hand, the depleted zones could also be regions cleared of ice grains by sublimation, or could signify a failure of any material to accumulate in those areas when these systems formed.

Weissman (1984) and Harper et al. (1984) have suggested that the emission around α Lyr is from small grains generated by sublimation or collisions in a cloud of comet-like bodies similar to that thought to have condensed in

the outer solar system. Weissman pointed out that it was improbable that planetary-sized bodies are present in the far-infrared emitting region itself because the accretion time for large bodies at these distances from the star are longer than the age of the system.

In the β Pic system, there may be a planet-mass perturber propelling dust particles close to the star to produce the transient absorption line events (Beust et al. 1991). The grain evaporation products may accumulate in a coma of ions observed in the stable heliocentric component of the Ca ion representing the massive "classical" shell.

B. Infrared Detectability of Our Solar System from "Outside"

One can consider how our solar system would appear to an instrument with IRAS' capabilities if viewed from β Pic ($d \sim 16$ pc).

1. The Sun itself would be detectable only at 12 and 25 μm . The diameter of the planetary region (Pluto's orbit) would subtend 5 arcsec. The sum of the infrared flux from the planets, moons, and large asteroids would be a factor of 10^4 below IRAS' best sensitivity limit in "pointed" observations.

2. The bolometric luminosity of the zodiacal dust in the inner solar system is about $8 \times 10^{-8} L_{\odot}$, with characteristic temperature of 230 K and typical grain sizes of 100 μm (Good et al. 1986; Grün et al. 1985). The presence of that material would produce at $\lambda \sim 20 \mu\text{m}$ (best contrast) a tiny excess of 2×10^{-4} Jy, less than 10^{-2} of IRAS' limit, on top of a solar photospheric flux density of 0.2 Jy. The emission would be contained within a diameter of less than an arcsec. Not only would the signal be too small in an absolute sense, but without high spatial resolution even a sufficiently sensitive infrared instrument would need to be coupled with extremely precise knowledge of the Sun's photospheric infrared spectrum to identify that amount of nonphotospheric emission.

This illustrates once again the principle that direct detection of optical or infrared radiation from extra-solar planetary material is sensitive to area rather than mass; the zodiacal dust contains less than 10^{-10} of the total mass of the planets, yet has an infrared luminosity 10^2 times larger. It is possible that other planetary systems might have more prominent zodiacal clouds. A zodiacal cloud around α Centauri with roughly twice the particle area of our own would be barely within the best sensitivity limit of IRAS in an ideal sense, but that star is seen against the background of a dense stretch of the galactic plane which frustrates attempts at sensitive searches.

3. The classical Oort cloud from which long-period comets are believed to come (see, e.g., review by Weissman 1990), contains of order 100 M_{\oplus} in comet nuclei (typical radii of order 10 km). These bodies orbit at least 2×10^4 AU (0.1 pc) from the Sun out to an outer limit of roughly 1.5×10^5 AU (0.75 pc) set by encounters with other stars and the galactic tide (Heisler and Tremaine 1986). Objects in this range of radii are loosely enough bound to the Sun that encounters with passing stars can perturb them into orbits that pass into the planetary region. Our Oort cloud would subtend a diameter of 5°

when viewed from β Pictoris. This would allow easy spatial resolution, but the material would be undetectable to IRAS if the mass were contained solely in comet-sized bodies because the total surface area and thus the luminosity would be extremely small (Stern 1990). Also, the temperature would be less than 5 K and its emission would be difficult to find in contrast with galactic material and cosmological background radiation. Therefore, if the classical Oort cloud consists only of larger bodies, it would not be seen by IRAS from a distance of 16 pc. Stern (1990) noted that erosion by ISM grains should result in the production of small grains and greatly enhanced surface area and detectability, but a search of several nearby stars resulted in no detections and an appreciation for how dirty the Galaxy is at the relevant wavelengths.

4. Many authors have speculated that the process of forming the Oort cloud could have left as much as 5 to 100 times more mass in a so-called "inner Oort cloud" or "Hills cloud" than in the classical Oort cloud (see, e.g., Tremaine 1990; Weissman 1990). If there are in fact objects closer to the Sun than about 2×10^4 AU, their orbits are more tightly bound than orbits in the classical Oort cloud and thus are not usually perturbed into the planetary region. The inner Oort cloud is imagined as a plausible central concentration of the known Oort cloud which might approximate a disk in its inner regions ($r \leq 5000$ AU; Tremaine 1990) but would tend towards sphericity in transition to the outer observed Oort cloud due to perturbations from passing stars.

Note that the "maximum" mass estimates for the resolved circumstellar disks in Table III are in the same range as estimates of the mass of the inner Oort cloud, which more than doubles the minimum gas mass needed in the original protoplanetary disk. However, even this large amount of material would have too little surface area for the IRAS sensitivity limits if it consisted only of large bodies. Also, material at $r > 100$ AU around the Sun would be colder than 30 K which is the approximate limiting temperature for good contrast to background material at low galactic latitudes. From β Pic the Sun appears near the boundary between Draco and Hercules, at $b_{ll} \sim 30^\circ$, so the limiting temperature in this specific hypothetical case might be cooler.

In summary, given the known characteristics of our system, IRAS would detect nothing from $d = 16$ pc at temperatures corresponding to the planetary region, $T > 50$ K, $R < 30$ AU, and the amount of material known or hypothesized to exist at $T < 30$ K, $R > 100$ AU is insufficient for IRAS sensitivity. The region of potential IRAS detection by process of elimination is therefore the region roughly between 30 and 100 AU from the Sun lying just outside the planetary region which may contain the Kuiper belt.

C. The Kuiper Belt

The Kuiper belt is imagined alternatively as (1) an extension of the protoplanetary disk in which low density of planetesimals and long encounter time scales prevented the formation of planets, or (2) a region into which Uranus-Neptune planetesimals were propelled during the formation of those planets. An excellent review of limits on "dark" (undiscovered) matter in the solar

system, including speculation regarding the properties of the Kuiper belt, has been written by Tremaine (1990). The simplest reason to believe there may be such a structure is the low inclination to the ecliptic of the orbits of short period ($P < 20$ yr) comets, also known as "Jupiter-family" comets. There is no simple way to produce this population dynamically unless their reservoir is a flattened system, in contrast to the Oort cloud (long-period) comets which have random inclinations and thus probably a spherical reservoir. Figure 9 shows that the surface density of the planetary region follows a power law which when extrapolated predicts about $5 M_{\oplus}$ in the region between 30 and 100 AU, below the present limits of detectability placed by measurement of planetary and spacecraft motions.

Figure 9. Mass surface density profile of the solar system if each Jovian planet's mass were spread half-way (in a logarithmic sense) to the adjacent planets. This can be imagined to represent the pre-solar nebula's surface density at some stage during the formation of the solar system. It is possible that the mass distribution continues beyond the known planets, allowing roughly 1 to 10 Earth masses to reside between 30 and 100 AU from the Sun in some form.

If one imagined that the nearby stars all have planets, zodiacal clouds, Kuiper belts, and Oort clouds with approximately the characteristics of the components of our planetary system, an instrument like IRAS would be sensitive only to the Kuiper belt component temperatures and scales. Table XII summarizes the detectability of the components of our solar system and makes comparison to the general properties of the Vega/ β Pic systems. The radius in this table characterizing the main-sequence grain disks is not the outer radius, but rather is the far-infrared size of the three resolved systems and the peak surface density in models of the β Pic disk. The best analog in scale to the

main sequence disks is the Kuiper belt. However, if only large bodies (comet nuclei) exist there, the solid surface area is insufficient for infrared detection.

TABLE XII
Circumstellar Dust Properties

Location	R (AU)	T (K)	Log Area, AU ²	Log L_g/L_\star	Morphology
Zodiacal Dust	3	200	-5	-7	flattened
Kuiper Belt (1 M_\oplus , 10 km objects)	> 50	40	-5	-9	flattened
Kuiper Belt (1 M_\oplus , 10 μm -10 km size distr.)	> 50	40	0	-5	flattened
Typical M.S. Grain Envelopes	100	30-150	0-2	-5 to -3	flattened ?
Oort Cloud (100 M_\oplus , 10 km objects)	10 ⁴	3	-5	-12	spherical

An order-of-magnitude check on the plausibility of our solar system having a collection of small grain fragments from Kuiper-belt comet collisions shows that such a disk would have a grain area very comparable to Vega/ β Pic disks. If 1 M_\oplus of 10 km bodies with material density 1 g cm⁻³ are imagined confined between 30 and 100 AU from the Sun (figure from Tremaine 1990), the collision time per parent body is about 10¹¹ yr so that most of them would be intact at the present age of the solar system. The number of collisions per year throughout the region would be approximately 10⁻¹.

If the fragments from each collision are assumed to have an $a^{-3.5}$ size distribution running from a minimum size somewhere in the range of 1 to 100 μm (like dust in comet comae, the zodiacal cloud, and the prototype main-sequence far-infrared sources) to a maximum size of 1 km (1/10 the size of the parents), then the PR destruction time scale for the smallest grains (those dominating the surface area and therefore the most detectable) would be in the range 10⁶ to 10⁹ yr depending on original orbit radius. The total amount of new small grain fragments produced by parent collisions during a PR time scale would yield a small-grain optical depth perpendicular to the ecliptic plane at $r = 30$ -100 AU in the range 1 Myr to 1 Gyr strikingly similar to the lower range of extrasolar examples. The small-grain mutual collision time scale in this case would be less than but within an order of magnitude of the PR time scale, just like in the 3 prototype sources. In the case of our Sun, the distances would make the characteristic temperature of the emission 50 K or colder.

D. Steps Toward a Connection

Is it true, then, that what we are observing with IRAS around nearby main-

sequence stars corresponds to their "Kuiper belts"? There are at least three ways to investigate the connection. *First*, are there planetary perturbations in any of the IRAS-detected systems, and where do the massive objects lie with respect to the IRAS material? *Second*, can systems be found with material at warm temperatures/radii corresponding to the planetary zone along with cooler Vega-type material? In other words, are the phenomena of clear zones in the "Big 3" resolved systems, and also the general lack of detection of material warmer than roughly 200 K around nearby stars (Aumann and Probst 1991), signs of *failed* planetary systems or *completed* planetary systems? *Third*, does our solar system have a cool grain disk outside the planetary zone?

1. *Solar-Type Stars With Planetary Perturbations.* Campbell et al. (1988b) investigated 12 slowly rotating, single, bright F-K dwarfs for radial velocity variations in the first search sensitive enough to find Jupiter-mass planets. Their technique depends on passing starlight through a cell of hydrogen fluoride which provides sharp-reference velocity lines insensitive to effects like flexure in the spectrograph. Their resulting mean external error is about 13 m s^{-1} .

Seven stars in the sample have marginal detections of velocity trends over 8 years' time, some with concavity or convexity implying periods of order a decade, although no system has been seen to go through a full cycle yet. There is no correlation between the radial velocity variations and stellar activity indicators such as equivalent line widths of Ca II H and K line emission. If the perturbations are real, the implied sizes of the companions are of order 1 to 10 Jupiter masses.

The significance of these results in the context of this review is that one of the systems with possible Jovian companions, ϵ Eri, is an IRAS far-infrared excess system. The emission temperature of 70 K could indicate material within or beyond the region of planetary companions, depending on grain size. The other six Campbell candidates do not have far-infrared excesses at IRAS sensitivity and thus would be prime targets for observation with more sensitive future instruments such as ISO or SIRTf.

2. *Young Stars with Hot Debris.* Calculations of collision dynamics and orbit evolution of planetesimals in our solar system yield a particle number density 1000 times larger than the present value as late as 500 Myr after the Sun reached the main sequence, with about a 100 Myr half-life for subsequent decline (Grinspoon 1988; Grinspoon and Sagan 1991). Witteborn et al. (1982) calculated the amount of infrared radiation which would be emitted from an $a^{-3.5}$ size distribution of grains and planetesimals orbiting main sequence stars assuming a spatial distribution like that of the planetary masses in our solar system. Their results are that 80% of the infrared excess will come from warm material in the "terrestrial" region despite the 100 times larger mass in the Jovian region, and that 1% of the solid mass of the planets is easily found at 10 to $20 \mu\text{m}$ if the photosphere of the parent star is detectable. This mass corresponds to the particle number density calculated for roughly 200 to

500 Myr after the formation of the solar system. Backman et al. (1990) made a study of coadded IRAS survey data on main-sequence A stars in open clusters younger than 1 Gyr. IRAS photometry was not accurate enough to discern individual stars in most cases because of the distances to the clusters, but statistical statements can be made about the presence or absence of infrared excesses in the cluster stars considered as groups. There appears to be greater emission from A stars at $12\ \mu\text{m}$ in the younger two clusters than in the older two. The trend with age may represent progressive destruction or accretion of grains.

Although the Pleiades are passing through a molecular cloud that is responsible for the spectacular optical reflection nebulae (Breger 1987), and calculations of radiation pressure efficiency imply that very small grains like ISM grains might be able to come close to luminous stars, the 12 to $25\ \mu\text{m}$ ratios suggest that ambient cloud grains are not the cause of the observed excesses. Assuming that a thin undisturbed distribution of grains around an unrelated star would be roughly $n(r) \sim r^0$, the expected thermal emission spectrum from ISM-size grains would rise steeply toward longer wavelengths, $F_\nu \sim \lambda^2$, because of the increase of grain number with distance (cf. Eq. 10).

These results need to be confirmed via groundbased observations especially in light of Aumann and Probst's (1991) studies of false $12\ \mu\text{m}$ excesses around nearby field stars. Also, sub-millimeter searches for this effect in the same clusters have returned null results (Zuckerman, personal communication) although that technique would be somewhat less sensitive to material at warm temperatures. Unfortunately these clusters are so distant that IRAS data could not be used to check for complementary cool excesses with properties like the Vega/ β Pic systems, so a direct comparison of location of material around the cluster stars versus generally older nearby field stars will have to await future instruments such as ISO or SIRTf.

3. Does Our Solar System Have a Cool Grain Disk? If our solar system had a grain disk outside the planetary region in the region corresponding to the Kuiper belt, it is surprising but true that grain surface area and temperatures like the examples turned up in IRAS surveys would be difficult to detect from *inside* because of the powerful interference viewed from Earth of bright warm foreground zodiacal dust. Backman and Gillett (1987) and Aumann and Good (1990) found that the difference between IRAS scans at 60 and $100\ \mu\text{m}$ of the zodiacal dust emission in the ecliptic plane, and models of the expected emission, could represent some emission from material beyond the planetary region. It is possible that all the emission observed is actually in the inner solar system and will be explained in the future by more sophisticated models of the zodiacal cloud. However, the uncertainties at this point in our knowledge of the zodiacal system *allow* a disk at temperatures below $40\ \text{K}$, located at $r > 50\ \text{AU}$, with total optical depth somewhat smaller than the material around $\alpha\ \text{Lyr}$.

The upper limit on optical depth for such a cloud is larger than the apparent mean amount of material observed in ensemble for nearby G dwarfs.

Aumann and Good (1990) argue that, since the typical G dwarf appears to have some cool circumstellar material, it would be peculiar if the Sun *did not*. If there is such material in our solar system, it cannot be concentrated too strongly towards the ecliptic plane, or its surface brightness would be too large. "Wedge" angles ι greater than 5° are consistent with the observations.

Tremaine (1990) points out that upper limits on number density of comet-nuclei-sized bodies in the Kuiper belt from the best present optical searches are just beginning to approach values corresponding to upper mass limits from dynamical calculations. Cruikshank et al. (1990), however, find that these bodies might be detectable with SIRTf.

VII. SUMMARY AND FUTURE DIRECTIONS

A detailed understanding of the genesis of planets is one of the major goals for the astronomical community, equal in import to investigation of the origin of the universe as a whole. The IRAS mission resulted in the startling discovery that normal main-sequence stars often host cool orbiting grains with likely but not certain connection to planets. The state of our knowledge about these systems after the IRAS mission can be divided into three categories: (a) a few systems close enough/luminous enough that hints of shape and structure have been discerned; (b) one hundred or more stars with cool far-infrared excesses but without IRAS spatial resolution or sufficiently good photometry to demonstrate conclusively that the emission is due to orbiting grains rather than to possible alternate mechanisms; and (c) most stars, up to 80% of the nearby A-K dwarfs and all but one M dwarf, with no circumstellar material apparent at IRAS sensitivity.

Future infrared observations should aim to: (1) explore the three prototype disks in detail, addressing questions of radial and azimuthal symmetry and precise nature of boundaries; also, perform reflectance mineralogic spectroscopy where possible; (2) spatially resolve IRAS candidates, checking whether the sources are centered on the stars (i.e., not background) and are disks in the stellar equatorial planes, estimating grain sizes from angular scale vs temperature, and performing sufficiently precise photometry that maximum temperatures (inner boundary locations) can be deduced; and (3) search for grains around stars with IRAS nondetections; a hundred-fold better sensitivity would make detection of systems as sparse as our solar system's zodiacal dust cloud possible in some circumstances.

The story behind the origin, maintenance and destruction of such disks will gradually become clearer as main-sequence circumstellar disks come to be understood in the context of stellar evolution. For example, we can ask what type of circumstellar disks normally remain after star formation? This could be answered by further examination of classical and "naked" (weak) T Tauri stars and open cluster stars, with ages of order 10^7 to 10^8 yr, in order to investigate inner disk clearing time scales and persistence of outer disks. Also, what happens to these disks when the stars evolve off the main

sequence? This calls for further observations of evolved stars in search of evidence of increased sublimation and possible augmented dust nucleation occurring when remnant disks are exposed to post-main-sequence luminosity increases and mass loss. Finally, do such disks represent success or failure modes in planet building? We need to continue searches of the distant regions of our own solar system's ecliptic plane for evidence of planetesimal-sized parent bodies and collision fragments, and to compare expanded lists of infrared excess stars with lists of suspected planetary-mass astrometric and spectroscopic binary companions. We can hope for eventual firm knowledge of the frequency with which normal stars possess material left over from the process of planet formation.

We thank F. Witteborn, M. Werner, P. Cassen, J. Lissauer, P. Artymowicz, and the referee M. Skrutskie for many helpful comments. We also thank A. Graps for computer searches relating to stellar surveys and N. Jennerjohn for assistance in preparing the tables and references.

PLANETARY NOBLE GASES

KEVIN ZAHNLE

NASA Ames Research Center

Noble gas elemental and isotopic abundance patterns should in principle provide constraints on the formation and early evolution of the terrestrial planets and their atmospheres, but at present these patterns are poorly understood. The seemingly reasonable suppositions that noble gases would behave like other volatiles (only more so), and that noble gases on planets derive from noble gases in meteorites have both proved more wrong than right. It is now fairly clear that the so-called “planetary” rare gases are not found on planets. The unexpected discovery that neon and argon are vastly more abundant on Venus than on Earth points to the solar wind rather than condensation as the fundamental process for placing noble gases in the atmospheres of the terrestrial planets; however, solar wind implantation may not be able to fully reproduce the observed gradient, nor does it obviously account for similar planetary Ne/Ar ratios and dissimilar planetary Ar/Kr ratios. More recent studies have emphasized escape rather than accretion. Hydrodynamic escape, which is fractionating, readily accounts for the difference between atmospheric neon and isotopically light mantle neon. It can also with more difficulty account for isotopically heavy Martian argon. Atmospheric cratering, which is nearly nonfractionating, can account for the extreme scarcity of nonradiogenic noble gases (and other volatiles) on Mars. Escape is less satisfying when used to force Ar and Ne on Venus and Earth into accord. Outstanding problems remain, namely, the different Ar/Kr ratios of Venus and Earth and the fractionated and underabundant Xe found on both Earth and Mars. At least two sources seem to be required.

For reasons which are becoming increasingly hard to recall, it was once thought that noble gases, being the most volatile elements and the simplest chemically, would tell a relatively straightforward story of volatile evolution in the solar system. The noble gases are chemically inert, or nearly so. Among real substances they are the closest approximations to that ideal atmospheric species, the obligate atmophile, that exists only in air. To the extent that they approach the ideal, the history of the noble gases is the history of the atmosphere. Of course, with the possible exception of a direct solar nebular source, the very existence of noble gases in planetary atmospheres demands that they fall somewhat short of the ideal. They are found in the mantle, small amounts are dissolved in seawater, and xenon at least can be adsorbed in crustal rocks. Noble gases are also found trapped in meteorites or driven into exposed surfaces by the solar wind. Where temperatures are low enough they might even be expected to freeze out. Because none of these means of incorporating noble gases into planetary atmospheres is very efficient they are rare, and so

they are also called the “rare gases.” Noble gases are also interesting for their radiogenic isotopes, which can be relatively prominent in view of the extreme scarcity of their nonradiogenic siblings. These are particularly useful as chronometers of planetary outgassing and early atmospheric evolution.

I. A BRIEF, TRUNCATED HISTORY

Apart from helium, noble gases do not readily escape from modern planetary atmospheres. Their low abundance in air implies that if Earth ever had a primary atmosphere of solar composition, it must have either been very thin or very efficiently lost. It was therefore early concluded that Earth's was a “secondary” atmosphere, i.e., one degassed from solid materials (see Walker 1977). It was assumed that the noble gases had degassed from the mantle, probably early and catastrophically (Fanale 1971). The mantle, of course, is just a stop along the way, and the original source materials were naturally sought among meteorites.

Nonradiogenic noble gases in meteorites were divided into two distinct classes based on relative elemental abundances (see Ozima and Podosek 1983; Swindle 1988). These were suggestively named “solar” and “planetary.” The solar pattern, characterized by roughly solar abundances, appears to have a genetic relationship with the solar wind. The “planetary” pattern is greatly depleted in the lighter noble gases. With the obvious exception of xenon and the more subtle exception of neon, it is elementally and isotopically like air (see Fig. 1).

Of the two meteoritic components, the “planetary” component better matches air (hence the unfortunate name), and therefore it was for some time presumed that the noble gases actually found on planets descend directly from “planetary” noble gases in meteorites. Moreover, the “planetary” pattern qualitatively resembles the elemental pattern produced experimentally when solar noble gases are adsorbed on grains (Fanale and Cannon 1972; Ozima and Podosek 1983). Quantitatively, terrestrial argon and krypton could be accounted for either by accumulating the bulk of the planet from meteorites like the H-type ordinary chondrites, or by accreting a relatively thin veneer of meteorites like the carbonaceous chondrites, which have higher intrinsic abundances of volatiles and rare gases (Anders and Owen 1977). A basically simple picture seemed to emerge. There were some unresolved problems—in particular, the discord at xenon was large, and could only be resolved if 96% of Earth's xenon were hidden somewhere other than the atmosphere and the isotopes were ignored—but these seemed surmountable.

Then we began to gather data from other planets. At first things seemed to go well enough, if not entirely according to plan. Viking's Mars resembled nothing so much as Earth depleted in volatiles across the board by a factor of about 30 (Anders and Owen 1977). Such apparent volatile poverty was distressing, both intellectually (prevailing theory had predicted that volatiles would be more abundant at greater distance from the Sun) and emotionally

Figure 1. Abundances of the nonradiogenic noble gas isotopes with respect to solar abundances [g/g] for a few solar-system objects of interest. Sources are listed in Tables I and II. The "planetary" meteoritic pattern plotted here is the AVCC (average carbonaceous chondritic) pattern. South Oman is an enstatite chondrite with high argon. It is an example of the "subsolar" pattern. Pesyanoe illustrates the "solar" meteoritic pattern. The abundance of ^{36}Ar on Venus is quantitatively similar to that in many meteorites.

("one of the great disappointments of the space age"; Anders and Owen 1977), but could be accommodated within a veneer model simply by assigning Mars a thinner veneer. The veneer became identified with carbonaceous chondrites. Again there was a problem with "missing" xenon, but, as with Earth, it was thought likely to be hidden, adsorbed in some crustal rock (Fanale et al. 1978).

Venus and Earth have comparable surficial carbon and nitrogen inventories, and so it was predicted that Venus and Earth would have comparable inventories of the nonradiogenic rare gases, with the exception of xenon, which could not reasonably be adsorbed in crustal materials at Venusian surface temperatures (Anders and Owen 1977). What Pioneer Venus found at Venus was something completely different. Nonradiogenic neon and argon are, respectively, 30 and 70 times more abundant than on Earth (Donahue and Pollack 1983), and the Ar/Kr ratio is more "solar" than "planetary" (Donahue et al. 1981). Venusian xenon is extremely uncertain, but the Kr/Xe ratio reported by Donahue (1986) is much closer to solar than to "planetary" meteorites. The absolute abundance of ^{36}Ar on Venus is strikingly large (Fig. 1). Of known solar system materials, it is matched only by a few meteorites and lunar soil samples heavily exposed to the solar wind. Venus not only killed the

hypothesis of a thin meteoritic veneer as the source of planetary rare gases but also the presumed linkage between the inventories of condensible volatiles and noble gases that gave rise to it.

Since then it has become apparent that the SNC meteorites come from Mars (Bogard et al. 1984; McSween 1985; Pepin and Carr 1992). Atmospheric gases trapped in one of these meteorites have greatly increased our knowledge of the isotopic composition of the Martian atmosphere, which for all four elements differ significantly from planetary. These data reinforce a conclusion that had become obvious after Pioneer Venus: "planetary" rare gases are not found on planets (Wetherill 1981). There remain some likenesses, particularly the Ne/Ar ratio, but there are at least as many differences: for both Earth and Mars, the "planetary" Xe/Kr ratio is some 30 times too high and the xenon isotopic patterns are grossly discordant, and neon is isotopically too light; Martian nonradiogenic argon is strikingly heavy; and the data for Venus, such as they are, more closely resemble the solar pattern than the "planetary" pattern (Fig. 2). It now appears that noble gases on planets do not look all that much like either the "planetary" or solar meteoritic components, and the resemblances that are perceived in the elemental pattern tend to vanish when one looks carefully at the isotopes.

Figure 2. The same as Fig. 1, but with all reservoirs also normalized to ^{84}Kr . This better illustrates the qualitative differences between reservoirs. Xenon fractionations on Earth and Mars are clearly visible even on this scale, as is a general tendency for the less abundant elements to be more isotopically fractionated.

In particular, the discrepancies with xenon never went away. When only Earth was known, it was suggested that the bulk of terrestrial xenon is hidden, adsorbed inside crustal rocks, particularly shales (Canalas et al. 1968; Fanale and Cannon 1971); a similar explanation (without the shales) was offered for Mars when Viking showed that it too was missing xenon (Fanale et al. 1978). Buried xenon has been vigorously sought on Earth, but it has not been found (Podosek et al. 1981; Ozima and Podosek 1983; Wacker and Anders 1984; Bernatowicz et al. 1984, 1985; Matsuda and Matsubara 1989). It now appears that crustal materials harbor no more xenon than does the atmosphere, and no attempt has ever been made to account for the isotopes. If some terrestrial hiding place is eventually found that can store 96% of the xenon while leaving the atmospheric residuum highly mass fractionated, then one can again seriously entertain the "planetary" hypothesis.

II. THE DATA

There is voluminous literature on noble gases in planetology. Ozima and Podosek (1983) survey the entire field, from nucleogenesis to Pioneer Venus. Donahue and Pollack (1983) review the wreckage of noble gas comparative planetology after Pioneer Venus. The last serious attempt to explain atmospheric rare gases by adding together different sources was made by Bogard (1987). Escape processes began to receive serious consideration with Sekiya et al. (1980*b*) and Donahue (1986), and have dominated the literature since Hunten et al. (1987) and Sasaki and Nakazawa (1988) pointed out that mass fractionation patterns similar to those observed on Earth and Mars are a predictable consequence of hydrodynamic escape of hydrogen-rich early atmospheres. By far the most ambitious study of this kind is Pepin's (1991). Ozima and Igarashi (1989) and Hiyagon and Sasaki (1988) have recently reviewed terrestrial rare gases; the latter review is mainly concerned with xenon. This chapter will emphasize escape.

Detailed reviews of the data are given by Ozima and Podosek (1983) and Pepin (1989, 1991). Swindle (1988) reviews meteorites; Donahue (1986) is the most recent source for Venus. Terrestrial MORB and Loihi data are presented by Allègre et al. (1987), Ozima and Igarashi (1989), and Honda et al. (1991). Some of these data are presented in Tables I and II and shown graphically in Figs. 1–4. Error bars have been omitted; the interested reader is urged to consult the sources noted above for detailed discussion.

Nonradiogenic rare gases on planets are neither "solar" nor "planetary," but something in between. The key observations for comparative planetology are that (i) atmospheric inventories of argon and neon fall off precipitously with increasing distance from the Sun, such that ^{36}Ar , e.g., drops as 11,000:160:1 going from Venus to Earth to Mars. (ii) The Ar/Kr ratio on Venus is nearly solar while the Ar/Kr ratio on Earth and Mars is "planetary"; as a result, unlike argon and neon, krypton abundances on Earth and Venus are not very different. (iii) Xenon on both Earth and Mars is isotopically strongly

mass fractionated and elementally underabundant with respect to krypton. (iv) The absolute abundance of ^{36}Ar on Venus is similar to that of the most argon-rich meteorites. (v) The Ne/Ar elemental ratio is roughly the same on Earth, Mars, Venus and “planetary” meteorites; however, (vi) neon on planets is isotopically between solar wind and “planetary” neon, and argon on Mars is isotopically heavier than either.

A. Neon

The $^{20}\text{Ne}/^{22}\text{Ne}$ ratio is quite variable in the solar system (Fig. 2, Table II). Meteoritic neon is notable for two oddities: the existence of a pure ^{22}Ne component, Ne-E, that apparently derives from the decay of ^{22}Na in the presolar grains; and solar-wind $^{20}\text{Ne}/^{22}\text{Ne}$ is ~ 13.7 , but the solar flare ratio is only ~ 10 (Mewaldt et al. 1984). The arguments given for accepting the solar wind ratio as truly solar seem stronger than those favoring the flare ratio, but the subject is not yet closed. The “planetary” meteoritic ratio is ~ 8.9 (Pepin 1991). Planetary ratios are intermediate: air is 9.8; Mars (SNC) is 10.1 ± 0.7 (Swindle et al. 1986b; Wiens et al. 1986); and Venus is reported as 11.7 ± 0.7 (Donahue 1986; Donahue et al. 1981). Terrestrial mantle and diamond ratios tend to be isotopically light (Ozima and Igarashi 1989).

B. Argon

Argon has stable isotopes of atomic weight 36, 38 and 40 (Table II). Argon in

air is mostly radiogenic ^{40}Ar , formed by the decay of ^{40}K (half-life 1.25 Gyr). The accumulation of ^{40}Ar in the atmosphere is the primary measure for the degassing of the mantle over geologic time. Dreibus and Wänke (1987) estimate that 53% of Earth's ^{40}Ar has been degassed; other models for Earth's K content differ somewhat. Because the nonradiogenic abundance of ^{40}Ar is negligible, the ratio of ^{40}Ar to ^{36}Ar in mantle samples is an excellent indicator of the extent to which the mantle has been degassed (Ozima and Podosek 1983).

Earth and most meteorites have an $^{36}\text{Ar}/^{38}\text{Ar}$ ratio of ~ 5.3 . The solar wind value is also usually given as ~ 5.3 . The actual solar value is probably higher; estimated values range from 5.4 to 5.8 (Swindle 1988; Pepin 1989, 1991). The Venusian ratio has been reported as 5.6 ± 0.5 (Donahue 1986). The SNC meteorites yield a Martian ratio of 4.1 ± 0.3 (Wiens et al. 1986; Swindle et al. 1986b) that is clearly quite distinctive.

C. Krypton

To first order, all four known (Earth, Mars, solar wind and planetary) krypton inventories are isotopically similar. Modest fractionation patterns have been identified. It was once thought that terrestrial krypton was isotopically lighter than solar-wind krypton (Ozima and Podosek 1983), but newer data have

reversed this (Pepin 1989). SNC krypton appears to be slightly lighter than terrestrial krypton, while "planetary" krypton is very slightly heavier than Earth's. In all cases, the reported krypton fractionations are quantitatively small, no more than 20% that of xenon. Krypton fractionations are small enough to admit many explanations. They are within the observed variance for adsorption (see adsorption data in Ozima and Podosek [1983]) and, as the difficulty defining solar Kr implies, the same goes for solar-wind implantation.

D. Xenon

Xenon has nine stable isotopes, several of which have been affected by the decay of extinct radionuclides and the apparent preservation of presolar isotopic anomalies (Ozima and Podosek 1983; Swindle 1988). Xenon isotopes with substantial radiogenic sources are ^{129}Xe , formed by decay of extinct ^{129}I (half-life 17 Myr) and $^{131-136}\text{Xe}$, formed occasionally by the spontaneous fission of ^{238}U (half-life 4.47 Gyr) or the (no longer) extinct ^{244}Pu (half-life 82 Myr). About 6.7% of Earth's ^{129}Xe is radiogenic, and about 60% of Martian ^{129}Xe is radiogenic (Table II). Fission xenon is harder to measure because it is spread over several isotopes, and therefore obscured by the general trend of fractionation of terrestrial xenon and the uncertain composition of primordial xenon. Pepin and Phinney (1978) find that 4.6% of the ^{136}Xe in air is plutogenic, while Igarashi and Ozima (1988) get 3.1%. Modern terrestrial Xe is then the sum of mass fractionated U-Xe and ^{244}Pu fission Xe. Fission xenon is not evident on Mars (Swindle et al. 1986b).

The known xenon components are all quite distinct. "Planetary" and solar wind (SUCOR) xenon differ in that the former has a large excess of the heavy isotopes ^{134}Xe and ^{136}Xe ; the excess, which is not consistent with known fission products, is called Xe-H (Ozima and Podosek 1983). Both terrestrial and Martian xenon are profoundly mass fractionated. Within measurement error, Martian xenon looks like SUCOR Xe fractionated by about 3.8% per amu or like planetary Xe fractionated by about 2.5% per amu (Fig. 3). Terrestrial Xe is fractionated to a similar extent (Fig. 4), but it is not yet clear what it has been fractionated from.

One of the problems with xenon is that the composition of solar xenon is uncertain. Pepin and Phinney (1978) argue that solar wind xenon has also been polluted with Xe-H. They suggest that the original terrestrial Xe is the true ancestral solar xenon, which they call U-Xe. If it is assumed that the heavier Xe isotopes in air have been supplemented by ^{244}Pu fission products after mass fractionation of nonradiogenic Xe took place, and that the extent of mass fractionation is that deduced for the light isotopes, then the known composition of plutonium fission products can be used to determine both the amount of plutogenic xenon and the composition of U-Xe.

E. Internal Rare Gases

Earth's mantle may harbor considerable quantities of rare gases, both radiogenic and nonradiogenic. There are basically two kind of mantle sam-

Figure 3. Xenon isotopes on Mars can be produced by mass fractionation of AVCC (average carbonaceous chondritic) xenon at 2.5% per amu or by mass fractionation of solar-wind (SUCOR) xenon at 3.8% per amu. It is not matched by mass fractionation of U-Xe.

ples: mid-ocean ridge basalts (MORB) that sample the highly degassed upper mantle, and hot spot volcanism that may sample a deeper, more primitive, possibly undegassed lower mantle.

Gases trapped in the glassy margins of MORB sample the depleted mantle (the depleted mantle is that part of the mantle from which the continents have been extracted). MORB rare gases are especially rare, and marked by a relatively high abundance of radiogenic isotopes. With the exceptions of helium and neon, the nonradiogenic rare gases are isotopically like air. Neon appears to be isotopically somewhat lighter than air; this may imply preferential neon loss from the atmosphere (Allègre et al. 1987; Staudacher 1987; Ozima and Igarashi 1989; Zahnle et al. 1990a). Neon in terrestrial diamonds is also often light (Honda et al. 1987; Ozima and Igarashi 1989). Very high $^{40}\text{Ar}/^{36}\text{Ar}$, greater than $\sim 10^4$, when combined with the low K abundance in depleted mantle, indicates that ^{36}Ar has been degassed to better than 99.6% (Ozima and Podosek 1983; Allègre et al. 1987). The xenon in these samples is also marked by small excesses relative to air of the radiogenic isotopes, both ^{129}Xe and fissionogenic (Allègre et al. 1987; Ozima and Igarashi 1989). It is the presence of excess ^{129}Xe , in particular, that implies the upper mantle was outgassed quickly, before all the ^{129}I decayed (see, e.g., Thomsen 1980; Ozima and Podosek 1983; Allègre et al. 1987). Typical estimates are

Figure 4. Nonradiogenic xenon isotopes on Earth can be produced by mass fractionation of U-Xe at 3.8% per amu. U-Xe is the hypothetical composition of primordial solar system xenon (Pepin 1991). Air is the sum of fractionated U-Xe and ^{129}Xe from decay of extinct ^{129}I and ^{131}Xe - ^{136}Xe from spontaneous fission of extinct ^{244}Pu .

that mantle degassing took place within 50 Myr (Allègre et al. 1987; Zhang and Zindler 1989).

Despite evidence for rapid, near total degassing of the upper mantle, there is also evidence that can be interpreted as implying that a considerable fraction of the mantle remains to this day practically undegassed (Allègre et al. 1987; Zhang and Zindler 1989). For example, Allègre et al. (1987), using a model in which they assume that the atmosphere was generated by degassing part of the mantle, estimate that the amount of nonradiogenic rare gases still held within the lower mantle exceeds the amount in the atmosphere. Primordial ^3He , with a present outgassing rate of order $4 \text{ atoms cm}^{-2} \text{ s}^{-1}$, is the most celebrated product of the undegassed mantle (Ozima and Podosek 1983). The most intriguing samples come from Loihi, an undersea volcano that is destined to be the next island in the Hawaiian chain. Loihi neon is isotopically light, and there is growing evidence that primitive neon is isotopically solar (Craig and Lupton 1976; Honda et al. 1991). Honda et al. (1991) also infer that $^3\text{He}/\text{Ne}$ is roughly solar, and so raise the possibility that Earth's internal rare gases are all solar. However, as the He/Ne ratio in both the solar and the "planetary" meteoritic rare gases is roughly solar (Ozima and Podosek 1983), it would have been more surprising if Earth's were not. Loihi krypton and xenon both look like air (Allègre et al. 1987), which, taken at face value,

would imply a strong genetic relationship between interior and atmospheric rare gases. Of course, with such an observation one fears contamination, here by atmospheric rare gases dissolved in seawater or by subducted air (Patterson et al. 1990)—a suggestion touching off a lively debate (Staudacher et al. 1991; Patterson et al. 1991). The reported Loihi $^{40}\text{Ar}/^{36}\text{Ar}$ ratio of 390 (Allègre et al. 1987) is only modestly larger than the atmospheric value of 296. If the Loihi samples really are snapshots of the lower mantle, one must conclude that the lower mantle is practically undegassed. Loihi argon would then also support the premise that the atmospheric rare gases are indeed the outgassed complement of the highly degassed upper mantle, and so would rule out a very late veneer as a plausible source of atmospheric rare gases. On the other hand, if the Loihi gases are contaminants, no such sweeping conclusions can be drawn.

Ott (1988) has reported evidence for nonatmospheric noble gases in Shergotty, Nakhla and Chassigny. These are strikingly unlike the Martian atmosphere, and they are also strikingly unlike either terrestrial mantle source. They are characterized by very low abundances of the radiogenic isotopes ^{40}Ar and ^{129}Xe , low Ar/Xe and Kr/Xe , and an unfractionated solar-like xenon isotope pattern. If these are representative of internal Martian noble gases, they imply an unearthly relationship between the interior and the atmosphere.

III. SOURCES

The very chemical simplicity that makes noble gases such hopeful tracers of volatile evolution also poses a problem: it is hard to get noble gases out of the solar nebula and into a planetary atmosphere. If anything, the problem is not that the planets have too little noble gas; the problem is that they have so much (Podosek 1991). The key here is Venus. Among meteorites only South Oman, an E-chondrite, has significantly more ^{36}Ar on a gram per gram basis than does Venus. There are four potential sources for atmospheric rare gases:

1. Direct gravitational attraction of a solar nebula atmosphere by very large planetesimals or full-grown planets (the Kyoto school, including Hayashi et al. 1979; Mizuno et al. 1980; Sekiya et al. 1980*a*, 1981; Mizuno and Wetherill 1984; Sasaki and Nakazawa 1988; Pepin 1989; Sasaki and Nakazawa 1990).
2. Adsorption and trapping in grains and planetesimals, which accreted to form planets (see, e.g., Fanale and Cannon 1972; Frick et al. 1979; Honda et al. 1979; Yang and Anders 1982*a, b*; Pollack and Black 1979, 1982; Wacker et al. 1985; Zadnik et al. 1985; Hunten et al. 1988; Wacker 1989; Pepin 1991).
3. Solar-wind implantation, mainly into smaller bodies that accreted to form planets (Wetherill 1981; McElroy and Prather 1981; Hostetler 1981; Bogard 1988; Sasaki 1991).
4. Condensation at very low temperature, either as clathrates, adsorbate, or

even as ices, in distant parts of the solar system, and subsequent delivery to planets by cometary impact (Bar-Nun et al. 1985; Owen 1985; Owen et al. 1991; Pepin 1991).

There are also some hybrid schemes in which solar nebular gases are gravitationally attracted by planetesimals, but in which adsorption also plays a role, either on grains in the atmosphere, or on the surface or inside the planetesimal.

Solar-wind implantation and grain accretion are alike in that noble gases are assumed to accrete homogeneously, i.e., all materials destined for a particular planet are more or less equally endowed with noble gases. Gravitationally captured atmospheres may occur early or late, given the presence of the nebula; cold condensates are more likely to arrive late. Gravitationally captured rare gases are necessarily of solar composition, both elementally and isotopically. Solar-wind implants are similar, but are somewhat mass fractionated in favor of the heavier gases. Adsorption tends to produce a pattern rather like the "planetary" pattern, but there is much variation. The compositions of cold condensates are not well known.

A. Nebular Atmospheres

A planet or large protoplanet that accretes within the solar nebula (i.e., before the nebular gases dispersed) attracts to itself a substantial primary atmosphere ("kyotosphere") of nebular composition. This is the only model I will discuss that has the problem of predicting larger rare-gas inventories than are observed. Typically Earth's primary atmosphere is calculated to be of order 10^{26} g, but this estimate is highly model dependent; an extremely dusty atmosphere can be as small as 10^{24} g (Mizuno et al. 1980; Mizuno and Wetherill 1984; Sasaki and Nakazawa 1990). The small amount of neon in air demands that most of the primary atmosphere has escaped, but in principle some atmospheric gases could be fractionated remnants of the primary atmosphere; a detailed discussion will be given in Sec. IV.B on hydrodynamic escape. The greenhouse effect of the kyotosphere is so enormous that the mantle is melted to considerable depth. Substantial quantities of the noble gases enter the planet in proportion to their atmospheric abundance and their solubilities in silicate melt. These models predict that 2 to 200 times the neon presently in air would have entered the mantle (Mizuno et al. 1980), in proportion to the mass of the primary atmosphere. That the larger amounts of neon are not evident in Earth has been taken as an argument against the Kyoto model. In any event, there is no obvious evidence that favors it.

Gravitationally concentrated nebular gases at the surfaces of protoplanets offers a closely related way to put rare gases into planetary materials. This is more plausible than the Kyoto model, mainly because protoplanets can grow very quickly by runaway accretion, so that growth within the nebula is plausible (Wetherill 1990b). The higher nebular gas densities at the surface can greatly increase the efficiency at which nebular gases are trapped. The

mass of the primary atmosphere is very sensitive to the mass of the protoplanet, so that harvesting the "right" amount of noble gases is in principle achievable. Zahnle et al. (1990*b*) make some use of this to trap xenon in planetesimals; Pepin (1991) employs it to place interesting quantities of adsorbed nebular gases into planetary interiors.

B. Adsorption and Physical Trapping

Adsorption involves a variable range of elemental fractionations, but isotopes are generally not greatly fractionated (Frick et al. 1979; Ozima and Podosek 1983; Bernatowicz and Fahey 1986; Bernatowicz and Podosek 1986). The heavier elements are usually, but not always, more prone to adsorption (Bernatowicz and Podosek 1986; Pepin 1991). In particular, Xe is usually more readily adsorbed than Kr, which is an attractive feature for explaining "planetary" rare gases, but a less attractive one for explaining rare gases on planets. There is another difficulty with adsorption. Laboratory adsorption experiments usually fall many orders of magnitude short of being able to match the quantity of noble gases actually found in meteorites (Zadnik et al. 1985; Wacker 1989; Pepin 1991). Quantitative agreement can be reached at very low temperatures, but even then, the comparison may not be apt: Fanale and Cannon (1972) were able to adsorb almost enough Xe onto ground Al-lende powder at 110 K given a maximum mass solar nebula, but the adsorbed Xe was very loosely bound. Some other process, perhaps collisional shock (Honda et al. 1979; Wiens and Pepin 1988), is needed to trap the adsorbate. The problem is actually much worse than might be deduced by simply comparing the noble gases of meteorites on a gram per gram basis with the laboratory data, because most of the "planetary" noble gases are localized in the carbonaceous "Q" carrier, which is by mass a tiny fraction of the meteorite.

In the grain-accretion model, noble gases are adsorbed onto grains in the solar nebula (Pollack and Black 1979, 1982). The primary purpose of the model was to explain the sunward gradient of planetary Ar while retaining the "planetary" Ne/Ar ratio. The gradient was attributed to the pressure gradient in the solar nebula. Grains accreted locally with little radial mixing, preserving the gradient in the completed planets. Because the quantity of adsorbed gas is expected to be linearly proportional to pressure but exponentially sensitive to temperature when adsorption is efficient enough to be of interest, Pollack and Black had to postulate that adsorption occurred at the same temperature throughout the inner solar system. This could plausibly be argued only by assuming that the prime adsorber formed and prospered within a very narrow temperature range. In essence, grain accretion was a post-Pioneer Venus version of the "planetary" hypothesis, and therefore it suffers from the same discrepancies as Xe. Nor does the model realistically account for the Venusian Ar/Kr ratio. The model could of course be broadened to other carriers than Q, with different adsorptive affinities (e.g., South Oman?). Grain accretion suffers from the quantity gap that characterizes other adsorption models. Finally, as Wetherill (1981) emphasized, it is very difficult to maintain a steep

radial gradient between Venus and Earth during accretion.

A different approach to fractionating Xe is to assume gravitational settling of nebular gas inside porous planetesimals (Ozima and Nakazawa 1980; Igarashi and Ozima 1988; Zahnle et al. 1990*b*). The planetesimals are presumed to be immersed in the solar nebula. Within the planetesimal each isotope assumes its own scale height, so that, at depth, concentrations of the heavier isotopes are much enhanced over their concentrations in the nebula. Like hydrodynamic escape (see Sec. IV.B), this model has the potential to produce mass fractionated xenon. Large planetesimals (>1000 km) are needed to achieve terrestrial xenon fractionation.

Ozima and Nakazawa (1980) and Igarashi and Ozima (1988) assume that the planetesimals are porous at all depths, regardless of size. Gases are not trapped, so that accretion of planets is implicitly assumed to occur in the presence of the nebula. Igarashi and Ozima (1988) attempt to produce the whole suite of terrestrial rare gases by summing a distribution of these planetesimals. They regard their model as a failure because it incorporates three orders of magnitude too little fractionated xenon to supply Earth. However, they do not allow for adsorption, which can greatly increase the yield at low temperature.

Figure 5. Xenon fractionation produced by gravitational settling of nebular gases inside porous planetesimals. Fractionated Xe is trapped when pores are closed off by lithostatic pressure. The extent of Xe fractionation is determined by planetesimal density ρ [g cm^{-3}], temperature T [K], and the characteristic pressure at which pores are closed (Zahnle et al. 1990*b*).

Zahnle et al. (1990b) replace the assumption that large planetesimals remain porous at all depths with the more realistic assumption that gases are trapped when pores are closed by high lithostatic pressure. This relates the degree of fractionation to the strength of rock, a material property, and thus the degree of fractionation is predicted and is the same in every planetesimal large enough to reach the pore-closing pressure (Fig. 5). Lunar seismic observations imply that the pore-closing horizon in the regolith occurs at a lithostatic pressure of ~ 1 to 1.2 kbar. The model's best point (i) is that at reasonable temperatures the predicted degree of Xe fractionation is that observed on Earth and Mars. It has other positives. (ii) It can explain why Mars and Earth have the same degree of Xe fractionation. (iii) Because the xenon is physically trapped, accretion of the planetesimals to form planets can occur after nebular dissipation. (iv) With adsorptive amplification included, the model planetesimals can provide enough xenon to supply Earth and Venus. (v) The corresponding amount of fractionated Kr is negligible. (vi) It is physically realistic. An analogous process is known to occur in the Antarctic ice cap (Craig et al. 1988), where at -30°C and 70 m depth porous snow transforms to impermeable ice. The trapped atmospheric gases are observed to be isotopically fractionated to just the extent predicted by application of the barometric law.

The planetesimal models can plausibly produce fractionated xenon, but at present they are not too useful otherwise. Planetesimal xenon could be used to replace hydrodynamically fractionated xenon on Earth and Mars. But, like hydrodynamic escape, it does not account for the high Kr/Xe ratios found on these planets. The difficulty is the same one that dogs hydrodynamic escape: what is the source of fresh Kr, and why is it not accompanied by fresh Xe?

C. Solar-Wind Implantation

Wetherill (1981) and McElroy and Prather (1981) suggested solar-wind implantation as a way to supply Venus with its observed high quantity of ^{36}Ar , and account for the steep sunward gradient of ^{36}Ar , abundances on Venus, Earth and Mars. (Hostetler [1981] proposes a variant in which differential ionization and separation of ions from neutrals in a magnetic solar wind affects elemental ratios.) The model assumes that the solar nebula cleared of gas before the terrestrial planets accreted, so that a high surface area of dust, fragments, and planetesimals were exposed to an intense early solar wind. The dust and small fragments are envisioned as constantly being formed by collisions and re-accreted into planetesimals. Most of this material is eventually incorporated into planets. Because much of the planetary material becomes exposed to the solar wind, noble gases accrete early and more or less homogeneously.

Solar-wind implantation has no difficulty supplying enough ^{36}Ar for Venus, which may be its greatest strength. T Tauri winds are very high, typically 10^6 times higher than today, but are probably associated with the

accretion of gas onto the star, and thus predate the gas-free debris disk. Later winds are no doubt less severe, but it would be rash to imagine that they fell abruptly to the modern level. A sensible compromise would be to assume solar-wind enhancements comparable to solar EUV enhancements, as both are ultimately related to solar activity. Wetherill achieves Venusian levels of argon over 10^7 yr with solar-wind enhancements of order 50 to 500, and this estimate may be too pessimistic: using somewhat more liberal assumptions, McElroy and Prather get there in 2×10^7 yr with the modern solar wind.

However, solar wind implantation does less well with the sunward gradient than one might initially suppose. A steep sunward gradient in noble gas abundance can be produced early if the debris disk is optically thick in the radial direction, i.e., if the inner edge of the disk absorbs all the incident solar wind, shadowing the interior. To the extent that planets form from local material in isolated feeding zones, the sunward gradient will be manifested in the completed planets. But, as Wetherill emphasizes, Venus and Earth very likely did not accumulate in isolation, so that it is difficult to maintain a steep gradient between them. Venus and Earth, as co-accumulating planets, necessarily scattered material between them. Wetherill finds that it is difficult to get a gradient larger than 10:1, which falls roughly an order of magnitude short of what is needed (note that this restriction applies to the grain accretion model, as well). Radial mixing is not the only reason why solar-wind implantation might not produce a steep inner solar-system rare-gas gradient. The debris disk may not be optically thick when the gas clears, for one. Also, popular disks tend to be flared owing to weaker solar gravity at greater distances from the Sun. Hence the surface of the disk may be obliquely exposed to the solar wind at all distances, permitting solar-wind implantation to occur with reasonable efficiency at asteroidal distances (Sasaki 1991). A possible patch to the model is to put essentially all the noble gas into the innermost planetesimal, and have it be incorporated into Venus (Wetherill 1981).

The solar-wind implantation model has two serious difficulties. The model predicts more implanted neon than argon, and to the extent that the solar-wind implantation model fails to solve the gradient problem, it may be required that Earth lose much of its original argon and neon, apparently without comparable losses of krypton and xenon.

The importance of producing the observed inner solar-system planetary argon gradient by accretional processes fades if escape is accepted as important. Certainly this must be so for Mars; no one seriously entertains the notion that the present Martian atmosphere is the atmosphere Mars was formed with. The present Martian inventory of Xe would be doubled by accretion of just 50 m of average carbonaceous chondrites—what is more, the Xe isotopes are so discordant that even 10 m of the stuff would be apparent. Granted, carbonaceous chondrites may have little to do with planets in bulk, but this is still a very thin veneer for a material that is so evident among modern impactors. Small bodies are particularly susceptible to impact erosion—the expulsion of atmospheric gases by impact—especially towards the end of accretion, when

high-velocity collisions with widely scattered stray bodies are most likely (Melosh and Vickery 1989). Escape can easily account for a thin Martian atmosphere (Melosh and Vickery 1989). Whether it can reconcile Venus and Earth is another question.

Solar-wind-implanted noble gases, such as those in lunar soils, have roughly solar elemental and isotopic abundances, colored by a modest elemental fractionation favoring retention of the heavier elements (Swindle 1988). The typical Ne/Ar ratio of ~ 10 in implanted gases is less than the solar ~ 40 , but clearly far removed from the Venusian ratio of ~ 0.2 . Thus solar-wind implantation can account for nearly solar Ar/Kr on Venus, but fails to account for low Ne/Ar. Highly selective neon loss is required, which is not observed in some heated lunar soils (Pollack and Black 1982). However, there are classes of meteorites with very high argon content and very low Ne/Ar ratios. Examples are ureilites and, most intriguingly, the E-chondrites. South Oman, the most argon-rich meteorite, has Ne/Ar of just 0.003 (Crabb and Anders 1981). This noble gas pattern differs from either the "planetary" or the solar pattern, and has been called "subsolar." As emphasized by Wetherill (1981) and Bogard (1987), the very existence of subsolar rare gases demonstrates that an otherwise apparently solar noble-gas reservoir can lose its neon without losing its argon. Hostetler's (1981) model is constructed to account for low Ne/Ar ratios by differential thermal ionization in a cool, dense solar wind. The more highly ionized Ar is presumed to get preferentially implanted.

South Oman is an enstatite chondrite, a highly reduced class of meteorites that is so fascinating chemically that it is extremely tempting to try to assign them an important role in the evolution of the solar system (see, e.g. Crabb and Anders 1981; Prinn and Fegley 1989; Pepin 1991). Its rare gases are somewhat similar to Venus', but even using South Oman, the most Ar-rich member of the class, Venus would need to accrete 20% of its mass as enstatite chondrites to supply enough ^{36}Ar . Like all other veneering candidates, enstatite chondrites carry far too much carbon and nitrogen for this to work easily; the vast majority of carbon and nitrogen would need to be hidden elsewhere.

It is interesting to note that the subsolar noble gas carrier in South Oman is not the ubiquitous carbonaceous Q carrier but appears instead to be the enstatite itself (Crabb and Anders 1982). This may indicate that the nebular adsorption onto optimal carriers is not the cause of high noble-gas abundances in meteorites. The noble gases may have been incorporated into solids by some other process—solar-wind implantation is a plausible source—and then were later released to move about inside planetesimals, migrating to preferred mineral phases like Q, as less-mobile elements do. This might explain the similar bulk concentrations of noble gases in meteorites and Venus. Such a scheme could also account for the high intrinsic noble-gas partial pressures needed to reconcile laboratory adsorption experiments with the extremely high noble-gas contents of the Q carrier. This is also the kind of process that might allow a solar-wind implantation model to yield a Ne/Ar ratio characteristic of adsorption.

D. Cold Comets

Low-temperature condensates are essentially unknown. Clathrates are expected to favor the heavier noble gases, while direct freezing of ices might be expected to follow the solar pattern for the heavier elements, with an abrupt cut-off at the uncondensed element. Neither seems likely to discriminate among isotopes of an element. Adsorption on ice may be more variable, with some suggestion that Kr may be more readily adsorbed than Xe at very low temperatures (Owen et al. 1991). Also at low temperatures, very high adsorption efficiencies might be expected.

Comets offer the only possibility for a simple, single source explanation of nonradiogenic noble gases. In a cometary model noble gases would have arrived in a late veneer. Venus, with its high native noble-gas abundance and lighter-elemental pattern, would have to be regarded as more or less reflecting the rare-gas composition of the comets. There are nonetheless some severe constraints that can be placed on the composition of the hypothetical comets. If a cometary source is to supply Earth and Mars—why should it not?—it would need to contain intrinsically mass-fractionated xenon and a slightly supersolar Kr/Xe ratio. This is a general requirement of any single-source model. The distinct differences between terrestrial and Martian xenon further complicates this demand. It may be possible for Xe to be mass fractionated in adsorption at very low temperatures, but if so, it must be postulated that a roughly solar Ar/Kr/Xe pattern can occur when none of these is harvested quantitatively. Such a model is still left with the need to reduce both terrestrial and Martian Ne and Ar in such a way that on both planets the Ne/Ar/Kr ratios come out essentially the same, but with Martian $^{36}\text{Ar}/^{38}\text{Ar}$ coming out quite different. This may be possible with judicious application of hydrodynamic (or other) escape, but in doing so, much of the simplicity that makes comets attractive is lost.

Another argument that can be raised against a late cometary veneer is that if the noble gases in Loihi basalts truly sample an undegassed mantle (and they may not; see Sec. II.E), ^{36}Ar in air is quantitatively consistent with it being the outgassed complement of the degassed upper mantle. If icy planetesimals are to be important, they must arrive early enough in accretion that they can be mixed throughout the mantle. This may rule out very distant sources.

To some extent these difficulties can be ameliorated by chance differences among the impactors on Earth and Venus. In general, it must be expected that a few large impactors dominated the delivery of volatiles. Venus' largest contributing comet could have had a "colder" composition than Earth's. Or it may be that chance availed Venus through a large comet striking at an improbably low impact velocity, such that its volatile inventory was retained with unusual efficiency.

IV. SINKS

Jeans escape is thermal escape at low flux. In Jeans escape the atmosphere

effectively has a top, the exobase, above which atoms are as free as satellites. Hydrodynamic escape refers to a planetary wind, analogous to the solar wind, that occurs when thermal escape fluxes are high. The escaping gas remains collisional and behaves as a fluid at all heights; i.e., it obeys the equations of hydrodynamics. Hydrodynamic escape is a plausible process in the early solar system, and it is inherently mass fractionating. Impact erosion, which refers to the expulsion of atmospheric gases by impact, is also plausible, especially towards the end of accretion when impact velocities are expected to be high (Walker 1986; Ahrens and O'Keefe 1987; Hunten et al. 1989; Ahrens et al. 1989; Melosh and Vickery 1989). It is expected to be almost nonfractionating, and so shrinks an atmosphere without much altering its composition. Impact erosion offers a straightforward explanation for the extreme scarcity of Martian rare gases. Giant impacts, such as the hypothetical Moon-forming event, may behave a little differently in this respect. For example, Cameron (1983) suggests that escape may occur when the atmosphere climbs up a massive disk of Earth-orbiting debris. By prolonging escape over an extended period, such a scenario could lead to significant mass fractionation.

A. Jeans Escape

Donahue (1986) considers moderately large planetesimals that accumulated after the dispersal of the nebula. Isotopically solar noble gases that had been adsorbed on grains at an earlier stage of nebular evolution are released to form a noble-gas atmosphere. Other less volatile volatiles are retained in the planetesimal interiors. The noble gases are then fractionated by Jeans escape. Because Jeans escape is extremely sensitive to mass, it produces extreme fractionations too easily; the gentler fractionating powers of hydrodynamic escape would probably work better. The model at present fails to produce Venusian argon; and it does not address Xe or Kr. Planetesimal atmospheres are also problematic. They may be difficult to form, difficult to retain in the face of numerous erosive processes, and easily lost during collisions with other planetesimals.

B. Hydrodynamic Escape

For hydrodynamic escape to occur from the terrestrial planets, it is probably necessary that hydrogen be a major atmospheric constituent, at least at the high altitudes from which escape begins. The likeliest energy source driving escape would have been solar EUV radiation ($\lambda < 100$ nm), i.e., radiation of short enough wavelength that it can be directly absorbed by hydrogen (Sekiya et al. 1980a; Watson et al. 1981). Hydrodynamic escape is a reasonable process to expect in the early solar system because hydrogen is for many reasons a likely component of early atmospheres, and EUV fluxes from the young Sun are likely to have been very large. Hydrodynamic escape from Venus is a natural consequence of the runaway greenhouse (Watson et al. 1981; Kasting and Pollack 1983). It has also been invoked for the removal of massive primordial hydrogen atmospheres predicted by the Kyoto school of

planetary accretion (Sekiya et al. 1980*a, b*), and as the means for removing the enormous amount of hydrogen formed by reaction of water and iron in other planetary accretion models (Dreibus and Wänke 1987, 1989; Ringwood 1979).

A reasonable estimate for the H₂ escape flux at high solar EUV fluxes is obtained by balancing the absorbed EUV energy with the energy needed to lift the escaping atmosphere out of the planet's potential well (Watson et al. 1981),

$$F = \frac{R_p \epsilon}{GM_p m} \approx 5 \times 10^{11} \epsilon \text{ cm}^{-2} \text{ s}^{-1} \quad (1)$$

where R_p and M_p are the radius and mass of the planet; m and F are the molecular mass and the escape flux; and ϵ is the globally averaged incident solar EUV flux. The numerical values refer to an H₂ atmosphere escaping from Earth. For the modern quiet Sun, $\epsilon \sim 0.3 \text{ erg cm}^{-2} \text{ s}^{-1}$ ($\sim 10^{-6} L_\odot$); the Sun is quite variable at these wavelengths. Observations of young Sun-like stars imply that the young Sun would have emitted some 100 to 1000 times more EUV energy, with EUV fluxes declining roughly inversely with the Sun's age. Zahnle and Walker (1982) estimated that

$$\epsilon \approx 0.3 \left(\frac{10^{10} \text{ yr}}{t} \right) \text{ erg cm}^{-2} \text{ s}^{-1} \quad (2)$$

while Pepin (1991), using more recent X-ray data and excluding the more extreme T Tauri stars (see Fig. 6), estimates that

$$\epsilon \approx 300 \exp \left(\frac{-t}{9 \times 10^7 \text{ yr}} \right) \text{ erg cm}^{-2} \text{ s}^{-1}. \quad (3)$$

Thus Eq. (1) implies that hydrogen escape fluxes of order 10^{13} to $10^{14} \text{ cm}^{-2} \text{ s}^{-1}$ could reasonably be expected from the terrestrial planets ca. 10 to 100 Myr, provided that hydrogen were available to escape. At the higher rate it would take just 3 Myr to lose the hydrogen present in the Earth's oceans. It need not have taken long to turn an Earth into a Venus.

Even higher escape rates would be possible if more abundant photons at longer wavelengths could be utilized. For example, Sekiya et al. (1981) have suggested using far-ultraviolet radiations with $\lambda < 185 \text{ nm}$ that can be absorbed by H₂O. This allows them to rid Earth of its hypothesized 10²⁶g kyotosphere in a reasonable time. However, in this study, Sekiya et al. neglected radiative cooling, which for H₂O at $> 500 \text{ K}$ is probably considerable. It is far from obvious that any of this far-ultraviolet energy is actually available for escape. This illustrates the need for a quantitative, self-consistent hydrodynamic escape model that includes both radiative heating and cooling, as well as the necessary chemistry and transport affecting the abundance of possible coolants.

Figure 6. Observed X-ray luminosities L_x/L_\odot of young stars relative to the modern Sun vs stellar age. The three curves represent different approximations to solar X-ray evolution (figure adapted from Pepin 1991).

Mass Fractionation by Hydrodynamic Escape. Mass fractionation occurs in hydrodynamic escape when the escape flux is high enough that heavier molecules are dragged along with the flow. In a two-gas atmosphere, the transition occurs when the hydrogen escape flux exceeds the “diffusion-limited” flux defined by Hunten (1973). The escape flux of a trace constituent j in a hydrogen escape flux F_1 is approximately (Hunten et al. 1987)

$$F_j = F_1 \frac{N_j}{N_1} \left(1 - \frac{(m_j - m_1)gb_{1j}}{F_1 kT} \right); \quad F_j \geq 0 \quad (4)$$

where N_1 and N_j are the column densities of the major and minor constituents; F_1 and F_j their escape fluxes; b_{1j} is the appropriate binary diffusion coefficient (Marrero and Mason 1972); and k is Boltzmann’s constant, T temperature, and g gravity. Hunten et al. (1987) and Pepin (1991) present their analyses in terms of a “crossover mass,” defined as

$$m_{cj} \equiv m_1 + \frac{F_1 kT}{gb_{1j}}. \quad (5)$$

The crossover mass is the heaviest mass that can be dragged to space by the escaping hydrogen. The crossover mass is different for different elements, because binary diffusion coefficients vary. Zahnle and Kasting (1986) consider a more general case, and verify that Eq. (4) is a good approximation for

escape of a trace constituent provided that

$$\frac{m_{cj} - m_j}{m_{cj} - m_1} > \frac{m_1}{m_j}. \quad (6)$$

A similar argument is derived by Sasaki and Nakazawa (1988). For noble gases escaping in a hydrogen-dominated atmosphere, Eq. (4) is good for Ne, Ar, Kr and Xe; it is less good for He. With $b_{1j} = 2.7 \times 10^{17} T^{0.712}$ for diffusion for Xe and H₂ (Marrero and Mason 1972), hydrogen escape fluxes from Earth must exceed

$$F_1 > 7 \times 10^{13} \left(\frac{T}{500\text{K}} \right)^{-0.288} \text{ cm}^{-2} \text{ s}^{-1} \quad (7)$$

to fractionate xenon. The needed escape flux is the same order of magnitude as that expected, and therefore mass fractionation in hydrodynamic escape must be considered seriously.

A simple case to treat analytically is that for which the hydrogen escape flux is high enough that all the elements (isotopes) of interest escape; i.e., if

$$F_1 > \frac{(m_j - m_1) g b_{1j}}{kT} \quad (8)$$

for all j of interest. Then the fractionation of two species i and j produced by hydrodynamic escape is just

$$\log \left(\frac{N_i(t)}{N_j(t)} \div \frac{N_i(0)}{N_j(0)} \right) = [(m_i - m_1) b_{1i} - (m_j - m_1) b_{1j}] \frac{g}{kT} \int_0^t \frac{dt}{N_1(t)}. \quad (9)$$

This expression shows that, provided F_1 is large enough to effect escape of the relevant isotopes, the mass fractionation pattern produced is independent of F_1 . If $b_{1j} \sim b_{1i}$, as it is for isotopes of a noble-gas element (other than helium) in H₂, then

$$\log \left(\frac{N_i(t)}{N_j(t)} \div \frac{N_i(0)}{N_j(0)} \right) \sim (m_i - m_j) \frac{g}{kT} \int_0^t \frac{dt}{N_1(t)}. \quad (10)$$

Because both the solar EUV flux and the hydrogen supply are expected to decline with time, albeit fitfully, the lighter noble-gas elements are more depleted and relatively more fractionated than the heavier elements by real hydrodynamic escape. It is possible that something like this pattern is seen in "planetary" rare gases (Pepin 1991), but the predicted pattern is most certainly not seen on Earth and Mars, the only planets for which we have adequate data. In particular, xenon is predicted to be more abundant and less fractionated isotopically than krypton, relative to the composition of the source. Precisely

the opposite is seen on Earth and Mars. Xenon is profoundly mass fractionated on both planets, while krypton is not; on Mars the Kr/Xe ratio is roughly solar, and on Earth it's even higher.

Total Hydrogen Loss During Hydrodynamic Escape. The assumption that hydrodynamic hydrogen escape proceeds at the maximum rate allowed by the solar EUV flux necessarily implies an enormous hydrogen loss and therefore an enormous hydrogen source. To illustrate, assume that the solar EUV flux history is given by Eq. (3). The total amount of hydrogen lost is then obtained by integrating Eq. (1):

$$\Delta M = \frac{4\pi R_p^3}{GM_p} \int \epsilon(t) dt \sim 7 \times 10^{24} \text{ g} \quad (11)$$

from Earth. A similar, somewhat smaller estimate of $\sim 2 \times 10^{24}$ g is obtained if the solar EUV flux history is obtained from Eq. (2). This is the hydrogen content of 15 to 50 oceans. The larger estimate is equivalent to accreting Earth from material that is 1% water by mass, a water content consistent with the geochemically driven terrestrial accretion models proposed by Ringwood (1979) and Dreibus and Wänke (1987). In such a model, most of the hydrogen is produced by the reaction of water with iron during accretion (Lange and Ahrens 1984). Evidently this magnitude of hydrogen escape is not beyond the bounds of reasonable expectation. Nevertheless, these enormous hydrogen losses are not demanded by the hydrodynamic escape model; they are simply a consequence of assuming that there is always enough hydrogen available for escape to proceed at the maximum possible rate. This need not be so. For example, the planet could simply run out of hydrogen, as Venus has. If Venus had had only an ocean's worth of hydrogen, it could have been lost in as little as 3 Myr, well before the solar EUV flux declined. Or escape may occur only during brief intervals. Consider an impact-dominated environment. The planet may only have had hydrogen to lose for short intervals following major impacts. Such, for example, may be the case for Venus today (Grinspoon and Lewis 1988). Or consider Earth; after a large impact the oceans are vaporized, and for a little while hydrodynamic hydrogen escape would be expected. But the oceans quickly condense and rain out again, so that, even with many impacts, most time is spent with the ocean condensed and therefore at most times little hydrogen escapes.

None of these hydrogen-poor scenarios would necessarily produce a different fractionation pattern than does the hydrogen-rich scenario. As noted earlier in Eq. (9), the magnitude of mass fractionation produced by hydrodynamic escape is proportional to $\int N_1^{-1}(t) dt$ where $N_1(t)$ is the hydrogen column density during episodes of escape. The same degree of fractionation is produced in a tenth the time if N_1 is on average a tenth the size. Pepin (1991) treats N_1 as a free parameter, so clearly his model can adapt to low hydrogen regimes. In summary, mass fractionation by hydrodynamic escape does not necessarily imply enormous hydrogen losses, although obviously it

Figure 7. The minimum $^{20}\text{Ne}/^{22}\text{Ne}$ ratio produced while fractionating argon by hydrodynamic escape from Mars. The initial $^{20}\text{Ne}/^{22}\text{Ne}$ ratio is assumed to be solar 13.7. The presence of an abundant impurity (like CO_2) or any extended period in which the hydrogen escape flux was large enough for neon to escape but not large enough for argon to escape would lower the predicted $^{20}\text{Ne}/^{22}\text{Ne}$ below the indicated curves.

can accommodate them. It does imply extremely vigorous escape during those intervals during which hydrogen loss occurs.

Some Applications. Mass fractionation in hydrodynamic escape may have contributed to the observed high D/H ratio on Mars (Owen et al. 1989). It has been invoked to explain the fractionation pattern of the isotopes of xenon on Earth (Hunten et al. 1987; Sasaki and Nakazawa 1988; Pepin 1991) and Mars (Pepin 1991), the high Martian $^{38}\text{Ar}/^{36}\text{Ar}$ ratio (Pepin 1989; Zahnle et al. 1990a; Pepin 1991), and isotopic differences between atmospheric and mantle neon (Sasaki and Nakazawa 1988; Zahnle et al. 1990a; Pepin 1991). Mass fractionation by hydrodynamic escape could also account for the observed modest elemental fractionation of the Martian noble gases with respect to Earth (Hunten et al. 1987); however, it cannot easily explain both the elemental and the isotopic fractionations, because the relatively strong isotopic fractionations are incompatible with the relatively weak elemental fractionation.

Martian Argon. Martian argon, with a $^{36}\text{Ar}/^{38}\text{Ar}$ ratio of 4.1 ± 0.3 , is strikingly heavy (Wiens et al. 1986; Swindle et al. 1986b). By comparison the terrestrial ratio is 5.32 and "planetary" ~ 5.3 . The solar-wind value is usually given as ~ 5.3 , but may actually be as high as ~ 5.8 (Swindle 1988; Pepin 1991). The only component as low as Mars' is solar-flare argon (see Swindle 1988), but pure solar flares are an unlikely source of Martian argon. Fractionation acting on Mars itself seems to be required. Hydrodynamic escape can account for fractionation of Martian argon (Zahnle et al. 1990a; Pepin 1991). This is marginally consistent with the composition of Martian neon, $^{20}\text{Ne}/^{22}\text{Ne} = 10.1 \pm 0.7$ (Swindle et al. 1986b; Wiens et al. 1986). If the original Martian ratios of $^{36}\text{Ar}/^{38}\text{Ar}$ and $^{20}\text{Ne}/^{22}\text{Ne}$ were 5.35 and 13.7, respectively, hydrodynamic escape predicts a final $^{20}\text{Ne}/^{22}\text{Ne}$ ratio no greater than 9.5 ± 1.3 (see Fig. 7). This is barely consistent with observation. To produce neon this light requires hydrogen escape fluxes high enough that both argon and neon escape at all times, and the escaping atmosphere must be mainly H_2 . The presence of abundant heavy atmospheric pollutants like CO_2 or any extended period in which the hydrogen escape flux was large enough for neon to escape but not large enough for argon to escape would lower the predicted $^{20}\text{Ne}/^{22}\text{Ne}$ below the range permitted by observation (Zahnle et al. 1990a).

Terrestrial Neon. Atmospheric neon is isotopically heavier than mantle neon (Craig and Lupton 1976; Staudacher 1987; Ozima and Igarashi 1989; Honda et al. 1991). The evidence points to an initially solar $^{20}\text{Ne}/^{22}\text{Ne}$ ratio. By contrast, mantle and atmospheric reservoirs of the nonradiogenic isotopes of argon, krypton and xenon appear to be isotopically the same (Allègre et al. 1987; Ozima and Igarashi 1989). Heavy atmospheric neon can be explained by the preferential loss of the lighter neon isotope from Earth's atmosphere, as has been noted by Craig and Lupton (1976), Allègre et al. (1987), and Staudacher (1987). Allègre et al. (1987) estimate that 28% of degassed neon has escaped.

Zahnle et al. (1990a) extended the theory of mass fractionation in hydrodynamic escape to atmospheres in which hydrogen was not the only major constituent. We were particularly interested in cases where an abundant heavy constituent did not escape. Under such circumstances hydrogen escape would be regulated by the diffusion-limited flux (Hunten 1973). This could be the case if the heavy constituent was an effective radiative coolant, and would surely be the case if the heavy constituent were overwhelmingly abundant. There is no lack of plausible candidates; N_2 , CO and CO_2 could all suffice.

Steam atmospheres are a likely, if intermittent, feature of the accreting Earth (Matsui and Abe 1986; Zahnle et al. 1988). In our calculations, steam atmospheres would have lasted some 10 to 50 Myr. They occur because, on average, the energy of accretion places Earth above the runaway-greenhouse threshold, so that liquid water is not stable at the surface. Zahnle et al. (1990a) showed that neon fractionation would have been a natural byproduct of hydrogen escape in diffusion-limiting flux through a steam atmosphere

polluted with significant amounts of CO_2 , N_2 , or CO . The reason neon can escape and argon cannot is that neon is less massive than any of the likely pollutants. Assuming that the initial $^{20}\text{Ne}/^{22}\text{Ne}$ ratio was solar, we found that it would have taken some 10 Myr to effect the observed neon fractionation with a 30-bar steam atmosphere and 10 bar of CO (see Fig. 8). Thicker atmospheres would have taken longer; less CO , shorter. This mechanism for fractionating neon has about the right level of efficiency. Because the lighter isotope escapes much more readily, total neon loss is fairly minimal; less than half of the initial neon endowment escapes.

Figure 8. Neon fractionation produced by vigorous hydrogen escape from steam atmospheres during accretion is shown as a function of the lifetime of the steam atmosphere. Three cases are shown. An initial solar $^{20}\text{Ne}/^{22}\text{Ne}$ ratio is consistent with reports of isotopically light neon emanating from the modern undegassed mantle (Ozima and Igarashi 1989; Honda et al. 1991). The time scales for neon fractionation are consistent with the expected lifetimes of steam atmospheres during accretion (Matsui and Abe 1986; Zahnle et al. 1988; figure adapted from Zahnle et al. 1990a).

Xenon. Xenon fractionation on Earth has been a long-standing problem (see Ozima and Podosek 1983). Hydrodynamic escape can fractionate xenon (Hunten et al. 1987; Sasaki and Nakazawa 1988). Indeed, hydrodynamic escape can produce terrestrial xenon whether one starts with U-Xe, SUCOR

xenon, or “planetary” xenon as the raw material (Hunten et al. 1987). With U-Xe the fit is straightforward, which is not surprising, because the composition of U-Xe is in part derived on the assumption that terrestrial nonradiogenic xenon is mass fractionated U-Xe (Pepin 1991). Terrestrial nonradiogenic xenon can be derived from “planetary” or SUCOR xenon if the three heavier xenon isotopes are subject to much less escape than are the lighter isotopes; i.e., much of the escape must have taken place with a xenon crossover mass fixed at 132. A problem specific to this explanation is that the hydrogen escape flux cannot have varied by more than $\sim 1\%$; it must have stayed tuned to a specific crossover mass for a period of time comparable to the time spent at all higher fluxes. As there is no obvious reason why the hydrodynamic escape flux should be so tuned, this explanation is not really satisfactory.

There are three general difficulties with producing terrestrial xenon fractionation by hydrodynamic escape. (i) The basic problem is that any escape episode that fractionated xenon must have fractionated krypton more greatly. Because Kr is both relatively abundant and relatively unfractionated, xenon fractionation must have preceded the arrival of atmospheric krypton. Unless most of the “atmospheric” xenon is buried (adsorbed) in yet undiscovered crustal reservoirs, the fresh krypton could not have been accompanied by the expected quantity of fresh xenon, lest the latter overwhelm the hydrodynamic signature. Thus at a minimum there must have been two atmospheres, an earlier one of which fractionated xenon is the only clear remnant, and a later one that was more or less xenon free. (ii) Martian xenon imposes precisely the same constraints on the evolution of the Martian atmosphere. This poses something of a puzzle, because Mars and Earth are not so much alike as planets that parallel evolution should be expected. (iii) Because xenon is one of the heaviest atmospheric gases, large-scale xenon escape demands that all other atmospheric gases must also escape. It is not obvious that such vigorous escape could actually occur from a planet as large as Earth. Wholesale escape of potentially abundant heavy atmospheric constituents, like H_2O , CO_2 , CO and N_2 , might place unreasonable demands on the energy source fueling escape. This problem would be exacerbated if radiative cooling by these or other infrared-active species were important.

Fractionating the Kyotosphere. Sasaki and Nakazawa (1988) also found that hydrodynamic escape could fractionate terrestrial xenon. The main difference is that they approach the problem from the perspective of the Kyoto school: they assume that Earth accreted in the presence of the solar nebula and thereby acquired an immense ($\sim 10^{26}$ g) primordial atmosphere which, of course, had to be removed. Sekiya et al. (1980a) showed that it might be possible to do this with solar EUV-fueled hydrodynamic escape. Sasaki and Nakazawa (1988) consider terrestrial Xe and Ne as possible remnants of the lost kyotosphere. They account for terrestrial nonradiogenic Xe by mixing a small amount of highly fractionated U-Xe, produced by hydrodynamic fractionation of the kyotosphere, with the fresh xenon that accompanied Kr and Ar outgassing. Kyotospheric Ar and Kr are completely lost, but some highly

fractionated Ne remains, which is supplemented with outgassed isotopically solar Ne to give air.

Because they presume the validity of the Kyoto model, Sasaki and Nakazawa make some rather specific predictions regarding the fate of the original 10^{26} g primary atmosphere. At the end of Ne loss, only about 10^{18} g (or less) of the primary atmosphere remain, i.e., 200 μ bar. This hardly seems realistic, but neither is it realistic to expect all the assumptions of the Kyoto model to be rigorously obeyed. Because Mars is not massive enough to have attracted a thick primordial atmosphere, the model does not attempt to explain why Martian xenon should also be fractionated.

A Comprehensive Model. Pepin (1991) proposes a comprehensive model for the present distribution of noble gases in the inner solar system. The actual model is rather complicated, but the underlying premise is straightforward. Pepin assumes that the primary source of the noble gases was the solar nebula and that the processes fixing noble gases into atmospheres, chiefly adsorption, are not isotopically fractionating. Thus the initial noble gas inventories are isotopically, but not necessarily elementally, solar. Subsequent elemental fractionations and all isotopic fractionations are caused by hydrodynamic escape. The main reason the model is complicated is because, as noted above, noble gas isotopes cannot be explained by hydrodynamic escape of an isotopically solar atmosphere. Xenon precludes this on Earth and Mars.

Pepin assumes the following:

1. Hydrogen escapes at the maximum rate allowed by solar EUV. The latter is chosen to be consistent with emissions of young Sun-like stars (as discussed above, this assumption is not absolutely necessary to the model).
2. The mass fractionation produced is adequately described by equations derived for the escape of trace constituents in an atmosphere composed mainly of hydrogen.
3. There are two important initial reservoirs of planetary rare gases. One is an external primary atmosphere, possibly supplied by comets or carbonaceous chondrites. The other is internal, and dates back to the planet's youth as a protoplanet immersed in the solar nebula.
4. On Earth and Venus the external source is mainly cometary; carbonaceous chondrites are relatively more important on Mars. The internal and external rare gases may have different elemental compositions, but both are isotopically solar.
5. The external atmospheres escape to varying degrees from the three planets. On Earth and Mars escape is severe and fractionated Xe is the only clear remnant. On Venus much of the external atmosphere remains, and is only modestly fractionated.
6. On Earth and Mars internal Ne, Ar and Kr are outgassed after the escape of the external atmosphere. These replacement atmospheres are also subject to hydrodynamic losses, but the losses are less severe. Outgassing on

Venus may also occur but against the background of the massive remnant of the primary atmosphere it is not large enough to be noticed.

7. Internal xenon is not outgassed, but is instead incorporated into the cores; i.e., it is assumed that xenon becomes a siderophile at high pressure.

With continuing hydrodynamic escape acting upon the replacement atmosphere, the model can be made to match the terrestrial data quite well. It can also accomodate subtle effects like isotopic fractionation of krypton and argon.

Pepin suggests that the internal noble gases were incorporated into the growing protoplanet by gravitational attraction of nebular gases and subsequent adsorption at the surface. Large gravitational enhancements are necessary because noble gases are too scarce in the nebula to be effectively captured in the needed quantity. Rather large protoplanets are required, at least Moon-sized and probably Mars-sized for Earth. Thus the internal rare gases are identified with the "cold core," the original solid, undegassed protoplanet predicted to lie at the heart of a growing planet until it is ultimately dislodged by core formation (Stevenson 1981). This also puts internal xenon in a good position to go into the core.

Venus' present atmospheric composition is almost independent of Earth's. Venus's high Ar/Kr and "planetary" Ne/Ar ratio are essentially properties of the external source material, most likely comets. An earlier attempt to identify the Venusian atmosphere with a kyotosphere failed because it left too much neon behind (Pepin, personal communication). Rare gases are mass fractionated from cold cometary composition. Therefore Venus defines the comets. Pepin predicts that Venusian xenon will be isotopically much less fractionated than terrestrial or Martian xenon.

Earth's original external atmosphere is also presumed to be cometary, and so would have had the same composition as Venus' external atmosphere. Essentially all the Ne, Ar and Kr from the external atmosphere must escape. In Pepin's model, hydrodynamic escape alone does not suffice to remove enough Ne and Ar. Additional selective escape of Ne and Ar is assumed to take place in the aftermath of the giant, Moon-forming impact. Present atmospheric Ne, Ar and Kr largely reflect the composition of the internal source, although they too have been subject to some late mass-fractionating escape.

The story for Mars is very much like the story for Earth, absent the giant impact. However, for Mars the original atmosphere is identified with "planetary noble gases, because Martian xenon is consistent with mass-fractionated "planetary" xenon. The dominance of "planetary" over cometary rare gases is consistent with the high carbonaceous chondritic composition of Mars that characterizes recent geochemical models (see, e.g., Dreibus and Wänke 1987). Like Earth, xenon is the only clear remnant of the primary atmosphere and, like Earth, the xenon in the outgassed component was scavenged by the core. Hydrodynamic escape acting on the replacement atmosphere fractionates argon. Because Pepin uses a very light solar argon ($^{36}\text{Ar}/^{38}\text{Ar} =$

5.8), neon becomes too heavy ($^{20}\text{Ne}/^{22}\text{Ne} = 8.5$) during argon fractionation. Consequently neon must be replenished a third time, here by later addition of solar-wind-impregnated cosmic dust. It is stark testimony to the thinness of Mars's atmosphere that the modern flux of cosmic dust is large enough to perceptibly alter its composition.

I have not here done full justice to the model. Pepin (1991) also tracks carbon and nitrogen, and he develops a relatively specific and interesting hydrodynamical escape explanation for isotopic fractionation of "planetary" rare gases. These matters may be pursued by the reader.

A key observation is that Pepin's (1991) model does not succeed in generating Venus, Earth and Mars from a single universal rare-gas reservoir. Instead, the rare gases on each planet are derived from different initial reservoirs. The exception is that Earth and Mars derive their Ne, Ar and Kr mainly from similar internal sources (although Martian Ne is supplemented by a late solar-wind source). Earth and Mars fractionate different xenons: Earth's is from cold comets, and Mars's from carbonaceous chondrites. Venus generates its rare gases from cold comets. Thus many of the perceived elemental and isotopic patterns that hint so intriguingly of a big picture are either reduced to coincidence or pushed back a frame into a darker past. Presumably many of the general similarities and particular dissimilarities are ultimately due to the consistencies and vagaries of adsorption, the physical process at the beginning of every thread.

How much of the model is likely to be right? It is unsettling that Venus, the one planet for which we have good reason to believe that a lot of hydrogen has selectively escaped, is the planet that shows the least evidence for selective hydrodynamic escape in its rare gases. The model's appeal to the giant impact as an agent of selective escape is also problematic, but in my opinion, the giant impact is not really germane to the issues at hand. In principle hydrodynamic escape can selectively remove any neon and argon; Pepin's argument that it cannot is rooted in the specific model he adopts for the EUV flux history of the ancient Sun. A potential inconsistency with the model arises from the controversial claim that internal rare gases in Earth's undegassed lower mantle are elementally and isotopically like air (Allègre et al. 1987; for a dissenting opinion see Patterson et al. [1990]). If verified, this near match of internal and external rare gases argues against different histories for xenon and the other rare gases, nor does it support the notion that xenon becomes siderophile at lower mantle pressures. Still, the assumption that xenon is siderophile at Martian core-mantle pressures is testable in the laboratory; it would be a serious blow to the model if it were to prove otherwise.

V. RADIOGENIC NOBLE GASES

Because they are born in rock and accumulate in the atmosphere, radiogenic noble gases serve as chronometers of planetary degassing and atmospheric evolution. Radiogenic isotopes include ^4He (from α decay of uranium and

thorium), ^{40}Ar , ^{129}Xe , and fissogenic $^{131}\text{--}^{136}\text{Xe}$. The short half-lives of ^{129}I and ^{244}Pu make the xenon isotopes useful for early events; ^{40}Ar is useful for determining the long term degassing history of the planets. About 6.7% of atmospheric ^{129}Xe is radiogenic (Pepin and Phinney 1978). Pepin and Phinney (1978) find that 4.6% of the ^{136}Xe in air is plutogenic, while Igarashi and Ozima (1988) get 3.1%.

Outgassing models assume that the atmosphere was generated by the degassing of part of the mantle, often identified with the upper mantle. Such models usually imply that the degassed mantle was degassed very thoroughly very early (see, e.g., Ozima and Igarashi 1989). For example, Allègre et al. (1987) conclude that about half the mantle was degassed, and that degassing was more than 99% efficient and took place within 50 Myr. Early catastrophic degassing is consistent with degassing taking place during accretion, and so can be consistent with degassing occurring promptly on impact.

A. Xenon

Using meteoritic estimates for the initial $^{129}\text{I}/^{127}\text{I}$ and $^{244}\text{Pu}/^{238}\text{U}$ ratios (^{127}I is the only stable iodine isotope, and uranium must serve as proxy for plutonium), it has been deduced that the atmosphere contains about 0.5% of the radiogenic ^{129}Xe expected from decay of the original solar system complement of ^{129}I , while it contains some 20 to 40% of the fission xenon expected from decay of primordial plutonium (Ozima and Podosek 1983). The first point to note is that the amount of ^{129}Xe in the atmosphere is very small. This cannot be due to low outgassing efficiency; daughters of longer-lived parents (^4He , ^{40}Ar and ^{136}Xe) have all been rather efficiently degassed (Ozima and Podosek 1983), and so has ^{129}Xe itself, judging by the very small quantities in MORB samples. The small amount of ^{129}Xe in the atmosphere must either be due to crustal burial (which, as discussed above, is not really a viable option), or to escape, either from Earth or else from the grains, rocks, planetesimals, and protoplanets that accreted to form Earth. At 17 Myr, the half-life of ^{129}I is long enough that most ^{129}Xe escape probably had to take place from large objects. (This should remind the reader that planetesimal atmospheres are a plausible site for noble gas fractionation.) A second point to note is that, if xenon in the lower mantle looks like air (Allègre et al. 1987), most ^{129}Xe was lost before nonradiogenic xenon was placed in the mantle.

If plutonium xenon has been correctly identified in the atmosphere, xenon in the atmosphere can be dated to 120 Myr after the origin of the solar system from isotope ratios alone (Wetherill 1975a). Other authors have repeated the exercise with somewhat different assumptions and similar results (Pepin and Phinney 1976; Ozima and Podosek 1983; Hiyagon and Sasaki 1988). Again, the age of ~ 120 Myr is most simply interpreted as implying substantial loss of any earlier terrestrial atmosphere, although other interpretations are possible (see, e.g., Hiyagon and Sasaki 1988).

While Earth's mantle contains detectable and correlated excesses of ^{129}Xe and uranium fission xenon, there is no trace of plutonium fission xenon (Stau-

dacher 1987; Hiyagon and Sasaki 1988). Because ^{244}Pu has a longer half-life than ^{129}I , the plutonium model for atmospheric xenon plainly predicts that plutonium xenon should be more evident in the mantle than either uranium or iodine xenon. The absence of plutonium fission xenon in MORB must be explained by postulating a special hiding place to which Earth's plutonium was removed immediately after catastrophic degassing took place. Alternatively, plutonium abundance in the early solar system has been badly overestimated, and fissionogenic xenon in Earth's atmosphere has been misidentified.

The question of missing plutonium recurs on Mars. Compared to its known reservoirs of other volatiles, Mars has relatively large amounts of radiogenic ^{40}Ar and ^{129}Xe . How much would be expected? The release factor for ^{244}Pu fission xenon should be between that for ^{129}Xe and ^{40}Ar . The amount of ^{40}Ar in the present Martian atmosphere is 2.6% of what has been generated internally by ^{40}K decay (Dreibus and Wänke 1987), or about 5% that of Earth. On a gram per gram basis, Mars has about 1/3 as much radiogenic ^{129}Xe as Earth. According to Dreibus and Wänke (1987, 1989), Mars was endowed with 2.4 times more iodine than was Earth, so that the equivalent scaling factor for ^{129}Xe would be $\sim 14\%$. Thus one would expect that between 15 and 50% of Martian ^{136}Xe should be plutonium fission xenon. However, although Mars has a clear excess of heavy xenon isotopes with respect to Earth, it has no discernable plutonium xenon (Swindle et al. 1986b).

B. Argon

In contrast to nonradiogenic argon, Venus has about 25% as much atmospheric ^{40}Ar as Earth (Pollack and Black 1982). If Venus has the same amount of potassium as Earth, this observation would imply that Venus is about 25% as degassed as Earth, corresponding to a release factor of about 10 to 15%. Most of this difference is probably timing. Venusian atmospheric ^{40}Ar is consistent with outgassing having effectively ceased ca 3.5 Gyr (Pollack and Black 1982). Martian atmospheric ^{40}Ar corresponds to a release factor of only 2.6% (Dreibus and Wänke 1987). Some of this may be due to escape, but mostly this too should be ascribed mainly to an effective early cessation of outgassing, probably well before 4 Gyr.

VI. CONCLUSIONS

Two issues that have dominated discussion of planetary rare gases were first a general resemblance between the so-called "planetary" rare gases found in meteorites and those in air, and later the discovery that atmospheric inventories of argon and neon fall off precipitously with increasing distance from the Sun. The former encouraged identifying atmospheric rare gases with certain classes of meteorites, but it is now fairly clear that "planetary" rare gases are not found on planets. In particular, the postulated missing xenon has not been found. The apparent and very unexpected heliotropism of the noble gases points to the solar wind rather than condensation as the fundamental process for

placing noble gases in the atmospheres of the terrestrial planets; however, extant models are unable to fully reproduce the observed gradient, nor do they account for similar planetary Ne/Ar ratios and dissimilar planetary Ar/Kr ratios.

More recent studies have emphasized escape. Hydrodynamic escape, which is fractionating, readily accounts for the difference between atmospheric neon and isotopically light mantle neon. It can also with more difficulty account for isotopically heavy Martian argon. Atmospheric cratering, which is nearly nonfractionating, can account for the extreme scarcity of nonradiogenic noble gases (and other volatiles) on Mars. Escape is less satisfying when used to force argon and neon on Venus and Earth into accord. Because the two planets appear to have similar amounts of krypton, carbon, and nitrogen, catastrophic volatile loss from Earth provoked by the famous Moon-forming impact is not the easy solution that it is sometimes claimed to be. If escape from Earth were nonfractionating, it would have preserved the Ar/Kr ratio. If escape were fractionating enough to produce the typically planetary ratios from an originally Venusian Ar/Kr ratio, it would also have greatly fractionated argon and neon isotopically, which is not observed.

In my opinion, some combination of solar-wind implantation, adsorption, and escape is probably required to begin explaining planetary noble gases. Solar-wind implantation helps to explain the sunward gradient, and it is a proven means of getting enough noble gas into the building blocks of Venus. Subsequent mobilization and adsorption in planetesimals might then account for the roughly adsorptive pattern common to planets and "planetary" meteorites. The high xenon abundance of "planetary" rare gases would be a peculiarity of the Q carrier. Where the Q carrier was not available, other carriers would have to suffice. In enstatite chondrites it is the enstatite itself that carries the subsolar rare gases (Crabb and Anders 1982).

There remain two outstanding problems: (i) Xe fractionation on Earth and Mars, and (ii) the different Ar/Kr ratios on Venus and Earth. Neither is close to being understood. The former imposes severe constraints on the composition of hypothetical source materials or on the evolution of the atmosphere, or both. It is not especially difficult to imagine environments in which xenon can be mass fractionated, but it is very difficult to fractionate xenon while not fractionating krypton. Thus one is forced to invoke at least two noble gas sources, one that consists mainly of fractionated xenon, and another for the other noble gases that is essentially Xe-free. An example of a two-source model is Pepin's (1991). Fractionated xenon is the only significant remnant of an early escaped atmosphere. Neon, argon and krypton are later outgassed from the mantle, but xenon is not outgassed; it is incorporated into the core.

The only possibility for a single-source explanation is a cometary veneer, if the comets are assigned the desired composition: a high Kr/Xe ratio and naturally mass fractionated xenon. Despite the freedom of working with a material of which we know next to nothing, even with prodigious escape from Earth, comets have great difficulty solving the second problem. Another

potential difficulty, unique to late-accreting sources, is that Earth's degassed mantle probably degassed within ~ 50 Myr, and the noble gases in Earth's undegassed mantle may be quantitatively consistent with the rare gases in air being the degassed complement of the undegassed mantle. If correct, these observations would leave no place for a late veneer in the atmosphere.

Acknowledgments. I would like to thank R. O. Pepin for many detailed discussions of nobility in general and this manuscript in particular. I also thank R. Miller for T_EXnical aid.

IMPACTS AND THE EARLY ENVIRONMENT AND EVOLUTION OF THE TERRESTRIAL PLANETS

H. J. MELOSH, A. M. VICKERY, and W. B. TONKS

University of Arizona

Early models for the accretion of the planets generally assumed that the planets grew gently by the steady addition of small grains swept up by the growing planetary embryos from the solar nebula. More recent models of the formation of the solar system, however, show that the population of impactors bombarding the growing planets increased in size and relative velocity with time, so that accretionary impacts tended to become progressively more violent until the last of the giant planetesimals were destroyed in collisions with planets. Accretion then tapered off during the period of heavy bombardment and continues at a much diminished rate today. The recognition of the importance of large individual impacts as well as of the cumulative effects of smaller impacts has led to a revolution in our approach to the modeling of the processes of planetary formation and differentiation, including the origin of the Moon and the origin and evolution of atmospheres. Once the planetary embryos reached a critical size, impact velocities became high enough to liberate volatiles due to shock heating, and proto-atmospheres could begin to form. Larger impacts resulted in planetary heating as the time between impacts became smaller than the time for cooling by radiation, an effect that would have been enhanced by the presence of an atmosphere. Very large impacts may have melted significant fractions of the planets, leading to rapid core formation. If the Moon was created in a giant impact, as is now widely believed, it is likely that melting would be widespread, at least in the hemisphere of the Earth in which the impact occurred and possibly throughout the entire planet. A magma ocean would form on the Earth, but because of the high gravity, convection would be sufficiently vigorous to prevent significant fractional crystallization, as is inferred to have occurred on the Moon. The effects of such an impact on a pre-existing atmosphere, and its implications for atmospheric evolution, have not yet been explored. Impacts during heavy bombardment probably resulted in some net atmospheric loss from the Earth and Venus, but the effect would have been much more pronounced on Mars, consistent with its very thin atmosphere. Such impacts may fractionate a planet's volatile inventory by sweeping away atmospheric gases but leaving condensable phases (such as water) little changed.

I. INTRODUCTION

Over the last two decades knowledge about the physics of high-speed impact processes has grown enormously. At the same time the role of impact and related processes in the formation and early evolution of the terrestrial planets has been increasingly well-defined. The most recent developments in this field are the recognition of the importance of "giant impacts"—collisions between

embryo planets and bodies of about 10% of their mass—in the last stages of accretion, and the realization that impact processes may have played a major role in the growth and retention of planetary atmospheres. In this chapter we review the nature and implications of these new ideas as they currently stand, although the reader should be warned that these are both areas of very active research at the present time, so that new developments may make this review obsolete in a short time.

The recognition of the importance of giant impacts grew mainly out of recent research on the Moon's origin. The idea that the Moon was born in a gigantic collision between the proto-Earth and a Mars-size protoplanet has continued to gain adherents since it was first proposed by Hartmann and Davis (1975) and by Cameron and Ward (1976). This theory received a great deal of attention at the 1984 Conference on the Origin of the Moon in Kona, Hawaii (Hartmann et al. 1986), and has subsequently been the subject of a number of reviews (Boss 1986c; Stevenson 1987; Newsom and Taylor 1989). It is probably not an exaggeration to claim that it has become the current consensus theory of the Moon's origin. Although a great deal of work has been, and is being, done on the details of this scenario, most work up until recently concentrated on the Moon, with little consideration given to the more general effects of such large impacts on the Earth or other planets. It is clear that such an event would have profound effects on a growing planet: by the time a planet has reached the size of Mars, impacts with objects half its diameter (i.e., about 10% of its mass) are capable of melting either the entire planet or at least one hemisphere, as the shock wave from the impact traverses the planet. In this scenario, core formation is quick and inevitable; metallic iron particles separate rapidly from the silicate melt, forming a pool of iron at the bottom of the molten volume. This pool may be large enough to displace even strong underlying silicate rocks and form a proto-core (Tonks and Melosh 1991). Subsequent large impact and melting events will add more material to the core in a batchwise fashion. Vigorous convection in the melted regions (magma oceans) causes the global magma sea to cool rapidly (cooling to 50% crystallization requires only a few thousands to tens of thousands of years) and prevents crystal-liquid density segregation when the Rayleigh number is high enough to ensure turbulent convection.

At a later stage of planetary evolution, the smaller impacts during late heavy bombardment may have played an important role in bringing volatiles to the planet, in stripping away the original gaseous atmospheres of the planets and in segregating condensible substances, such as water, from volatile ones, such as CO₂. A large meteorite or comet that strikes the surface of a planet possessing an atmosphere can interact with the atmosphere in three ways: during its initial passage through it, by means of high-speed ejecta thrown out from the growing crater, and by the expanding high-energy ejecta plume that is produced at sufficiently high impact velocities. The leading edge of this plume may have a velocity many times greater than the impact velocity. In sufficiently large impacts on Earth (meteorites >300 m in diameter), the

Figure 1. The "physicist's model" of planetary accretion. This model, which was current between about 1950 and 1975, assumes that the gravitational energy of infalling material is balanced primarily by thermal radiation from the surface with a small additional contribution from conduction. This model is valid only if the planet grows from planetesimals smaller than about 10 km in diameter.

plume may have enough momentum to blow aside the atmosphere and vent vaporized rock and other debris directly into space. In still larger impacts (>10 km diameter), the overlying atmospheric gases may be accelerated to greater than escape velocity so that atmospheric erosion occurs. Mars may have lost most of its primordial atmosphere in this way during the era of heavy bombardment.

II. ENERGY DEPOSITION BY IMPACTS ON GROWING PLANETS

A. Accretion of Infinitesimally Small Impactors

The history of accretion models of the Earth and planets mirrors a gradually increasing appreciation for the importance of large impacts. Early models (Hanks and Anderson 1969; Mizutani et al. 1972; Urey 1952) of the Earth's accretion assumed that material is added by the deposition of infinitesimally thin, laterally homogeneous layers. The accreted material adds a net energy per unit mass consisting of gravitational binding energy and initial kinetic

energy of the mass, $GM/R + v_\infty^2/2$, where G is Newton's gravitational constant, M is the planet's mass when it has grown to radius R , and v_∞ is the velocity of encounter between the growing planet and the infalling material at great distance from the planet. Some of this energy is lost by radiation, and the rest goes into heating the planet—initially into heating the surface layer, then gradually into heating the interior of the planet by conduction. The basic equation describing the equilibrium between infall energy, radiation and conduction is

$$\rho \left(\frac{GM(t)}{R(t)} + \frac{v_\infty^2}{2} \right) \frac{dR(t)}{dt} = \epsilon \sigma [T^4(R, t) - T_a^4] + \rho c_p T(R, t) \frac{dR(t)}{dt} + k \left(\frac{\partial T}{\partial r} \right)_{r=R} \quad (1)$$

where $T(R, t)$ is the temperature at the surface of the growing planet, T_a is the effective temperature of the atmosphere, σ is the Stefan-Boltzman constant, ϵ is the emissivity (generally set equal to 1), c_p is heat capacity and k is the thermal conductivity. Radius r is the position *within* the growing planet of total radius $R(t)$. The second term on the right side accounts for the heat content of the hot added material and should include latent heat if melting occurs. The thermal state of a growing planet is determined by Eq. (1) as soon as the growth rate, $dR(t)/dt$, is specified.

The studies based on Eq. (1) had great difficulty explaining why any of the planets should be differentiated. Thermal radiation is so efficient at removing energy that the planets would have had to grow extremely rapidly for temperatures to reach the melting point anywhere in their interiors. Thus, Hanks and Anderson (1969) require the Earth to grow in 10^5 to 10^6 yr for melting to occur, while Mizutani et al. (1972) find the Moon must accrete within 1,000 yr if melting is to occur in its outer portions. These times are far shorter than the 10^7 to 10^8 yr time scale derived from standard planetesimal accretion models (Wetherill 1980a). This implies that the Earth and Moon accreted cold, and the Earth later differentiated when enough radiogenic heat had accumulated to cause internal melting. This model also implies that the Moon should not have differentiated, a prediction that was quickly proved wrong when the Apollo missions returned Moon rocks to Earth for analysis.

B. Accretion of Small Planetesimals

A solution to this quandary was first suggested by Safronov (1972, 1978) and more recently was elaborated by Kaula (1979b, 1980). They realized that the idealization of the gradual addition of infinitesimally thin global layers is not a valid representation of the actual process of accretion, which involves the impact of individual planetesimals onto the planet's surface. Each impact heats the target rocks directly beneath the impact site and causes the deposition of an ejecta blanket of finite thickness and localized extent, as shown in Fig. 2. Under these conditions radiation is able to cool only a thin layer on the top of

the ejecta blanket before yet another ejecta sheet is deposited on top of it. A large fraction of the initial energy of the infalling material is thus retained in the overlapping ejecta blankets.

Figure 2. Heat deposition in the vicinity of a large impact. Shock waves deposit heat directly in the rocks beneath the crater, the amount of heating decreasing with increasing distance from the impact site, illustrated by the schematic temperature contours. The heavy black line inside the crater indicates a thick layer of melted target rocks. Such layers are observed inside large fresh lunar craters such as Copernicus and Tycho. The ejecta also contain a considerable amount of heat and thickly blanket the terrain to a distance of about 1 crater diameter from the rim. The temperature in the ejecta blanket (inset) declines as a result of thermal radiation from the surface and thermal conduction into the cooler substrate.

It is easy to estimate the thickness δ of an ejecta sheet for which heat retention outweighs radiative loss. If the planet grows at a rate dR/dt , the average time interval Δt between deposition of ejecta sheets of thickness δ at any given site is simply $\delta/(dR/dt)$. But the conductive cooling time of an ejecta sheet is of order δ^2/k , where k is the ejecta's thermal diffusivity. This cooling time equals the average time between deposition events for $\delta_0 = k/(dR/dt)$. Layers thinner than δ_0 radiate all of their heat before the next ejecta deposition event, whereas thicker layers do not have time to cool between events. Making the conservative assumption that the Earth grew over a period of about 100 Myr and that $\kappa \approx 10^{-6} \text{ m}^2 \text{ s}^{-1}$, yields a crossover thickness δ_0 of about 3 km. The maximum ejecta thickness of a fresh crater is about 0.02 of the crater diameter, which itself is about 10 times larger than the projectile diameter (Melosh 1989), so the crossover condition is met by planetesimals about 15 km in diameter. Moreover, much of a projectile's energy is deposited more deeply beneath the crater floor than in the ejecta blanket, so that it is plausible that most of the heat added by 10 km or larger diameter planetesimals is retained by the growing planet rather than lost by radiation.

The details of the overall heat deposition process are complex and depend sensitively on impact mechanics. Thus, of the projectile's initial kinetic energy, about 30% is initially partitioned into the kinetic energy of the ejecta

and most of the remainder is directly deposited as heat in the target rocks (Melosh 1989). The kinetic energy of the ejecta is converted into heat when it comes to rest on the surface after mixing with a variable amount of preexisting surface material, resulting in a mixed sheet of hot rock debris thickly covering the surface within one or two crater diameters of the crater's original rim. The rocks beneath the crater (and the expelled ejecta) are directly heated by the shock from the impact which, depending upon the impact velocity, may melt or vaporize large quantities of material. The amount of material thus heated depends mainly upon the projectile's size and the square of its velocity (Melosh 1989). On the other hand, a large impact cools the target planet by raising deeply buried materials closer to the surface, where their heat may be more readily conducted to the surface and ultimately lost by radiation. Some of the initial heat of the ejecta may be lost by radiation during its ballistic flight from the impact crater to its site of deposition, while at high impact velocities a portion of the ejecta (especially that in the vapor plume) may travel at velocities greater than escape velocity and thus leave the planet entirely. The net thermal effect of an impact is thus a sum of gains and losses which tend to offset one another and hence make accurate estimation of the net heat deposition difficult. Crude consideration of these processes indicates that large impacts are more efficient at depositing energy than small impacts, and that for kilometer-size planetesimals the radiation term in Eq. (1) is almost entirely negligible.

Kaula's (1980) solution to the uncertainty in estimating the net heat deposition of impacts is to lump all the poorly known processes into a single numerical factor h and write Eq. (1) in a form that neglects both radiation and conduction. Thus, rearranging Eq. (1),

$$T(R, t) = \frac{h}{c_p} \left(\frac{GM(t)}{R(t)} + \frac{v_\infty^2}{2} \right). \quad (2)$$

Note that with the neglect of radiation and conductive heat loss the accretion rate $dR(t)/dt$ drops out, so that the interiors of planets growing over the 10^8 yr accretion time scale may easily reach temperatures high enough to initiate melting and differentiation. The unknown dimensionless factor h must lie somewhere between 0 (no net burial of heat) and 1 (all kinetic energy of infalling matter is retained as heat). In the absence of better information h is generally assumed to be about 0.5 for kilometer-size or larger planetesimals.

In Safronov's (1972) theory, the random velocity component v_∞ of approaching planetesimals at any time t is proportional to the escape velocity $v_{\text{esc}} = (2GM/R)^{1/2}$ of the planet growing in their neighborhood, so the entire right-hand side of Eq. (2) is proportional to GM/R times factors of the order of unity. Because M is proportional to $R^3(t)$, the surface temperature T of a growing planet at time t is proportional to $R^2(t)$. This temperature is "locked in" at radius $r = R(t)$ as more material accumulates on the former surface of the planet, establishing an internal temperature distribution of the form

$T(r) \sim r^2$. This relation holds until T approaches the melting temperature in the outer portion of the planet, at which time convection begins and the mantle temperature remains near the melting point (Kaula 1980). Melting in the Earth begins when it has reached about 10% of its final mass, or about half its final diameter. A core is presumed to form at about this time, further heating the mantle and stirring it so that the original $T \sim r^2$ thermal structure is wiped out in a manner similar to that described by Stevenson (1981).

Subsequent to core formation the mantle temperature must have been closer to the solidus than the liquidus, because convection in a completely liquid mantle is so vigorous that its cooling time is only about 10^4 yr (Tonks and Melosh 1990), far shorter than the time scale for Earth's growth from planetesimals. Once more than about 50% of the mantle material crystallizes, however, convection is regulated by the high viscosity of solid-state creep in the crystalline fraction, thus greatly lowering the cooling rates. Craters formed by impacts subsequent to core formation would therefore have excavated either the conductive boundary layer or, if sufficiently large, the semimolten convecting mantle. The extent to which the deposition of impact energy is altered in a planet with a hot mantle has not yet been thoroughly investigated (although Minear [1980] studied the disrupting effect of impacts on the boundary layer of a cooling lunar magma ocean, concluding that impacts decrease the cooling time), nor has the related problem of convection in the presence of rapid accumulation of thick ejecta sheets been studied.

Although Eq. (2) is more realistic than Eq. (1), it is nevertheless limited by the implicit assumption that the impacting planetesimals are small in comparison to the growing planetary embryo. Impact energy is still assumed to be added in thin (although not infinitesimally thin) shells that are, on average, uniformly distributed over the planet's surface (Fig. 3). Thermal radiation losses can be neglected because most of the infalling planetesimals' energy is buried below the surface, but the overall pattern of energy deposition is much the same.

C. Accretion of Large Planetesimals

In recent years, however, it has seemed increasingly likely that the distribution of planetesimal sizes follows a rough power law extending from the smallest sizes up to objects half the size of the largest planetary embryo (Hartmann and Davis 1975; Wetherill 1985), at least during the later stages of accretion. This power distribution is expected to be of the form $N_{\text{cum}}(D) = CD^{-b}$, where N_{cum} is the number of planetesimals with diameters greater than or equal to D , C is a constant, and the power b is frequently observed to be close to 2 in numerical simulations of accretion processes (Greenberg et al. 1978), impact fragmentation experiments (Fujiwara 1986) and in the size distribution of comet nuclei (Delsemme 1987). The $b = 2$ distribution has the special property that the total surface area of planetesimals in successive logarithmically increasing size intervals is constant. That is, the surface area of planetesimals with diameters between, say, D_1 and $2D_1$ is the same as

Figure 3. A more realistic model of planetary accretion. In this model, a large fraction of the planetesimal's energy is trapped in the growing planet as heat. Melting temperatures are reached by the time the Earth has grown to about 10% of its present mass. In this model the planetesimals are assumed to be much smaller than the diameter of the planet so that growth is gradual; no provision is made for the effects of very large impacts that deposit their heat catastrophically through a substantial depth of the planetary embryo's mantle.

the surface area of planetesimals with diameters between $2D_1$ and $4D_1$ (see Fig. 4). It seems natural that a distribution of this kind should arise from processes such as impact or coagulation that depend upon cross-sectional area (Chapman and Morrison 1989).

While the largest numbers of planetesimals in a $b = 2$ distribution are concentrated at the small sizes, most of the mass (and therefore energy) resides in the largest objects (see Fig. 5). Thus, although a growing planetary embryo would be constantly battered by small planetesimals, most of the overall mass and heat transfer would occur in large, rare events that bury their heat deep within the embryo's interior. If this catastrophic mode of growth was indeed important, then the assumption that the infalling planetesimals were much smaller than the growing planet fails for the most significant events, and a revised thermal analysis must take account of impacts between objects of comparable size. In the following section, we examine the effects of a single such giant impact between the proto-Earth and an object half its size.

III. EFFECT OF A GIANT IMPACT ON EARTH'S THERMAL STATE

The collision between a Mars-size protoplanet and the proto-Earth adds a truly prodigious amount of energy to the Earth over a time interval measured

Figure 4. Schematic illustration of the distribution of planetesimal sizes in a population described by a $b = 2$ cumulative number distribution. In this distribution, the projected area of planetesimals in logarithmically decreasing size intervals is constant.

in hours. The mass m , velocity v , and impact parameter b of the projectile are constrained only by the total angular momentum L of the Earth-Moon system, $3.49 \times 10^{34} \text{ kg m}^2 \text{ s}^{-1}$. Because the angular momentum is a product of all three terms, $L = mvb$, the value of each individual quantity is uncertain within broad limits. The impact parameter is bounded between zero and the sum of the Earth's and the projectile's radii. The impact velocity must be at least as large as the proto-Earth's escape velocity. The overall geochemical similarity of the Earth and Moon implies that the projectile had an initial orbit close to that of Earth's, which in turn implies that the impact velocity was probably not as much as twice the escape velocity. These constraints point to an impact by a body with a mass about 10% of the Earth's mass, hence a diameter approximately half of the Earth's—about the size of Mars.

The energy released in such a collision is the sum of gravitational and kinetic energies, and was probably within the range 2×10^{31} to 5×10^{31} J. Averaged over the Earth's mass, this is about $7.5 \times 10^6 \text{ J kg}^{-1}$. Several authors have used this energy in conjunction with a single value of silicate heat capacity to infer rather high average temperatures for the Earth. Thus, a silicate heat capacity of $10^3 \text{ J kg}^{-1} \text{ K}$ yields an average temperature of 7500 K for the Earth. However, such estimates neglect the relatively small latent heat of melting, $\sim 4 \times 10^5 \text{ J kg}^{-1}$, the large latent heat of vaporization, $\sim 5 \times 10^6 \text{ J kg}^{-1}$, and the rapid increase of heat capacity with temperature, ranging from zero at 0 K and reaching a constant maximum at the Debye temperature (about 676 K for dunite, the main constituent of the Earth's mantle). According to the ANEOS equation of state for dunite (Benz et al. 1989), an internal energy

Figure 5. This figure shows dependence of various quantities on planetesimal diameter D in a population where the cumulative number N_{cum} is a function of D^{-2} . In such a population the number distribution is dominated by the smallest objects, the area (either total surface or cross sectional) is uniformly distributed, and the mass distribution is dominated by the largest objects.

of $7.5 \times 10^6 \text{ J kg}^{-1}$ corresponds to a temperature rise of about 3200 K for dunite near the Earth's surface and about 7000 K deep in the mantle, where vaporization does not limit the temperature rise. Nevertheless, it is clear that melting, even vaporization, should be widespread in a giant collision.

Impacts at velocities on the order of 10 km s^{-1} in dunite generate pressures on the order of 300 GPa and will thus melt and partially vaporize a few projectile masses of the target, but such melting is confined to regions within about 2 projectile radii of the impact site. More distant regions of the planet will be warmed by impact heating, but will not necessarily melt unless they

are close to melting already (see Fig. 6). Large impacts thus deposit their energy deeper than small impacts, and impacts with objects half the size of the proto-Earth can be expected to melt at least one hemisphere of the Earth's mantle right down to the core. The melt pool following a large impact will undergo further change in shape after it forms, because the melt will have a different (generally smaller) density than surrounding rocks at the same depth. Because the surrounding rocks were likely to be hot, and therefore relatively fluid, subsolidus viscous deformation subsequent to the melting event should close the initial melt-solid crater, producing a global magma ocean of nearly uniform depth overlying hot, more dense, solid mantle material. Although the time scale of this relaxation is difficult to estimate, it was probably not longer than the time scale of post-glacial relaxation in the present Earth; i.e., a few thousand years.

Figure 6. Schematic illustration of the pattern of heat deposition in a planet struck by a projectile of comparable size ($1/4$ its diameter in this figure). Adjacent to a melted region roughly twice the projectile's diameter, the shock level, and thus temperature, falls off steeply with increasing distance from the impact site.

Although the total energy available from the collision of a Mars-size projectile with the proto-Earth is impressive, the distribution of the energy within the Earth is equally important. If, as has been suggested by Stevenson (1987), this energy is mainly expended in vaporizing the projectile, the Earth may acquire a transient silicate vapor atmosphere without strongly heating the deeper mantle. This is much more likely to occur, however, if the impactor were much less dense than the target, i.e., a comet. The similarity between the compositions of the Earth and Moon, however, strongly suggest that the impactor was a silicate body instead of a comet. For this case, the simple considerations of shock wave geometry discussed above indicate that only partial vaporization occurs (although jetting [Melosh and Sonett 1986] may enhance the local production of hot vapor), and that deep melting should be

widespread in at least the hemisphere that the impact occurs.

An additional factor not previously considered here (but see also Benz and Cameron [1990]) is that the projectile might have an iron core which will sink through the Earth's mantle shortly after the collision and merge with the Earth's core, releasing its gravitational potential energy. Assuming a core equal to 30% of the projectile's mass, the energy released by sinking 3000 km through Earth's mantle is of order 3×10^{30} J, which itself will cause strong heating of the mantle through which it sinks and of the Earth's core when it arrives. After the cores have merged, this heat is applied to the bottom of the mantle, so that any portion of the mantle that escaped melting by the direct shock wave will likely be melted by this means.

To address the temperature rise in the Earth during a Moon-forming collision more exactly, H. J. Melosh performed a series of 3-dimensional numerical hydrocode computations in conjunction with M. E. Kipp of Sandia National Laboratory. These computations were designed to simulate the impact between the proto-Earth and a Mars-size protoplanet. They used the code CTH, implemented on the Cray X/MP supercomputers of the Sandia National Laboratory. This computation uses the ANEOS equations of state for dunite in the mantles and iron in the cores of the two colliding planets. The Earth has a central gravitational field, and is adjusted so that its initial temperature profile is similar to that of the present-day Earth. These models thus start out relatively cold, with mantle temperatures well below the solidus of dunite. The computations were performed at a variety of initial velocities and impact parameters, including pairs that give the Earth-Moon system its present angular momentum.

At the lowest velocity ($v_\infty = 0$), for impact parameters b of 0.88 (Fig. 7a) and 1.25 times the Earth's radius R_e , the strongest heating upon impact is confined to the hemisphere on which the projectile strikes. Shock-induced temperature rises are typically 2000 to 3000 K between the site of the impact and the Earth's core. A crater forms that extends most of the way down to the core. The gravitational energy of this excavation itself is of order 10^{30} J, which appears as heat within an hour or two as mantle material flows inward to fill the crater cavity. Unfortunately, in the high impact parameter runs the computations do not extend to long enough times for the entire projectile to merge with the Earth. This limitation is a result of the finite grid size: by the time fallback should have occurred a substantial amount of material had left the grid and could not be taken into account properly. These computations were thus stopped while some of the projectile was still falling on portions of the Earth more distant from the impact site. In these cases, more than half the mantle will be strongly heated, so the quoted results are a lower limit. Figure 7b illustrates the temperature contours for the $b = 0.88R_e$ computation 1800 s after the impact (this impact parameter and velocity correspond to the angular momentum of the present Earth-Moon system). Most of the Earth lies within contour D , that is, is at temperatures greater than 1800 K, and so is probably melted. Note that in this computation a very hot (>4200 K)

low-velocity vapor plume is expelled backwards from the impact site. This plume eventually spreads over the entire Earth, producing a transient silicate vapor atmosphere.

The results for the higher impact velocity $v_{\infty} = 7.8 \text{ km s}^{-1}$ are more spectacular. For the impact parameters studied (0.59 and $1.25R_e$) the hemisphere near the impact was heated nearly uniformly by 1000 to 3000 K . The projectile's core was almost entirely vaporized and a much larger crater formed in the proto-Earth. A fast, hot vapor plume also carries several lunar masses of material out along trajectories that eventually take up elliptical orbits about the Earth. Figure 8b illustrates temperature contours for $b = 0.59R_e$, corresponding to the angular momentum of the present Earth-Moon system, at 1200 s after the impact. Again, a hot, low-velocity backwards vapor plume is formed that will eventually cover the Earth's surface.

IV. IMPLICATIONS OF GLOBAL MELTING

The three-dimensional hydrocode computations, in conjunction with the more general considerations described above, indicate that a Moon-forming impact would have had a profound effect on the Earth's thermal state. The shock produced by the impact would have heated the Earth to great depths, raising at least the hemisphere adjacent to the impact above the melting temperature. Later phenomena, such as the merger of the projectile's and proto-Earth's cores and the collapse of the mantle-deep crater created by the impact would have added comparable amounts of energy to the Earth. There seems to be no way to avoid the conclusion that a large Moon-forming impact is inevitably accompanied by widespread melting of most or all of the Earth's mantle.

Although the idea of molten planets is not new, having arisen most recently in the context of the lunar "magma ocean" (Wood 1970), modern geochemists have a difficult time accepting that the Earth once had a similarly extensive molten mantle. Kato et al. (1988) argue that fractionation of a small amount of perovskite and/or majorite garnet from a terrestrial magma ocean would drive the nearly chondritic ratios of most refractory lithophile elements substantially away from their observed chondritic values. Fractionation would also result in a primitive crust rich in Ba, K, Rb and Cs and relatively depleted in U, Th, Pb, Sr, Zr and Hf. In a similar vein, McFarlane and Drake (1990) argue that fractionation of olivine by flotation at high pressure would yield ratios of Sc/Sm, Ni/Co, and Ir/Au more than 10% above their observed chondritic values.

Ringwood (1990) argues that Kato et al.'s (1988) results can be used as a test of the giant impact hypothesis and Safronov accretion theory. Because the giant impact leads to global melting of the Earth, he infers that such an impact could not have occurred because the oldest ($\sim 4.2 \text{ Gyr}$) zircons and most ancient ($\sim 3.9 \text{ Gyr}$) crustal rocks would show no signature of the element fractionations noted above. Ringwood thus proposes that the Earth accreted

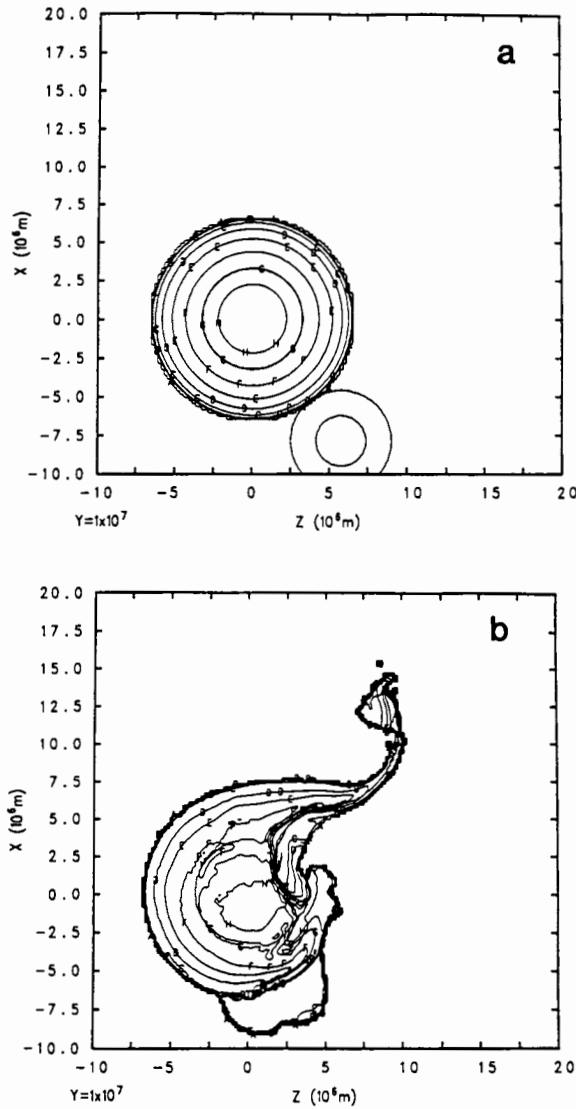

Figure 7. Temperature contours in the collision between the proto-Earth and a protoplanet half its diameter. This computation is for $v_{\infty} = 0 \text{ km s}^{-1}$ (8 km s^{-1} at contact) and an impact parameter of $0.88 R_e$ at contact. Plot (a) shows the initial configuration before impact in which the projectile is traveling upward (positive x -direction) and the proto-Earth is at rest. Plot (b) shows the configuration 1802 s after contact. The contour values are $A = 300 \text{ K}$, $B = 600 \text{ K}$, $C = 1200 \text{ K}$, $D = 1800 \text{ K}$, $E = 2400 \text{ K}$, $F = 3000 \text{ K}$, $G = 3600 \text{ K}$ and $H = 4200 \text{ K}$. Figures 7 and 8 were computed by M. E. Kipp at Sandia National Laboratory, Albuquerque, NM using the three-dimensional hydrocode CTH. These plots are in the symmetry plane of the two colliding spheres.

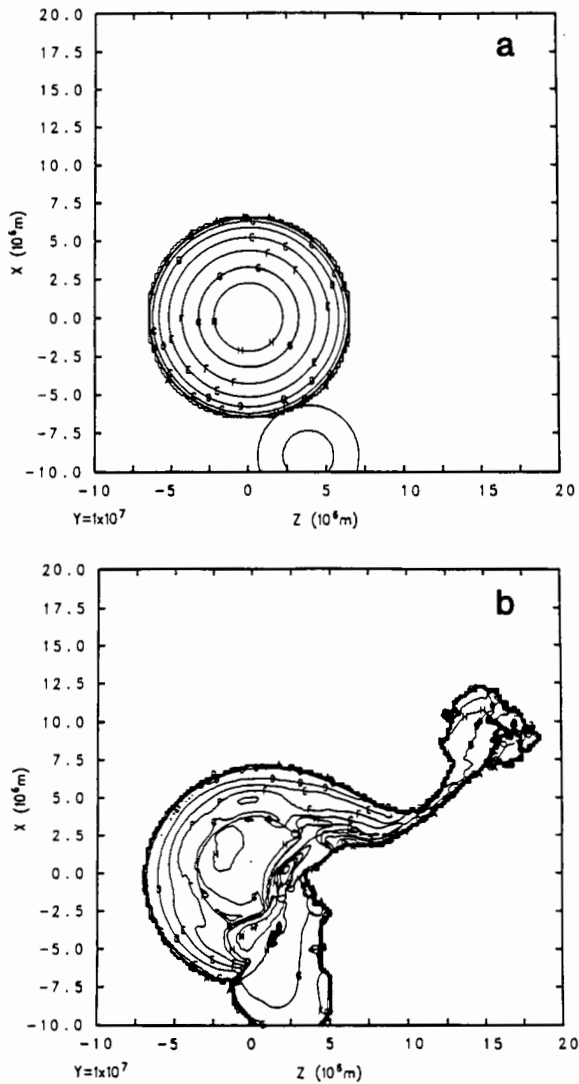

Figure 8. (a) Initial configuration and (b) temperature contours 1193 s after the impact between the proto-Earth and a protoplanet half its diameter moving at $v_\infty = 7.8 \text{ km sec}^{-1}$ (12 km sec^{-1} at contact) and an impact parameter of $0.59 R_e$ at contact. Contour values are the same as in Fig. 7.

without widescale melting and suggests several conditions under which this might occur.

All of these objections make the implicit assumption that a magma ocean necessarily undergoes fractional crystallization, that is, that the crystals that

grow within the cooling magma are removed from the magmatic system by either settling or floating (because of density differences) and do not subsequently interact with the magma. However, it seems obvious that if convection is sufficiently vigorous, separation may be either inhibited or even prohibited. Thus, the reconciliation of the theoretical arguments for widespread melting in the Earth and the geochemical arguments prohibiting it may be rooted in the mechanical behavior of crystals in a convecting magma ocean.

The mode of convection in such a magma ocean, or any other naturally convecting system, is approximately characterized by the Rayleigh number Ra and Prandtl number σ (Chandrasekhar 1961), given by

$$Ra = \frac{\alpha g \Delta T D^3}{\kappa \nu} \quad (3)$$

$$\sigma = \frac{\nu}{\kappa} \quad (4)$$

where α is the thermal expansion coefficient, g the acceleration of gravity, D the depth of the convecting fluid, κ is the fluid's thermal diffusivity, ν its viscosity, and ΔT is the superadiabatic temperature gradient. Although these two parameters must be supplemented by others describing the temperature dependence of viscosity and the change of viscosity with depth in an exact model of magma ocean convection, the success of parameterized convection models suggests that the Rayleigh and Prandtl numbers define the major convective regimes to first order.

On the basis of the values of the Rayleigh and Prandtl numbers, magma ocean convection is utterly different from that of the more familiar sub-solidus convection now occurring in the planets, shown in Fig. 9. Magma ocean convection and crystal settling has more affinity to aeolian transport in a deep planetary atmosphere than to traditional studies of convection. In this range of conditions, a vigorously convecting system can be divided into three distinct regions (Kraichnan 1962): an upper conductive boundary layer, a sublayer dominated by viscous forces, and a volume of turbulent fluid whose flow is controlled by inertial forces (see Fig. 10). This inertial flow zone, which does not exist in the subsolidus convection familiar to most geophysicists, is dominated by large scale turbulent eddies that are analogous to gusty winds in a planetary atmospheric convective system. The inertial flow zone appears in the central part of a convecting fluid when the following inequality between the Rayleigh and Prandtl numbers is satisfied:

$$Ra^{1/3} \geq 35\sigma^{1/2}. \quad (5)$$

Convection in a magma ocean is expected to remain vigorous so long as the liquid can lose its heat near the free outer surface. Although a thin conductive skin may form at the immediate surface, differential convective

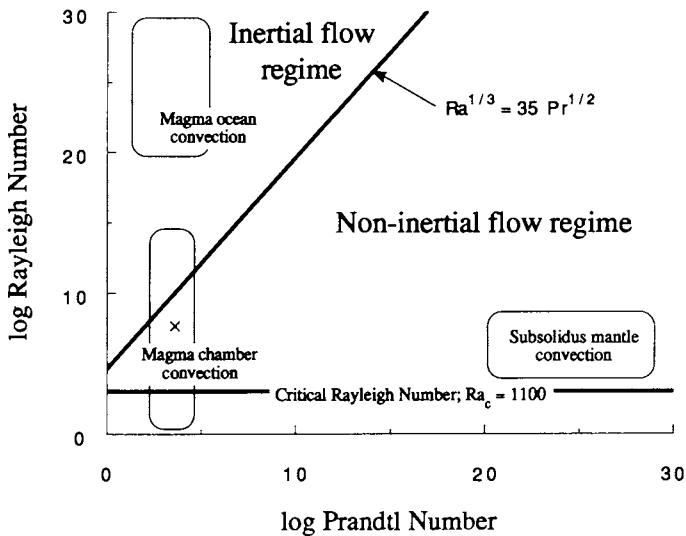

Figure 9. Rayleigh number vs Prandtl number, showing the convective regimes of common geologic processes and of planetary magma oceans. The inertial flow zone exists above and to the left of the inertial flow zone disappearance boundary and disappears to the right of the boundary. See the text and Fig. 10 for further explanation. The x marks where an experimental study (Martin and Nokes 1988) showed the onset of crystal suspension.

velocities are generally high enough to overcome the skin's strength and keep the heat loss near the theoretical value. This situation is quite different from that of a magma chamber, where a thick roof may strongly inhibit convection (Brandeis and Marsh 1989). The presence of an atmosphere may also have an important effect in limiting the rate at which heat is lost from a magma ocean. By blocking or limiting the rate of heat loss to space by infrared radiation, an atmosphere can effectively blanket the top of the magma ocean, becoming a partial substitute for the thin upper conductive skin and controlling the cooling time scale of the planet's interior. A very thick initial atmosphere may even lead to the formation of a magma ocean without the intervention of a giant impact (Abe and Matsui 1985). The role of such atmospheric blanketing in controlling the surface temperature and rate of heat loss from a planet with a magma ocean is not well understood, and is an obvious target for future research.

A criterion for crystal suspension near the upper and lower margins of a convecting magma ocean can be derived from empirical studies of sediment transport. The Rouse number is defined as the ratio between the terminal

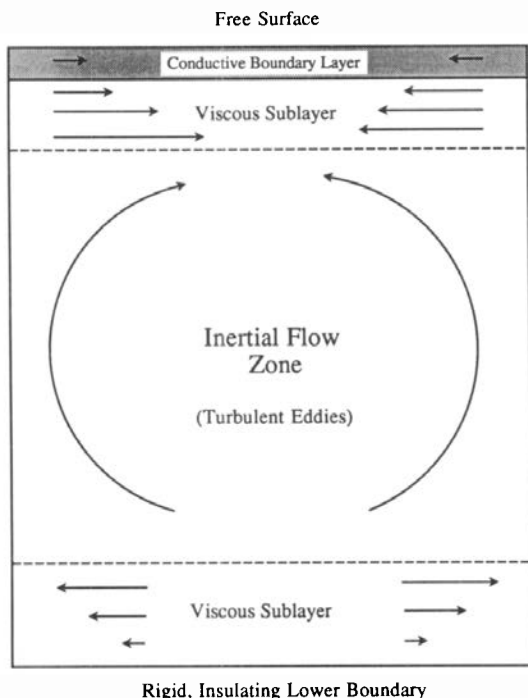

Figure 10. Diagram showing convection breaking into three distinct regions of behavior at very high Rayleigh number. The topmost region is a conductive boundary layer underlain by a viscous sublayer. In the third region, flow is dominated by inertial forces which produce large-scale turbulent eddies (the inertial flow zone).

velocity of the crystals in the fluid and the turbulent friction velocity. Settling (or flotation) takes place only for Rouse numbers greater than about 1 (Vanoni 1975). A study of the evolution of an ultramafic magma ocean with realistic magma rheology (Tonks and Melosh 1990) found that on both the Earth and Moon crystals up to 1 to 2 cm in diameter can be suspended from the onset of cooling. In the later stages of cooling, as viscosity increases, crystals of 10 cm to more than 1 m in diameter may easily be suspended. A surprising feature of the analysis is that the ability of a magma ocean to suspend crystals is only weakly dependent on gravity and depth: viscosity is the major factor determining suspension. This result, although gratifying for the Earth, raises a serious problem for the *lunar* magma ocean hypothesis, because the differentiation of an anorthositic crust on the Moon strongly suggests that crystal fractionation did occur there.

One explanation for this apparent paradox appeals to the low lunar gravity. Because pressure in the Moon increases slowly with depth compared to the Earth, the solidus and liquidus temperatures are nearly independent of

depth. In a convecting magma ocean on the Moon, adiabats lie between the solidus and liquidus at all depths, so that growing crystals circulate through the ocean for long periods of time without dissolving. Under these circumstances crystals may grow large enough to settle out, producing the observed differentiation. In contrast, on the Earth the liquidus and solidus profiles are steeper than an adiabat so crystallization only takes place over a restricted depth range. Convective velocities are so high that crystals nucleating in this zone do not have time to grow larger than a few microns and are thus incapable of settling out. In this way, even a totally molten initial Earth may have failed to differentiate by fractional crystallization.

Although magma ocean convection may be sufficiently vigorous to prevent fractionation between silicate melt and silicate crystals (whose density differs only a few hundred kg m^{-3} from that of the melt), the density difference between the silicate melt and droplets of molten iron (typically 2000–3000 kg m^{-3}) is great enough to allow iron droplets to rain out of the magma ocean, especially in the early stages when melt viscosities are low, and accumulate in a dense pool at the base of the magma ocean. Such dense pools of molten iron may, if sufficiently large, descend to the center of the growing planet, forming (or adding to) its protocore (Tonks and Melosh 1991).

V. ORIGIN AND EVOLUTION OF ATMOSPHERES

The origin and evolution of planetary atmospheres is a complex and poorly understood process. Elemental and isotopic compositions of planetary atmospheres differ from one another and from the composition of any single (or simple combination) of plausible volatile reservoirs in the early solar system (Pepin 1989). These reservoirs include solar nebular gas, solar wind, comets, and volatile-rich meteorites. Accretionary impacts have two competing effects on the development of planetary atmospheres: the release of volatiles due to shock heating and/or vaporization of the impactor and part of the target in relatively low-energy events may add to the planet's volatile inventory (Arrhenius et al. 1974; Benlow and Meadows 1977; Chyba 1990), and sufficiently large impacts may cause the loss of part of the existing volatile inventory.

During most of the accretionary process, impact velocities generally differ little from the escape velocity of the growing protoplanet because most of the collisions are between bodies in nearly matching orbits. At some stage in planetary growth, the impact velocities become high enough that the shock pressures resulting from the impact are high enough to devolatilize the impactor (and possibly part of the target). For carbonaceous chondrites, partial devolatilization can begin on the Earth and Venus when the planetary embryos reach approximately 12% of their current size, and complete devolatilization begins when the embryos are approximately 30% of their current size (Ahrens et al. 1989; Lange and Ahrens 1982). The corresponding values for Mars are roughly 23% for partial devolatilization and 56% for complete devolatilization. Devolatilization of comets presumably occurs at lower planetary radii

because comets are more volatile than silicates and because their lower density with respect to the target means that a larger fraction of the impact energy is partitioned into heating the projectile. Abe and Matsui (1985) consider thermal models of accretion in which CO_2 , H_2O and fine impact ejecta are produced in accretionary impacts. They conclude that the proto-atmosphere forms a thermal blanket that traps the internal energy added by impacts at or near the planet's surface. The result of this thermal trapping is that the surface temperature becomes high enough to induce devolatilization regardless of the shock pressure produced by an impact, once the Earth (or Venus) achieves $\sim 30\%$ of its final radius. This modeling thus strongly suggests that substantial atmospheres/hydrospheres could develop this way.

VI. ATMOSPHERIC EROSION

Toward the end of accretion, however, collisions are rarer but much more energetic, involving large planetesimals and higher impact velocities, as discussed above. Such impacts may cause a net loss of atmosphere from a planet, so that the cumulative effect of impacts during the period of heavy bombardment might have dramatically depleted the planets' original atmospheres (Cameron 1983). The basic concept is that the fraction of the projectile's momentum that is transferred to the atmosphere may be sufficient to accelerate a portion of the atmosphere to velocities greater than the escape velocity of the planet.

A meteorite or comet may transfer momentum to the atmosphere of the target planet in three ways: first, during the initial passage of the impactor through the atmosphere, there is a direct transfer of momentum as the impactor penetrates the atmosphere, compressing and accelerating the gas in front of it. A small meteorite or comet may be broken up by, or significantly ablated during, its passage through the atmosphere, and thus deposit most or all of its energy directly in the atmosphere, mainly as shock waves and heat. This is apparently the explanation for the famous Tunguska event of 1908, in which shock waves from a meteoroid that did not quite reach the ground leveled about two thousand square kilometers of dense Siberian forest, snapping off meter-diameter trees like matchsticks. Large impactors, however, are not significantly slowed by the atmosphere: O'Keefe and Ahrens (1982) showed that in this case, the impactor delivers only a small fraction of its momentum directly to the atmosphere, and Walker (1986) showed that this momentum is distributed in such a way that no significant amount of atmosphere escapes from a planet with an escape velocity $\geq 10 \text{ km s}^{-1}$. This mechanism is thus negligible for the Earth and Venus, but it may have contributed to atmospheric erosion on Mars. Second, solid ejecta thrown out of the growing crater can transfer momentum to the atmosphere in a similar fashion, but again this has been shown to result in negligible atmospheric loss even for large, high-speed impacts (Melosh and Vickery 1988), even on Mars. Third, for a sufficiently energetic impact, a great deal of very highly shocked impactor (and possibly target) material expands upward and outward at high velocities, driving the

overlying atmosphere ahead of it (Melosh and Vickery 1989; Vickery and Melosh 1990; Watkins 1983). This last mechanism is by far the most important for atmospheric erosion, and we discuss it in more detail below.

A. Minimum Projectile Size

In order that a high-energy ejecta plume should form, the most basic requirement is that the projectile should be large enough to strike the target surface at high velocity and remain intact. The minimum diameter L_{\min} of a projectile that reaches the surface with about half of its initial (pre-atmospheric) velocity, neglecting ablation and crushing effects, is

$$L_{\min} = P_a / (\rho_0 g \sin \theta) \quad (6)$$

where P_a is the surface atmospheric pressure, g is the acceleration of gravity at the planet's surface, ρ_0 is the projectile's density and θ is the angle of entry, measured from the horizontal. Thus, a vertically incident ($\theta = 90^\circ$) stony projectile on Earth with its current atmospheric pressure must be larger than about 3.4 m in diameter to strike with half or more of its initial velocity, while on Venus such a projectile must exceed a diameter of 350 m. If atmospheric pressures were greater than their current values at early times in the history of a given planet, this minimum size would have been correspondingly greater. In actuality, these limits are probably much too small because they neglect ablation and atmospheric breakup, both of which tend to increase the minimum size of a projectile that can reach the surface with high velocity. Ablation is most important for meter-sized projectiles, so that a limit placed by the process of atmospheric breakup is probably more realistic.

Projectiles entering a planetary atmosphere encounter aerodynamic stresses of order $\rho(z)v_e^2$, where $\rho(z)$ is the atmospheric density at altitude z and v_e is the entry velocity. These stresses may reach many kilobars in the lower atmospheres of the Earth and Venus, and so the entering projectiles are nearly certain to be crushed. This effect is independent of the diameter of the projectile. Although the broken fragments of smaller projectiles may be scattered by these stresses, creating the familiar km-wide elliptical strewn fields, the fragments of larger projectiles do not have time to separate significantly. These fragments thus fall in nearly the same location and produce a crater almost indistinguishable from one produced by a single intact projectile. For a vertically incident projectile, the diameter L_c above which breakup is not important is given by (Melosh 1981)

$$L_c = 2(\rho_a / \rho_0)^{1/2} H \quad (7)$$

where ρ_a is the density of the atmosphere at the surface and H is the scale height. Because the surfaces of both planets are quite young, we use current values for the atmospheric parameters to calculate L_c , then use scaling relations to predict minimum crater sizes, and compare these to observations. On

Earth, L_c is about 300 m for stony projectiles, while on Venus it is 4500 m. This implies that the minimum-size hypervelocity impact crater that can form on Earth is a few km diameter (for iron projectiles, the minimum is about a kilometer—about the size of Meteor Crater, Arizona, which was clearly formed by an iron projectile that at least partially fragmented in the upper atmosphere), while the minimum size crater that can form on Venus is about 30 km in diameter, in good agreement with the observations of the Magellan spacecraft (Phillips et al. 1991). We believe therefore that this model gives a reasonably accurate estimate of the minimum size projectile that can survive atmospheric passage as a function of the density structure, and so may be applied to early (hypothetically) denser atmospheres.

B. Melt and Vapor Plume Formation

When a projectile strikes a planet's surface at high speed, a rapid but orderly sequence of events is initiated that ultimately results in a crater. The principal topic here, however, is not the crater itself but the plume of hot melt and vapor that expands into the atmosphere above it. The ultimate origin of this plume lies in the thermodynamics of shock compression and release. When the projectile first strikes the surface, a region of high pressure develops at the interface that spreads into both the projectile and surface rocks as shock waves expand away from the contact area. These waves quickly reach the sides and rear free surface of the projectile and are reflected from there as rarefaction waves that then propagate back downward, releasing the compressed projectile to low pressure. In the surface rocks the shock waves travel outward and downward, engulfing more material and weakening as they proceed.

The resulting pattern of maximum shock pressure is shown schematically in Fig. 11. The projectile and a roughly equal mass of target (surface) rocks are shocked to the highest pressure P_o in a volume comparable to that of the projectile itself (strong shock compression decreases the initial volume of most materials by a factor of about 2). For a target and projectile of the same composition, P_o can be simply estimated using the Hugoniot equations and impedance matching to give

$$P_o = \rho_o \left(C + S \frac{v_i}{2} \right) \frac{v_i}{2} \quad (8)$$

where v_i is the impact velocity, ρ_o is the density of the uncompressed material and C and S are material constants. For a typical crustal rock (granite), $\rho_o = 2630 \text{ kg m}^{-3}$, $C = 3.68 \text{ km s}^{-1}$ and $S = 1.24$ (Kieffer and Simonds 1980). At an impact velocity of 20 km s^{-1} , this yields a maximum pressure P_o of about 425 GPa, somewhat higher than the pressure at the Earth's center. For the more complex case where the target and projectile differ in composition see Melosh (1989).

The maximum shock pressure outside this "isobaric core" (Croft 1982a) falls approximately as a power of distance away from the impact site

$$P = P_o \left(\frac{a}{r} \right)^n \quad (9)$$

Figure 11. Schematic illustration of shock contours beneath the site of an impact. The projectile of radius a strikes the surface at a velocity v_i . A region of nearly uniform high pressure P_0 develops with a volume comparable to that of the projectile itself. Outside this region the pressure falls off with increasing distance r from the impact site. The free surface is constrained to zero pressure, so the pressure contours fall off rapidly in a narrow near-surface zone.

where a is the radius of the projectile and the power n ranges between 3 for strong shocks, declining to 2 at shock pressures lower than 100 GPa. The shock wave thus establishes a pattern of highly shocked rocks near the impact site surrounded by roughly concentric zones of successively less shocked material. The near-surface zone is a special case, where a very thin layer of target material is protected from high shock pressure by the boundary condition at the free surface. The small amount of material within this zone experiences only low shock pressures, but the pressure gradients are high, and the material is ejected at high speed. The concentric shock pressure structure is established long before the excavation flow has time to open the crater. The pattern is subsequently altered by the cratering flow, and may not be discernible except in the deformed rocks directly beneath the final crater.

The heating of shocked materials is the result of a thermodynamic cycle. Shock compression is a thermodynamically irreversible process. At a shock front, mass, momentum and energy are conserved, but not entropy. On a P - T plot, the state of the shocked material jumps discontinuously from its initial state to a final state lying on the Hugoniot curve, a locus of points each of which results from different degree of shock compression, i.e., this curve does *not* define a thermodynamic path traversed by the shocked material. The shocked material then decompresses along an adiabat, which does define a continuous path of P - T states attained by the material.

The standard P - T plot, however, is not very convenient for illustrating phase transformations induced by shock, as the adiabats are complicated curves whose paths give little insight into the ultimate state upon decompression, especially near the critical point. In this chapter, we introduce a P - S

plot (S is entropy) which, although perhaps unfamiliar, contains far more information about the ultimate fate of shocked material. One major advantage of this plot is that release adiabats are vertical lines (constant entropy), and the state of the material at 1 bar (10^{-4} GPa) is generally well known. Thus, if the entropy along the Hugoniot can be computed, the phases present upon decompression to 1 bar, at least, are well determined.

Figure 12 shows an example of a Hugoniot and the phase structure of forsterite on a P - S plot. The Hugoniot and liquid-vapor phase curve were computed from the ANEOS equation of state (Benz et al. 1989), modified slightly to correct a small error in the input parameters. The thermodynamic cycle of shock compression followed by adiabatic release does work on the material, and upon release to low pressure the shocked material may be in the form of a hot solid (for weak shocks), a liquid or a gas (at the highest pressures). Figure 12 indicates that at shock pressures less than about 500 GPa (with a corresponding particle velocity of 10 km s^{-1}), the entropy of the shocked material is less than that required to reach the critical point, and the release curve crosses the liquid/vapor phase curve from the liquid side. Thus, for most asteroidal impact velocities, silicates never vaporize completely (for this to occur the release adiabat must pass to the right of the critical point in Fig. 12), but instead come to a boil, rapidly releasing vapor bubbles and breaking the melt apart into discrete clumps as the pressure declines (Melosh and Vickery 1991). Once the material reaches the liquid/vapor phase curve, its temperature and pressure are linked by the phase relation $P \text{ (GPa)} \approx 220 \exp(-48,900/T)$. The relative masses of liquid and vapor (or solid and vapor below the triple point at about 10^{-9} GPa) can be determined from this diagram by the lever rule. When considering the problem of atmospheric erosion, it is not critical whether the material expands into the liquid field and breaks up into droplets or expands into the vapor field and condenses into droplets: in both the cases the plume expands adiabatically, engulfing and accelerating the ambient atmosphere. The difference may be important, however, for the problem of tektite and microspherule formation.

The specific internal energy initially deposited in the shocked material is approximately equal to one-half of the particle velocity squared. Because the particle velocity itself is about one-half of the impact velocity (for projectile and target composed of the same material), the internal energy of the shocked material per unit mass is given by $E \approx v_i^2/8$. When the impact velocity is high enough that melting or vaporization occur, this energy is available for acceleration of the material out of the growing crater. The average final velocity attained by the isentropic expansion of a fluid with initial internal energy E is given by $v_\infty = (2E)^{1/2}$, or in this case $v_\infty = v_i/2$. Thus, the plume of melt and vapor expanding away from the site of an impact eventually achieves a mean speed of about half the impact velocity. Furthermore, detailed numerical computations with the ANEOS equation of state for dunite show that the edge of the expanding plume typically moves at twice this speed, or at nearly the impact velocity itself.

Figure 12. The thermodynamic path of shocked dunite in P - S (pressure-entropy) space. The Hugoniot curve and solid liquid-vapor phase curve are based on the ANEOS equation of state for dunite (Benz et al. 1989), with the slightly corrected parameters $ZB(11) = 2.23 \times 10^{11}$, $COT(1) = 0.571$, $COT(2) = 0.143$, $COT(3) = 0.286$. The entropy of the 1 bar (10^{-4} GPa) reference state (from the JANAF tables) is shown as a heavy black circle, the near-vertical light lines denoting incipient and complete melting are constrained at 1 bar by JANAF data, and the points for incipient (square) and complete (triangle) vaporization are from Ahrens and O'Keefe (1972). Note that although the ANEOS phase curve agrees well with the point for incipient vaporization, it lies at much too high an entropy at complete vaporization. Similarly, the critical point is at about a factor of 10 higher pressure than that derived from the hard sphere formalism (Ahrens and O'Keefe 1972). These displacements are a result of ANEOS's implicit assumption that the gas phase is a monatomic mixture of species, whereas vaporized dunite is likely to consist mainly of a mixture of MgO , SiO and O_2 . The long-dashed curve is an interpolation through the hard-sphere critical point indicating the probable true nature of this phase boundary. Release adiabats are shown schematically as downward pointing arrows. Note that even for the hard-sphere critical point at $S = 5600 \text{ J kg}^{-1} \text{ K}^{-1}$ the shock pressure must exceed about 500 GPa (with corresponding particle velocity of 10 km s^{-1}) to reach the liquid-vapor curve from the vapor side.

C. Atmospheric Erosion by Melt and Vapor Plumes

The structure of this expanding plume of hot melt and vapor is initially rather complex, as revealed by detailed numerical computations (O'Keefe and Ahrens 1982), but as time goes on, it quickly attains a roughly hemispherical shape (Basilevsky et al. 1983). The mean density of the plume declines below the melt density by the time it has expanded to about twice the projectile radius, indicating that by this time the plume is composed of droplets of melt in local thermodynamic equilibrium with vapor. The gas and melt droplets are strongly coupled, however, until much later in the expansion. As this fast-

moving dispersion of liquid droplets and vapor meets the ambient atmosphere, shock waves form at the interface that decelerate the plume while accelerating the surrounding air.

In the case of a small impact, the mass of the atmosphere may be sufficiently great that the plume's expansion is entirely halted. If this occurs over a distance small compared to the atmospheric scale height H , the hot melt and vapor form a hemispherical bubble that rises into the stratosphere under the influence of its own buoyancy, like a hot air balloon. This is the classic fireball scenario, familiar to everyone as the mushroom cloud emblematic of nuclear explosions. An upper limit on the projectile size for this scenario can be roughly derived by equating the radius of a vapor "fireball" to the atmosphere's scale height H (see Melosh 1989; Jones and Kodis 1982). Assume that the projectile and an equal mass of target begin expanding from an initial pressure given by the second Hugoniot equation, $P_i = \rho_p(v_i/2)[C + S(v_i/2)]$, where v_i is the impact velocity on the surface (the initial particle velocity is $v_i/2$ if projectile and target materials are similar), C and S are material constants in the linear shock-particle velocity equation of state, and ρ_p is the projectile density. At high velocities, only the S term is important: $P_i \approx \rho_p S v_i^2/4$. Then the radius of the smallest projectile that can generate an atmosphere-piercing plume is:

$$a_p = H \left(\frac{P_a}{S \rho_p v_i^2} \right)^{1/3\gamma} \quad (10)$$

where P_a is the surface atmospheric pressure and γ is the ratio of specific heats ($\gamma = 1.4$ for air). As $S \approx 1.3$ for most silicates (Melosh 1989, Table AII.2), $H = 10$ km on Earth, and taking $v_i = 20$ km s⁻¹ this equation yields $a_p \approx 200$ m, corresponding to a transient crater about 6 km in diameter. Larger projectiles than this produce vapor plumes that cannot be stopped by the atmosphere.

Because the smallest mass of atmosphere is vertically above the crater (Fig. 13), it is expected that projectiles somewhat larger than the limit (Eq. 10) will create strongly focused vertical plumes above the impact site. The maximum velocities in these plumes may approach the impact velocity, and thus some material (mostly derived from the projectile itself) may be ejected back into interplanetary space. A simple method of estimating whether the atmospheric gases will be ejected is to compute the momentum of the expanding melt and vapor plume in a small element of solid angle extending outward from the impact site. The mass of the atmospheric gases in the same solid angle is then computed and added to the mass of the crater ejecta. Momentum conservation then determines the mean velocity of the mixture. If the mean velocity is greater than escape velocity, then the atmosphere in this element of solid angle is considered to be ejected. A minimum requirement is that the mean velocity of the melt and vapor plume must exceed escape velocity, so that the initial impact velocity must be twice the escape velocity, or about 20 km s⁻¹ on the Earth. Similarly, the mass of the plume must be sufficient

to accelerate the atmosphere along with it. This puts a lower limit on the projectile size for atmospheric loss to occur, which we have found to be close to 10^{13} kg or roughly 2 km in diameter (Vickery and Melosh 1990) for silicate projectiles and Earth's current atmosphere. This lower limit would be greater for Venus and less for Mars at the present time, because it increases with increasing atmospheric mass, and decreases with increasing H/R , the ratio of the atmospheric scale height to planetary radius.

Figure 13. Mass in the Earth's atmosphere as a function of zenith angle (0° is vertical, 90° is horizontal), normalized by the mass in a uniform hemisphere of the same total mass. This gives the "coupling factor" between an expanding hemisphere of gas and the ambient atmosphere. The mass in the Earth's atmosphere is small directly overhead and strongly concentrated toward the horizon. The mass in an element of solid angle is the same as a uniform hemisphere at a zenith angle of 83.2° (based on the U. S. Standard Atmosphere).

As the size of the projectile increases, more and more of the atmosphere is liable to be stripped away from the planet by the expanding plume of vapor mixed with melt droplets. The maximum that can be stripped is given approximately by the mass lying above the plane tangent to the planet at the impact point, $m_{tp} = 2\pi P_a H R_p / g$, where R_p is the radius of the planet, P_a is the surface atmospheric pressure and g is the surface acceleration of gravity (Melosh and Vickery 1989). This amounts to about 0.1% of the total mass of the atmosphere (the fraction is H/R_E), or 3×10^{15} kg on the Earth. Detailed numerical computations (Vickery and Melosh 1990) have shown that at impact velocities of $>20 \text{ km s}^{-1}$, the atmospheric mass ejected is not a strong function of impact velocity and that projectiles with masses in the range of 10^{17} kg and above are capable of removing essentially all of the atmosphere

above the tangent plane on Earth. These computations are difficult, however, because most of the atmosphere's mass is concentrated at low elevations from the impact point (see Fig. 13), whereas the expanding plume of melt and vapor is more or less isotropic. The two thus do not couple well together. The coupling may be enhanced, however, by the concentration of the plume's mass at low angles, as is expected for oblique impacts (Schultz and Crawford 1987). Such low-angle processes as jetting (Melosh 1989) or ballistic curvature of lower-speed ejecta may also enhance the efficiency of atmospheric loss. To achieve accurate estimates of the process of atmospheric erosion by impacts, it is thus necessary to perform full scale numerical computations on the fast, low-angle ejecta from an impact, and to consider the radius of curvature of the target planet. Such computations have not yet been done with sufficient accuracy: this is clearly a direction that future work on atmospheric erosion by impacts must take.

Although an exact treatment of the projectile mass needed to eject the atmosphere above the tangent plane is still lacking, the computations discussed above (Vickery and Melosh 1990) show that a projectile mass m_* between 1 and 10 times m_{tp} is needed to strip the atmosphere above the tangent plane. Using this estimated threshold along with a postulated cratering flux permits the rate of atmospheric erosion by impacts to be roughly computed. The present cumulative flux (number/sec/m²) of projectiles with mass greater than or equal to m is parameterized by $N_{cum}(m) = am^{-b}$, where a and b are constants. Unfortunately, neither the over-all flux a nor the slope of the distribution b are well known. A pair of constants that predicts the correct present lunar crater distribution via the revised Schmidt-Holsapple scaling law (Schmidt and Housen 1987) is $a = 1.55 \times 10^{-23} (MKS)$, $b = 0.47$. The slope of the crater distribution on the Martian plains is the same as the lunar distribution (Neukum and Wise 1976; Strom 1984), while the overall cratering rate on Mars at present is estimated to between 1 and 4 times the lunar rate, with a preferred mean of about 2 (BVSP 1981).

Using a constant cratering rate, the rate of mass loss from a planet's atmosphere dM_{atm}/dt is given by the flux $N_{cum}(m_*)$ of projectiles large enough to remove the atmosphere above the tangent plane, times the planet's surface area $4\pi R^2$, times the mass above the tangent plane m_{tp} . As m_* itself depends upon M_{atm} , a simple differential equation for M_{atm} (or, equivalently, P) results whose solution, converted to a convenient and universal form, is:

$$\frac{M_{atm}(t)}{M_0} = \frac{P(t)}{P_0} = \left(1 - \frac{t}{t_*}\right)^{1/b} \quad (11)$$

where the M_0 is the present ($t = 0$) atmospheric mass, P_0 is the present surface atmospheric pressure, and t_* is the length of time required for impacts to reduce the atmospheric pressure to zero. In terms of previously defined quantities,

$$t_* = \frac{f_{crit}^b}{2\pi ab(RH)^{1-b}} \left(\frac{4\pi P_0}{g}\right)^b \quad (12)$$

where f_{crit} is the ratio of the critical projectile mass m_* to the mass above the tangent plane m_{tp} . This ratio is assumed to be a constant. As $b = 0.47$, the characteristic time t_* is not very sensitive to uncertainty in f_{crit} .

Note that the above equation for the time dependence of atmospheric mass or pressure can be used for times before the present ($t < 0$), so that the atmospheric pressure at any previous era can also be computed. It is interesting to note that the atmospheric pressure declines rigorously to zero at time t_* —it does not simply fall exponentially towards zero. This interesting fact is a unique characteristic of the impact erosion mechanism. As the atmospheric pressure declines, smaller projectiles are capable of removing the atmosphere above the tangent plane. But by the distribution law, there are more smaller projectiles than larger ones, so a greater fraction of the atmosphere is removed in each unit time interval. The net result is the complete stripping of the atmosphere after time t_* , barring volcanic or other sources of replenishment.

The post-late-heavy-bombardment flux, along with other parameters and the assumption $f_{\text{crit}} \approx 1$, gives a value $t_* \approx 60$ Gyr for Mars at the present time (note that t_* for Earth and Venus is longer by several orders of magnitude, so that impact erosion of their atmospheres is entirely negligible). This value for t_* predicts an atmospheric pressure on Mars at the end of late heavy bombardment (3.2 Gyr) only 1.1 times the present low pressure. This would not explain the geomorphic evidence (Baker and Partridge 1986) for running water on Mars' surface early in its geologic history. However, it is widely known (BVSP 1981) that the impact flux on the Moon in the first Gyr of its history was many orders of magnitude larger than at present. It is presumed (Neukum and Wise 1976) that Mars, too, shared in this era of heavy bombardment, so that the enhanced impact fluxes of this era may have produced an early period of rapid atmospheric pressure change. The heavy bombardment flux can be adequately fit by the expression

$$N_{\text{cum}}(m, t) = a (1 + B e^{-\lambda(t+4.6)}) m^{-b} \quad (13)$$

where a and b are the same as before, and $B = 1.17 \times 10^4$ and $\lambda = 6.94 \text{ Gyr}^{-1}$ (Chyba 1990).

The differential equation for the rate of atmospheric mass loss implied by Eq. (13) can be readily integrated, giving a simple analytic expression similar to Eq. (11) for the evolution of atmospheric pressure as a function of time t from the present:

$$\frac{M_{\text{atm}}(t)}{M_0} = \frac{P(t)}{P_0} = \left(1 - \frac{t}{t_*} - \frac{B e^{-4.6\lambda}}{\lambda t_*} [1 - e^{\lambda t}] \right)^{1/b}. \quad (14)$$

The atmospheric pressure of Mars predicted by this expression is shown in Fig. 14. It is clear that early in Mars' history its atmospheric pressure may have been as much as 100 times its present value, or approximately 1 bar. It is interesting to note that this pressure is near that considered necessary for Mars

to have supported free water on its surface (Cess et al. 1980; Kasting and Toon 1989). Of course, other processes besides impact erosion probably played major roles in determining Mars' atmospheric pressure, so this computation should be regarded merely as an indication of the magnitude of the effect and time interval over which impact erosion may have been important.

Figure 14. The history of atmospheric pressure on Mars in a model where impact erosion alone can affect the mass of the atmosphere (although this is an unrealistic assumption, it serves to highlight the effect of this process). The different curves reflect different assumptions about the ratio f_{crit} between projectile mass at the threshold of atmospheric erosion and the mass above the tangent plane. The atmospheric pressure declines rapidly through the period of heavy bombardment.

In the above computation, we neglected the flux of volatiles delivered by impacts (as well as those from mantle degassing, etc.). Whether a given impact will add or erode volatiles is a function of its impact velocity as well as its size, so that the spectrum of velocities as well as the compositions of projectiles striking a planet's surface must be known (or assumed from a plausible model). A beginning on this problem has been made by (Chyba 1990), although it is clear that a great deal of additional work must be done before this topic is fully understood.

One additional consequence of the impact erosion of atmospheres, however, is worth noting. Volatile constituents in the atmosphere above an impact site are vulnerable to stripping by the expanding plume of vapor. The mass that may be removed is $m_{ip} = 2\pi P_a H R_p / g$, which is a fraction $H/2R_p$ of the total atmospheric mass. However, if the volatile is condensed on the surface of the planet, the maximum amount expelled with the expanding vapors is roughly equal that intersected by the projectile, equal to the area of the projectile projected onto the surface of the planet times the thickness t of

the condensed volatile, $\pi a^2 t$, where a is the projectile radius. As the total amount of this material on the planet is $4\pi R_p^2 t$ (assuming a uniform distribution) the fraction of the condensed volatile removed is thus $a^2/4R_p^2$. At the threshold for removal by atmospheric erosion $m_* = f_{\text{crit}} m_{tp}$, so at radius $a_* = (3m_*/4\pi\rho_0)^{1/3}$ we can show

$$\frac{\text{Condensibles Ejected}}{\text{Total Inventory}} = \left\{ \left[\frac{3}{4} f_{\text{crit}} \left(\frac{\rho_a}{\rho_0} \right) \right]^{2/3} \left(\frac{H}{2R_p} \right)^{1/3} \right\} \frac{H}{2R_p}. \quad (15)$$

Because this ratio is generally much smaller than $H/2R_p$, it is clear that surface condensates are much less vulnerable to impact erosion than atmospheric gases. In this way, condensible volatiles may have been fractionated from noncondensible ones during accretion or heavy bombardment. For example, Mars may have acquired a substantial inventory of water (which condenses or freezes on or near the surface) while only retaining a small amount of the noncondensible gas nitrogen. The fate of CO_2 is more complex, as it can both form carbonates on the surface as well as remain uncondensed in the atmosphere.

VII. SUMMARY

The effects of "giant" impacts (i.e., impacts by bodies roughly half the diameter of the primary) on the thermal state of a growing planetary embryo is a more general problem than that of the hypothetical Moon-forming impact on the proto-Earth. If the cumulative spectrum of planetesimal sizes is close to a power law of slope -2 , then most of the mass and energy added to a growing planet will be deposited by such "giant" impacts. In this case a simple pattern of temperature versus radius may never develop, as the thermal state at any given era will depend upon the time, velocity and obliquity of the last large collision. The process of core formation and differentiation in a catastrophically growing body may be qualitatively different than that suggested by current gradualist models of planetesimal growth. Global melting and the formation of "magma oceans" may have occurred repeatedly in the history of all planetary-size bodies. The implications of such catastrophic growth have yet to be worked out, but it is clear that much more work needs to be done on the effects of large impacts on protoplanets of all sizes, and the chemical and mechanical evolution of planetary-scale magma bodies.

Impacts also contribute in a fundamental way to the origin and evolution of atmospheres. Devolatilization of impactors (and of surface rocks, if they have a volatile-rich composition) during accretion may lead to the formation of relatively dense proto-atmospheres. Giant impacts, such as that which is believed to have formed the Moon, influence atmospheric development in ways that are presently unclear: although a number of authors declare that giant impacts will simply strip away any pre-existing atmosphere, the loss mechanism is sufficiently obscure that this conclusion is open to doubt.

The cumulative effect of the smaller, but much more numerous, impacts during heavy bombardment was to strip away a fraction of the primordial atmospheres; this effect would have been much more pronounced for Mars than for the Earth or Venus. Impact erosion is much more effective for atmospheric gases than for condensed liquids or ices on the surface, and may thus have helped to segregate noncondensibles from condensible substances.

THE LONG-TERM DYNAMICAL EVOLUTION AND STABILITY OF THE SOLAR SYSTEM

MARTIN J. DUNCAN

Queen's University

and

THOMAS QUINN

Oxford University

The question of the long-term stability of the solar system is one of the oldest unsolved problems in Newtonian physics. Although the general solution remains elusive, several recent theoretical and numerical advances suggest that the simple “clockwork” model of the solar system envisaged by early workers must be replaced by one incorporating the deterministic chaos recently found in many nonlinear dynamical systems. We begin with a brief review of research on the gravitational N -body problem, with an emphasis on recent developments which pertain to the long-term evolution of orbits. We then describe how this work may be used to understand the results of computer simulations of (1) the structure of the asteroid belt, (2) the formation and evolution of the Oort comet cloud and the origin of short-period comets, (3) the gravitational sweeping of minor bodies between the giant planets, and (4) the possible existence of a belt of comets just beyond Neptune. We continue with a summary of the status of current research into the long-term dynamical evolution and stability of the solar system and conclude with a discussion of promising areas for future investigation.

I. INTRODUCTION

Most of the chapters in this book review current theories of the formation of the solar system up to the time several billion years ago when the planets acquired most of their material and settled into nearly circular, nearly coplanar orbits. In this chapter, we describe efforts to study the subsequent dynamical evolution of such a system. The issue of the long-term stability of the solar system is of course one of the oldest unsolved problems in Newtonian physics, but recent (largely numerical) work has provided some insight into the problem. In particular, several lines of investigation suggest that the solar system is subject to the deterministic chaos recently found in many nonlinear Hamiltonian systems. This inherent unpredictability has profound implications for the dynamics of the solar system, not the least of which is the demise of the “clockwork” picture favored by many earlier workers in the field.

We return at the end of this review to the results of simulations of the

evolution of the planets. However, many aspects of the dynamical evolution of the orbits of "test" bodies (such as comets and asteroids) under the perturbing influence of one or more planets (1) are of considerable intrinsic interest, (2) can be numerically more tractable, and (3) may offer considerable insight into the more general dynamical problem. Therefore, in the next section we summarize progress in the past decade in the gravitational N -body problem, using the restricted 3-body problem to illustrate the distinction between quasi-periodic and chaotic orbits and the useful features of area-preserving mappings, Poincaré surfaces of section and Lyapunov exponents. With this mathematical machinery as a basis, we then describe in Sec. III an example of chaos in action—the origins of the 3:1 gap in the asteroid belt. We also discuss the extent to which it is possible that the structure in the outer asteroid belt has been shaped by the gravitational influences of the giant planets (particularly Jupiter).

In Sec. IV, we describe recent simulations of the formation of the Oort comet cloud and of the origins of short-period comets. The latter simulations provide indirect evidence for an as yet undiscovered belt of icy planetesimals beyond Neptune (the Kuiper belt) and we will briefly describe observational searches for the members of this belt. In Sec. V, we discuss numerical simulations designed to test the dynamical stability of test particles between the giant planets and beyond Neptune. In Sec. VI, we return to the larger question of the long-term stability of the planets themselves. We conclude (Sec. VII) with a summary of the results of the previous sections and briefly discuss promising areas for future research.

II. RECENT DEVELOPMENTS IN THE GRAVITATIONAL N -BODY PROBLEM

Insofar as the Sun, planets and minor bodies can be approximated as point masses interacting solely via their mutual gravitational forces, the solar system can be viewed as a nonlinear Hamiltonian system. It is therefore not surprising that many of the mathematical techniques used in the study of other nonlinear dynamical systems can be applied to the problem at hand. In the remainder of this section we present a very nonrigorous summary of concepts which are useful in understanding the numerical results presented in subsequent sections. Interested readers will find more information in the superb reviews by Hénon (1983) and Berry (1978) on Hamiltonian systems in general and by Wisdom (1987*b*) on chaotic dynamics in the solar system in particular.

Consider then a self-gravitating system of N particles, for which one can write down the Hamiltonian in the standard way. Each particle in the system will in general have three degrees of freedom and with each degree of freedom one can associate a generalized coordinate and its conjugate momentum. The state of the system at any instant in time may then be represented as a point in a $6N$ -dimensional phase space and the evolution of the system is then a

trajectory (line) in this space which begins at some point determined by the initial spatial coordinates and momenta for each particle.

In some cases, there exist one or more independent single-valued functions of the spatial coordinates and momenta which are conserved along each trajectory of the system. Each of these functions is called an integral of the motion (sometimes called an isolating integral; cf. Binney and Tremaine 1987). If the functions are mutually independent (technically if they are all "in involution"; see, e.g., Berry 1978) then each integral restricts a given trajectory of the system to a submanifold of one less dimension of the $6N$ -dimensional phase space. If there exists an independent integral for every degree of freedom then the system is said to be integrable and it is always possible via canonical transformations to the phase space coordinates to cast the Hamiltonian in a form in which there is no explicit dependence on the spatial coordinates. The relevant coordinates are known as action-angle variables and Hamilton's equations can be used to show that each trajectory is then confined to a manifold which is topologically a torus of dimension equal to one half of the dimension of the phase space. One can then envision a given trajectory winding its way around the multi-dimensional torus upon which it is confined. For each degree of freedom and set of initial conditions, there exists a unique angular frequency (given by the partial derivative of the Hamiltonian with respect to the associated action variable) so that unless two of the frequencies are commensurable (i.e., are in the ratio m/n where m and n are integers), a given trajectory will densely cover its confining torus. These trajectories are called quasi-periodic and are the general case for an integrable Hamiltonian. In some cases (such as the Kepler problem) two or more of the angular frequencies are commensurate, in which case there is said to be a resonance and the trajectory is restricted to a lower-dimensional submanifold on the torus. For example, in most integrable systems with two degrees of freedom, a typical trajectory covers the two-dimensional surface of a "donut," but if there exists a commensurability between the two relevant angular frequencies, then the trajectory is a closed line on the surface of a donut. Resonances play a key role both in the theory of Hamiltonian systems and in the actual solar system, as we shall see.

It is clear that for systems with only one degree of freedom the trajectories under time-dependent Hamiltonians are always integrable, because the Hamiltonian itself is an integral. For systems with two or more degrees of freedom, the question which must now be answered is: do most Hamiltonians possess an integral for every degree of freedom—i.e., is integrability exceptional or generic? Furthermore, what are the consequences of nonintegrability? Historically, researchers have attacked the problem by beginning with an integrable system (such as the Kepler problem) and introducing a small perturbation (such as the influence of a third object of small mass). Most of classical perturbation theory assumed that all problems are integrable and their perturbation expansions typically pushed the nonintegrable parts of the Hamiltonian to successively higher orders in the perturbation parameter.

However, Poincaré (1892) showed that these perturbation series are in general divergent and have validity only over finite time spans. We return to this issue in Sec. VI.

Significant progress on the mathematical issue was provided by the work of Kolmogorov, Arnold and Moser (see, e.g., Hénon 1983 for a review and references). This work (which is now termed the KAM theorem) showed that the quasi-periodic trajectories of an integrable problem usually remain quasi-periodic under the influence of a "sufficiently small" perturbation to the Hamiltonian. The exceptions are trajectories where the ratios of characteristic frequencies of the original problem are sufficiently well approximated by rational numbers—i.e., the theorem failed near resonances. As rational numbers are inextricably mixed with irrationals along the real number line, regions of quasi-periodic and chaotic behavior are similarly intertwined (see, e.g., Berry 1978 for a good discussion). Furthermore, the tori which are "destroyed" form a finite set which grows with the strength of the perturbation. The KAM theorem is thus fundamental in showing the persistence of tori under very small perturbations, but much of our understanding of the structure of phase space in more realistic Hamiltonians comes from numerical investigations.

Numerical integration of orbits (as exemplified in the classic paper of Hénon and Heiles [1964] in their investigation of the existence of another integral in two-dimensional potentials) has generally shown results which are consistent with the KAM theorem—quasi-periodic and chaotic orbits are inextricably intermixed in phase space. For systems with two degrees of freedom, the chaotic regions are bounded by tori corresponding to quasi-periodic trajectories. A useful tool for visualizing the phase space in such cases was employed by Poincaré and is sometimes called a Poincaré surface of section. For systems with two degrees of freedom, the trajectory in four-dimensional phase space is in general a 3-surface because the Hamiltonian itself is an integral of the motion and hence constrains the motion. If we now consider a slice through this three-dimensional volume (for example by plotting one coordinate and its conjugate momentum whenever the other coordinate is zero), the resulting two-dimensional plot is the locus of points created as the trajectory "pierces" the surface. If there exists a second integral, the resultant plot will be a one-dimensional curve; if the orbit is chaotic, an area on the plane will be populated (and in a seemingly random manner). This approach can be illustrated with a particularly relevant example. A classic case of orbits in a system with two degrees of freedom is the planar restricted circular 3-body problem, in which a test particle (taken to have zero mass) moves under the gravitational influence of two massive objects moving in circular orbits about their mutual center of mass. In the appropriate rotating frame, the massive objects are fixed and the resultant time-independent Hamiltonian is known as the Jacobi integral (cf. Binney and Tremaine 1987). If one integrates the trajectory of the test particle, surfaces of section such as those shown in Fig. 1 ensue. The particular example is for the case of two equal massive bodies and is discussed more fully in Hénon (1966*a, b*, 1983). The x -axis is along the

line joining the two masses and the section is obtained by plotting the velocity in the x -direction versus x whenever the particle goes through $y = 0$ with positive y -velocity. For the particular value of the Jacobi integral depicted here ($C = 0.39$), but for otherwise different conditions, there is a zone of quasi-periodic orbits centered near $x = 0.74$ (we show three orbits here) and a region where orbits are chaotic, as exemplified by the dotted area. Note that the unconnected dots are produced by the motion of *one* particle.

Figure 1. Surfaces of section for the circular, planar, restricted 3-body problem. Shown are the trajectories of test particles started with the same Jacobi constant but otherwise different initial conditions. See the text for further discussions of the initial conditions. Three regular orbits are shown, which are centered on a period orbit near $x = 0.74$. Note that the unconnected dots are produced by the motion of *one* particle.

A particularly appealing aspect of the use of surfaces of section is that in some cases it is possible to devise what is known as an area-preserving map which carries one point on the surface to the next algebraically (i.e., without having to integrate the particle's trajectory in between passages through the surface). This approximation (if it can be found) typically speeds up the time necessary to explore the phase space by a factor of 100 to 1000.

For systems with more than two degrees of freedom, a similar analysis would require multidimensional hypersurfaces of section. However, regardless of the number of degrees of freedom, there is a key feature of the irregular orbits which we will use here as a definition of "chaos": two trajectories which begin arbitrarily close in phase space in a chaotic region will typically diverge exponentially in time. Ironically, the time scale for that divergence in a given chaotic region does not typically depend on the initial conditions. Thus, if

one computes the distance in six-dimensional phase space $d(t)$ between two particles having an initially small separation it can be shown that for quasi-periodic orbits, $d(t) - d(t_0)$ grows as a power of time t (typically linearly) whereas for irregular orbits $d(t)$ grows exponentially as $d(t_0)e^{\gamma(t-t_0)}$ where γ is conventionally called the Lyapunov exponent. Thus, chaotic orbits show such a sensitive dependence on initial conditions that the detailed long-term behavior of the orbits is lost within several Lyapunov time scales.

In Fig. 2, we illustrate the distinction between adjacent trajectories which are regular versus those which are quasi-periodic as characterized by the Lyapunov exponent described above. The quantity $\gamma \equiv \ln[d(t)/d(0)]/t$, for chaotic trajectories eventually levels off at a value which is the Lyapunov value in that region (the inverse of the characteristic time scale for divergence) whereas γ continues to decline for quasi-periodic orbits when plotted as a function of time. The examples shown correspond to orbits within and without a chaotic region of the asteroid belt near the 3:1 mean-motion resonance with Jupiter (see, e.g., Wisdom 1983, and references therein).

Figure 2. Distinction between regular (lower curve) and chaotic (upper curve) trajectories as characterized by the Lyapunov exponent discussed in the text. For chaotic trajectories, a plot of $\log(\gamma)$ vs $\log(t)$ eventually levels off at a value of γ which is the inverse of the characteristic time scale for the divergence of initially adjacent trajectories.

For systems of more than 2 degrees of freedom, the chaotic regions of phase space are no longer bounded by quasi-periodic tori so that the chaotic regions can communicate. The process by which a particle evolves from one chaotic region to another is termed "Arnold diffusion." The time scale for

this process is very important for our understanding of solar system stability, as we shall see.

III. CHAOS IN ACTION: STRUCTURE IN THE ASTEROID BELT

The number density of the asteroids in the asteroid belt as a function of semi-major axis (or mean motion) shows an intricate structure. There are several influences that could affect this structure, but we will limit the discussion to the gravitational hypothesis. (Other explanations for gaps which we will not discuss include the statistical hypothesis, the collisional hypothesis, and the cosmogonic hypothesis; see Greenberg and Scholl [1979] for a review of these.)

The gravitational hypothesis states that virtually all of the structure in the asteroid belt can be attributed to gravitational interactions with the planets which clear asteroids from certain regions over the age of the solar system. This is supported by the coincidence of depletion and enhancement bands with mean motion resonances of Jupiter, the main gravitational perturber in the asteroid region. As well as gaps corresponding to mean motion resonances, there are gaps corresponding to secular resonances, i.e., regions where the precession rate of an asteroid's longitude of perihelion or line of nodes corresponds to one of the eigenfrequencies of the solar system. The existence of secular resonances was noted as early as the 19th century (Le Verrier 1856), and it has long been evident that the inner edge of the asteroid belt near 2 AU is near such a resonance. Williams (1969, 1971) introduced a powerful approach to analyzing secular resonances, and showed that asteroids with $a < 2.6$ AU are severely depleted at the locations of the three strongest resonances. Further applications of this approach and numerical studies have accounted for much of the observed depletion in the inner regions of the asteroid belt (see Scholl et al. 1989 for a recent review). Knezevic et al. (1991) have extended such studies to the outer planetary region.

An obvious mean-motion resonance is at the location of the Trojan asteroids, a 1:1 resonance with Jupiter. These asteroids librate about the points 60° behind or ahead of Jupiter and therefore, never suffer a close approach to Jupiter. Another example of a protection mechanism provided by a resonance is the Hilda group at a mean motion 3:2 resonance. These asteroids have a libration about 0° of their critical argument, $\sigma \equiv 2\lambda' - \lambda - \varpi$, where λ' is Jupiter's longitude, λ is the asteroid's longitude, and ϖ is the asteroid's longitude of perihelion (Schubart 1968). In this way, whenever the asteroid is in conjunction with Jupiter ($\lambda = \lambda'$), the asteroid is close to perihelion, ($\lambda' \sim \varpi$) and well away from Jupiter.

Using resonances to explain the gaps in the outer asteroid belt and the general depletion of the outer belt proves to be more difficult. A feature subject to much investigation has been the gap at the 3:1 mean motion resonance. Scholl and Froeschlé (1974) investigated this commensurability using the averaged planar elliptic restricted 3-body problem. They found that most orbits

starting at small eccentricity were regular and showed very little variation in eccentricity or semimajor axis over time scales of 5×10^4 yr.

Investigation of more realistic models was limited because of the amount of computer time needed to follow orbits over long periods of time. A breakthrough occurred when Wisdom (1982) devised an algebraic mapping of phase space onto itself with a resonant structure similar to the 3:1 commensurability. His surprising result was that an orbit near the resonance could maintain a low ($e < 0.1$) eccentricity for nearly a million years and then have a sudden increase in eccentricity to over 0.3. Wisdom also showed that this behavior could not have been seen in the averaged planar eccentric restricted 3-body problem because the averaged Hamiltonian admits a quasi-integral which confines the orbits to low eccentricities.

Any doubts about this apparent chaotic behavior were later dispelled by numerical integrations and the measurement of a non-zero maximum Lyapunov exponent (Wisdom 1983) and by a semianalytic perturbative theory which explained many of the features found in the mappings (Wisdom 1985). Figure 3 plots the eccentricity as a function of time for a typical chaotic trajectory near the 3:1 resonance in Wisdom's perturbative theory. Note that the time is measured in Myr, so that the particle can remain in a low-eccentricity state for many tens of thousands of orbits before relatively rapidly entering a high-eccentricity phase. Approximate surfaces of section explaining this behavior may be found in Wisdom (1985). There it can be seen that the particle spends some time in low-eccentricity islands near the origin, while being free to explore a fairly large chaotic zone of higher eccentricity.

Wisdom (1987*b*) gives other (albeit rarer) examples of trajectories which exhibit long periods of low-eccentricity punctuated by bursts of short-lived but highly eccentric behavior. The relevant surfaces of section clearly demonstrate that although a wide chaotic zone surrounds the origin, there also exists a narrow branch that extends to high eccentricity. An orbit wandering in the band near the origin could appear to be constrained to low eccentricities, and suddenly suffer a large jump in eccentricity as it went down the branch.

The outer boundaries of the chaotic zone as determined by Wisdom's work has been shown to coincide well with the boundaries of the Kirkwood gap as shown in the numbered minor planets and the Palomar-Leiden survey. Since orbits which begin on near-circular orbits in the gap acquire sufficient eccentricities to cross the orbit of Mars, the perturbative effects of Mars are believed capable of clearing out the 3:1 gap over the age of the solar system.

The depletion of the outer asteroid belt (3.6 AU to 5.2 AU) has long been assumed to be due to the gravitational influence of Jupiter (see, e.g., Nobili 1989 for a review). This seems plausible because of the large number of strong resonances that occur in the outer belt. These resonances overlap at moderate eccentricities which corresponds to a sharp cutoff in the asteroid distribution (Dermott and Murray 1983). The argument for depletion by Jupiter's perturbations was first checked by a numerical integration by Lecar and Franklin (1973) who numerically integrated orbits in the planar elliptic

Figure 3. Eccentricity as a function of time of a typical chaotic trajectory near the 3:1 resonance in the elliptic restricted 3-body problem with parameters appropriate to the Sun-Jupiter-asteroid case. Note that the particle can remain in a low-eccentricity state for many tens of thousands of orbits before relatively rapidly entering a high-eccentricity phase.

restricted 3-body problem for a period of a few thousand years. They found that the region outside of 4.0 AU could be depleted in this time span, but the depletion inside 4.0 AU was very small. Froeschlé and Scholl (1979) extended this by integrating orbits in the three-dimensional Sun-Jupiter-Saturn model for 10^5 yr. For small eccentricities, they again found very little depletion inside 4.0 AU. By carefully selecting their initial conditions, Milani and Nobili (1985) were able to find orbits that crossed Jupiter very quickly. However, for an initial semimajor axis less than 4.0 AU, only orbits with initially high eccentricities ($e > 0.15$) were found to be Jupiter crossers in their relatively short integrations.

Gladman and Duncan (1990) have performed integrations for 12 Myr of the equations of motion of the Sun, Jupiter, Saturn and 80 test particles which began on circular orbits at various radii distributed between 3.1 and 3.9 AU. Particles which evolved into orbits that crossed that of Mars or which brought them to a close approach with Jupiter or Saturn were removed from the integrations. Gladman and Duncan found depletions at some of the stronger mean motion resonances, in particular the 2:1 resonance, but most of their orbits were stable over this time scale. It appears likely that longer

direct integrations will show considerable depletion over Gyr time scales in the region beyond the 2:1 resonance, but this remains to be shown. Indeed, the study of the orbits near resonances other than the 3:1 remains an active area of research which is beyond the scope of this review, but it is quite possible that cosmogonical effects have played a role in shaping some of the gaps (see, e.g., Yoshikawa 1991).

IV. ORIGINS OF LONG- AND SHORT-PERIOD COMETS

Four decades have passed since Oort (1950) deduced the existence of the cloud of comets which bears his name and proposed a mechanism for delivering a steady-state flux out of that reservoir into orbits which brings one every few years close enough to the Sun at pericenter to become visible as a new long-period comet. Although many of the basic ingredients of Oort's classic picture remain, there has been considerable refinement and some modification of the theory (see Weissman 1990). Chapters by Mumma et al. and by Van Dishoeck et al. describe in more detail the present orbital properties of current comets, their chemical compositions and theories of their formation. In keeping with the theme of this chapter, however, we discuss herein our current understanding of the dynamical processes which (1) may have formed and thereafter sculpted the Oort cloud, and (2) may be responsible for producing the current population of short-period comets (i.e., those with periods shorter than 200 yr, hereafter called SP comets).

The current version of Oort's original theory is that comets formed as icy planetesimals on nearly circular orbits in the outer planetary system. Some of these accreted to form Uranus and Neptune, while the remainder were repeatedly scattered by the growing planets until they reached semimajor axes large enough for galactic tidal fields and stellar perturbations to remove their perihelia from the planetary region, after which they are relatively immune to planetary perturbations. The bodies which reach "safety" in this way comprise the comet cloud which is present today. Tidal torquing by the smooth distribution in the galactic disk has only recently been recognized as being more important (by a factor of 2 to 3) than stellar perturbations (Heisler and Tremaine 1986; Morris and Muller 1986; Smoluchowski and Torbett 1984; Torbett 1986) although stellar perturbations are still important in randomizing the orbits in the cloud (see, e.g., Weissman 1990) and occasional close stellar encounters can produce an unusually large influx of comets called comet showers (Hills 1981; Heisler 1990). Several competing theories of comet formation have been proposed (for example, that comets form *in situ* in the outskirts of an extended solar nebula), but they are not considered here (see Fernández 1985 for a review).

It has not yet been possible of course to follow the detailed evolution of the planetesimal swarm as the outer planets grew to their final masses. However, Duncan et al. (1987) have "picked up the story" at the stage when the outer planets have attained their final masses and have gravitationally

scattered a large fraction of the unaccreted planetesimals to semimajor axes of a few hundred AU (although the perihelia of the comets remained in the planetary region). Details of the approach used and approximations made in the numerical simulations may be found in the original reference. (See also a simulation using an Öpik approximation by Shoemaker and Wolfe [1984].) The simulations showed that planetary perturbations acting on moderately eccentric orbits caused a form of random walk in energy with little change in pericentric distance. Thus the formation of the comet cloud was driven by the interaction between planetary perturbations which drove diffusion in semimajor axis a at constant pericentric distance q , and galactic tidal torques which changed q at fixed a , thereby removing cometary perihelia from the planetary region for sufficiently large a . Consequently, a typical comet evolved more or less in the ecliptic plane with pericenter near to its birthplace until it was either ejected or torqued by the galactic tidal field into a roughly spherical cloud with a more nearly isotropic velocity distribution. An inner edge to the cloud was found at ~ 3000 AU—roughly the radius at which the time scales for the two effects are equal for comets formed in the Uranus-Neptune region. The density profile between 3000 and 50,000 AU is roughly a power law proportional to $r^{-3.5}$. The inner cloud ($a < 2 \times 10^4$ AU) thus contains roughly five times more mass than the classical Oort cloud.

Figure 4 depicts the evolution of the simulated comet swarm as a function of time. Note that the galactic plane in each snapshot is a horizontal line, so that the ecliptic is inclined at an angle of $\sim 60^\circ$ in these diagrams. The dotted circle in each snapshot is at a radius of 20,000 AU indicating the inner edge of the classical Oort cloud. It is evident from Fig. 4 that the distribution after 100 Myr was still biased toward the ecliptic for orbits with $a \lesssim 10^4$ AU. However, by 1 Gyr the distribution was isotropic for $a \lesssim 2000$ AU, and roughly 20% of the survivors were in the Oort cloud, with the remainder populating the inner cloud (except for the $\sim 4\%$ that became SP comets).

Between 1 and 4.5 Gyr, the total number of survivors decreased by a factor of ~ 2 , but the relative populations of the two clouds remained essentially unchanged. It is important to note, however, that the simulations did not include encounters with passing molecular clouds which may, over Gyr time scales, have a perturbing influence on the comets which is comparable to that of stars (Biermann and Lüst 1978; Biermann 1978; Bailey 1983*a*, 1986*a*). This is particularly true for comets with $a \gtrsim 2.5 \times 10^4$ AU which are not protected by adiabatic invariance (i.e., those with orbital periods longer than the duration of a typical encounter). However, the influence of molecular clouds is difficult to estimate because their physical parameters are so uncertain. Indeed, the large observed fractions of wide binary stars with separations of order 20,000 AU suggests that the Oort cloud has probably not been disrupted by giant molecular clouds (Hut and Tremaine 1985). Nonetheless, a complete treatment of the long-term dynamical evolution of the Oort cloud will probably require the inclusion of molecular clouds (cf. Heisler 1990).

Having discussed the formation and evolution of the reservoir which

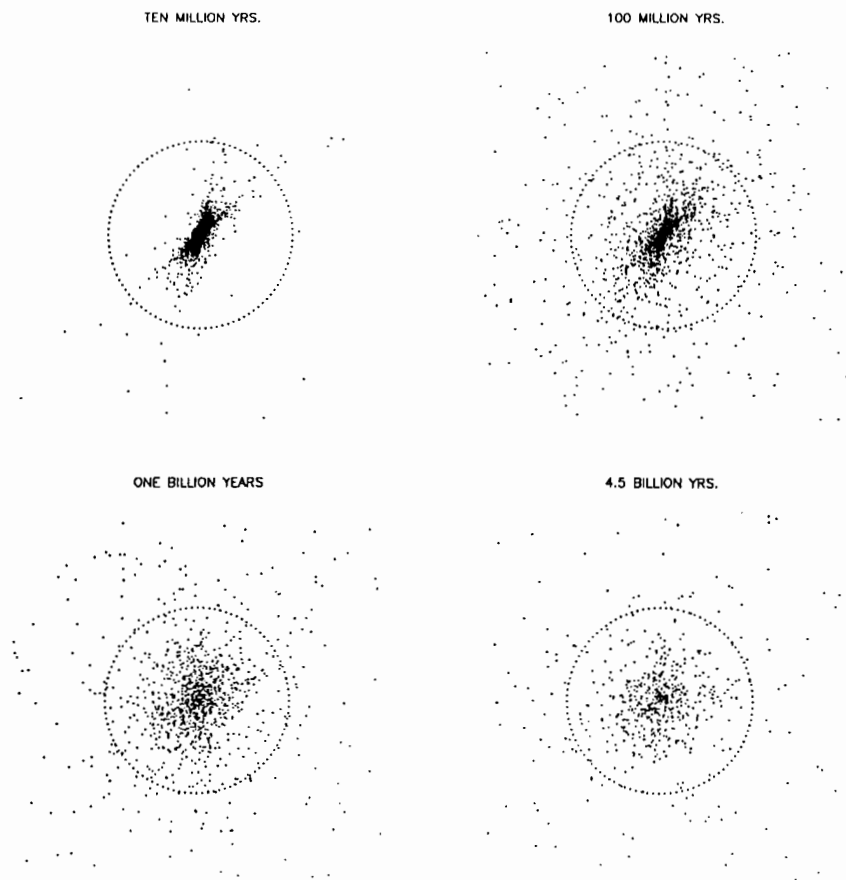

Figure 4. The formation of the Oort comet cloud in the simulation of Duncan et al. (1987). The galactic plane in each snapshot is a horizontal line. The dotted circle denotes a radius of 20,000 AU, indicating the inner edge of the classical Oort Cloud.

supplies the current population of long-period comets, let us now turn to the origins of the SP population. There are several striking features in the distribution of orbital elements of SP comets: (1) the distribution is strongly peaked towards periods $\lesssim 15$ yr; there are 100 known comets with orbital period $P \leq 15$ yr but only 21 with $15 \text{ yr} < P < 200$ yr (Marsden 1983); (2) the SP comets are mostly on low-inclination prograde orbits; out of 121 known SP comets, only four are on retrograde orbits; the inclinations i satisfy $\langle \cos i \rangle = 0.88$ ($\langle \cos i \rangle = 0$ for isotropic orbits and $= 1$ for prograde orbits in the ecliptic); (3) the arguments of perihelion ω (the angle between perihelion and ascending node) of the SP comets are strongly peaked near 0 and 180° .

Until recently, it has been believed that the SP comets originate in the Oort comet cloud. In an influential paper, Everhart (1972) argued from an extensive set of orbital integrations that repeated interactions with Jupiter can produce SP orbits from near-parabolic orbits, so long as the initial inclination is small and the initial perihelion distance is near the orbit of Jupiter. He showed that the distribution of orbital elements for SP comets formed by this mechanism agreed well with observations. There was immediate concern, however, that Everhart's mechanism might not produce the correct number of SP comets. Joss (1973) has argued that the efficiency of this process is too low (by a factor of order 10^3 to 10^4) to produce the observed number of SP comets from the known flux of near-parabolic comets, although Delsemme (1973) argued that the discrepancy could be removed by the proper inclusion of all return passages of comets initially from the Oort cloud. (See Stagg and Bailey [1989] and Yabushita and Tsujii [1991] for further references.)

In an ingenious Monte Carlo simulation, Everhart (1977) subsequently showed that a fraction of near-parabolic orbits with perihelion as large as Neptune's orbit will be gravitationally scattered by the outer planets into orbits that are Jupiter crossing and that a fraction of these will eventually become SP comets. In conventional models of the Oort cloud, the efficiency of this process is too low to remove the flux discrepancy noted by Joss. However, Bailey (1986*b*) has suggested that if a very massive inner Oort cloud (inner radius $\simeq 5000$ AU, mass $\simeq 700$ Earth masses) is present, the flux of near-parabolic comets into Neptune-crossing orbits may be sufficient to supply the SP comets. (Note however that this inner cloud is much more massive than that found in the simulations of Duncan et al. 1987.)

An alternative theory proposes that SP comets originate in a belt of low-inclination comets just beyond the orbit of Neptune, between about 35 and 50 AU (e.g., Fernández 1980; Fernández and Ip 1983). The belt could be a natural remnant of the outermost parts of the solar nebula (Kuiper 1951; Whipple 1964), possibly producing a component of the infrared background at $100\text{ }\mu\text{m}$ detected by IRAS (Low et al. 1984). IRAS data also indicates the presence of flattened dust shells around other stars, extending from 20 to 100 AU (see Weissman 1986*c* for a review). If some of the belt comets can be perturbed into Neptune-crossing orbits, subsequent scattering by the outer planets converts some of these into observable SP comets, in the manner described by Everhart (1977).

In order to test these two hypotheses, Duncan, Quinn and Tremaine (1988: hereafter called DQT88) performed an extensive series of numerical integrations of a representative sample of comet orbits in the field of the Sun and the giant planets. Comets which began with perihelia either near Jupiter (q between 4 and 6 AU) or in the outer planetary region (q between 20 and 30 AU) were integrated until the comet was either ejected or became visible to an Earth-based observer, which the authors assumed occurred when $q < 1.5$ AU. A numerical obstacle that the authors had to overcome was that orbital evolution can be a slow process: evolution from a Neptune-crossing orbit to

a visible orbit typically takes millions of orbits. However, as gravitational scattering is a diffusion process, the authors argued that multiplying the mass of all the giant planets by a fixed factor μ should change the rate of evolution but not the statistical properties of the final distribution of orbits. (We shall return to this point below.)

The results showed that the inclination distribution of comets with large perihelion ($q \lesssim 30$ AU) that evolve to observable comets (i.e., those with $q \lesssim 1.5$ AU) is approximately preserved. Thus, the short-period (SP) comets, which are mostly in prograde, low-inclination orbits, cannot arise from gravitational scattering of any spherical population of comets (such as the Oort cloud). However, the distribution of orbital elements of SP comets arising from a population of low-inclination Neptune-crossing comets is in excellent agreement with observations. The authors concluded that the SP comets arise from a cometary belt in the outer solar system (now called the Kuiper belt). An example of the agreement between the Kuiper belt simulations and the observed short-period comet orbital elements is shown in Fig. 5.

Stagg and Bailey (1989) have argued that a massive inner Oort cloud may still be a viable source for the SP comets if the mass enhancement factor used by DQT88 badly underestimated the effects of close encounters and if there exists a large population of unobserved extinct high-inclination comets. Quinn et al. (1990) have replied with a more extensive series of experiments, taking into account a variety of nongravitational and selection effects, and conclude that those SP comets with periods less than 20 yr (sometimes called the Jupiter family) cannot arise from an isotropic distribution. They argue that the results from simulations with $\mu = 40$ do not differ substantially from those with $\mu = 10$. Furthermore, Wetherill (1991a) used an Öpik (1951) approximation using Arnold's (1965a, b) method and $\mu = 1$ and obtained results very similar to DQT88. A definitive resolution to the problem requires an extremely CPU-intensive direct integration with $\mu = 1$, with modeling for observational selection effects and the finite lifetimes of comets.

If the proposed Kuiper belt indeed exists, two questions naturally arise: (1) as comets on Neptune-crossing orbits typically are ejected or evolve to SP comets on time scales which are much shorter than the age of the solar system, what mechanism injects comets from the Kuiper belt into planet-crossing orbits, and (2) can one detect the larger members of this putative belt? We shall return to a possible answer to the first question in the next section. Let us now briefly consider the second.

It is possible that the minor body Chiron (Kowal 1979) originated in the Kuiper belt. Chiron, which is a roughly 100-km-sized object, is on a Saturn-crossing orbit which is unstable on a time scale of 10^5 to 10^6 yr (Oikawa and Everhart 1979). It has recently been shown to exhibit cometary behavior (Luu and Jewitt 1990) such as the formation of a resolved coma (Meech and Belton 1990). Because of the short lifetime of its current orbit, it seems likely that it is representative of a much larger population of similar objects which currently reside in the Kuiper belt. Such objects might be detected by their

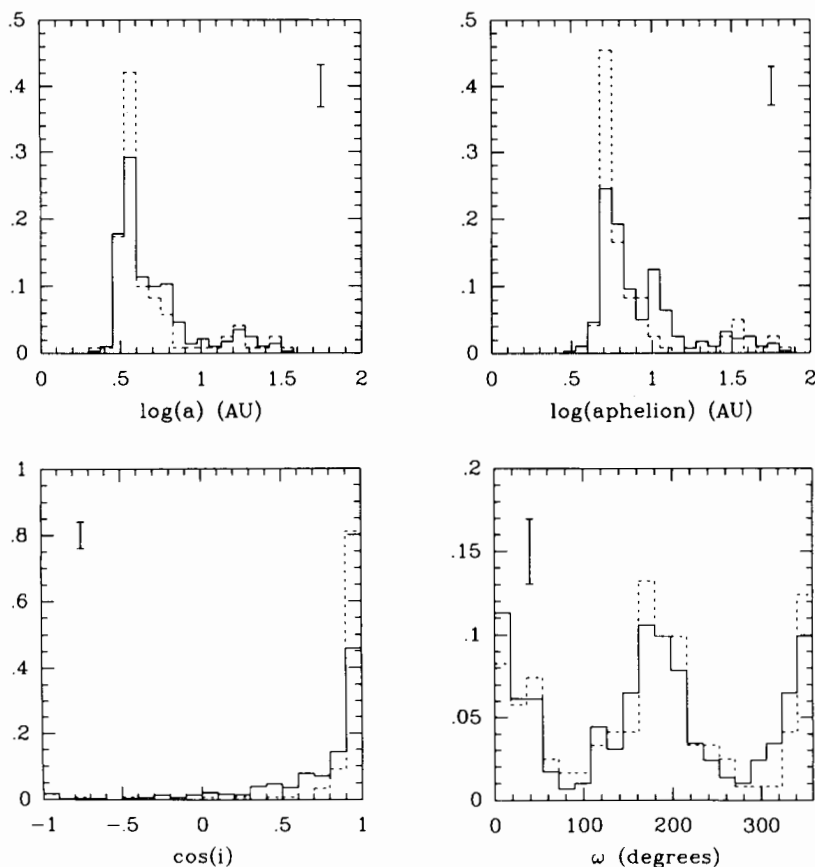

Figure 5. The solid histograms show the distributions of semimajor axis a , inclination i , argument of perihelion ω and aphelion for comets that evolve to short-period orbits with $q < 1.5$ AU in the simulations of Duncan et al. (1988). The initial inclinations are uniformly distributed in $\cos(i)$ for i between 0 and 18 deg, the initial perihelia are uniformly distributed between 20 and 30 AU and the initial semimajor axis is $a = 50$ AU. The dashed histograms show the distributions in the same four orbital elements for the comets in Marsden's (1983) catalog. Some typical statistical error bars are plotted. The histograms are based on 281 simulated comets and 121 observed comets.

retrograde motion as seen at opposition from the Earth, which amounts to roughly $150/r$ arcsec per hr, where r is the heliocentric distance of the object in AU. Figure 6 demonstrates the lower limit to the diameter of objects which could be detected at a given heliocentric distance for two assumed limiting magnitudes (assuming an albedo of 0.1). The proper motion corresponding to the distance is also shown. Note that Chiron itself would be fainter than $V = 22$ if it were beyond 40 AU.

Figure 6. Detectability of planetesimals in the outer solar system (based on an unpublished figure of W. Baum). The dashed curve (calibrated by the vertical scale on the right) shows the retrograde motion as seen from the Earth (in seconds of arc per hour) exhibited by an object in a low-eccentricity orbit at the indicated distance from the Sun. The two solid lines indicate the distance from the Sun out to which objects of a given diameter (calibrated by the vertical scale on the left) can be detected above a given limiting magnitude. The limiting magnitudes shown are $V = 22$ and 26 , respectively, assuming an albedo of 0.1 for the object. Shown for reference are the approximate diameter and semimajor axis of Chiron and the location of Neptune.

There have been four major proper motion surveys designed to search for objects in the outer solar system, and with the exception of Chiron, the surveys have found no objects. Figure 7 shows the upper limits to the surface density of objects in the sky as a function of the surveys' limiting magnitudes. However, as has been discussed in Levison and Duncan (1990), the lack of detections cannot be used to place severe constraints on the mass of the Kuiper belt because the size distribution of the belt members is unknown. Indeed, if all of the proto-comets had sizes less than 40 km, then no objects beyond 25 AU would have been detectable in Levison and Duncan's survey. Furthermore, we shall see in the next section that there are now theoretical reasons to believe that the region from Jupiter's orbit to somewhere beyond Neptune's orbit has been gravitationally swept clean of planetesimals. Thus,

the inner edge of the putative Kuiper belt is probably beyond 40 AU, making the detection of even Chiron-sized objects difficult (but not impossible).

Figure 7. Upper limits to the surface density of objects in the sky Σ , as a function of various surveys' limiting magnitudes in V . The symbols are: T = Tombaugh (1961), K = Kowal (1989), LJ(C) = Luu and Jewitt (1988) CCD work, LJ(S) = Luu and Jewitt (1988) Schmidt telescope, and LD = Levison and Duncan (1990) CCD survey.

V. CHAOTIC ORBITS IN THE OUTER PLANETARY REGIONS

In a sense, the solar system seems to be remarkably devoid of objects. In the generally favored model for the formation of the solar system discussed in other chapters, the planets accumulate through the accretion of vast numbers of planetesimals that formed on nearly circular orbits in the early solar system. As it is unlikely that all of these objects would have been incorporated into the present planets, a question that immediately arises is: can any of these objects have survived to the present day? Because of the physical complications present in the early solar system (e.g., gas drag, nebular dispersal, etc.) one can ask the following simplified question: are there any regions in the *current* solar system where test particles (negligible mass) placed on initially circular orbits are stable against having a future close approach with one of the giant planets? Having a close approach is not in itself a guarantee of ejection (although over sufficiently long time scales it usually is) but it usually means that the orbit is chaotic.

A complete answer to this question would of course require the direct integration over Gyr time scales of all of the planets together with many test

particles distributed between them. This is not technically feasible at this time (see Sec. VII). More modest investigations over shorter time spans have been performed for the case of test particles between Jupiter and Saturn by Lecar and Franklin (1973) and Franklin et al. (1989). In the first of these papers, a band of semimajor axis was discovered in which initially low eccentricity orbits were found to be stable over the time scales studied (500 Jupiter orbits). In the second paper, the stable region (between 1.30 and 1.55 Jupiter semimajor axes) was studied more intensely, and the authors concluded that essentially no particles between Jupiter and Saturn were stable against becoming planet crossers for longer than 10 Myr.

Wisdom (1980) showed for the planar, circular restricted 3-body case that there exists a band in semimajor axis centered on each planet's semimajor axis within which virtually all test particle trajectories are chaotic due to resonance overlap. These chaotic zones are shown for each planet as the shaded regions in Fig. 8.

Gladman and Duncan (1990) have performed the longest and most accurate integrations to date of the evolution of a swarm of test particles on initially circular orbits ranging from the outer asteroid belt to the Kuiper belt. Using a very accurate symplectic integration scheme (Gladman et al. 1991), the orbits of roughly one thousand test particles were followed for up to 22 Myr. The test particles were placed on initially circular orbits about the Sun and felt the gravitational influence of the Sun and four (or in some cases two) of the giant planets. The initial conditions of the planets were obtained from their current orbital elements and their mutual gravitational interactions were fully included. Test particles that underwent a close approach to a planet were removed from the integration.

The dynamical clearing of gaps found near some of the resonances with Jupiter in the asteroid belt has been discussed in Sec. III. Exterior to Neptune there appeared to be a dynamical erosion of the inner edge of the Kuiper belt, although, as we shall see, much longer integrations are needed in this region. The majority of the test particles *between* the giant planets were perturbed to a close approach to a planet on time scales of millions of years. These results suggest that there are very few initially circular orbits between the giant planets that are stable against a close approach to a planet over the lifetime of the solar system. This may explain the apparent absence of a large number of minor bodies between the giant planets discussed in the last section.

The results of the simulations are summarized in Fig. 8. As stated above, with the exception of regions in the asteroid belt and the outer Kuiper belt, most of the orbits become planet crossing on surprisingly short time scales. This of course raises some rather disturbing questions about the stability of the planets themselves (see the next section) and may have implications in the field of planetary formation (see Gladman and Duncan 1990).

An approximate mapping technique described in Duncan et al. (1989) suggested that most near-circular orbits with semimajor axes >33 AU (i.e.,

Figure 8. Composite diagram of removal times for all of the simulations of Gladman and Duncan 1990. The single-planet crossing zones (see text) of the giant planets are shaded. A cross at the upper portion of the diagram indicates that all three of the test particles placed on an initially circular orbit at that semimajor axis were removed. The top of a histogram bar indicates the removal time of a test particle originally at that value of semimajor axis. The simulation ran 22.5 Myr (indicated by the horizontal line). See the text for additional explanations.

in the proposed Kuiper belt) were stable against becoming Neptune crossers over the lifetime of the solar system. However, Torbett (1989) performed direct numerical integration of test particles in this region including the perturbative effects of the four giant planets, although the latter were taken to be on fixed Keplerian orbits. He found evidence for chaotic motion with an inverse Lyapunov exponent on the order of Myr for moderately eccentric, moderately inclined orbits with perihelia between 30 and 45 AU (a “scattered disk”). Torbett and Smoluchowski (1990) extended this work and suggested that even particles with initial eccentricities as low as 0.02 are typically on chaotic trajectories if their semimajor axes are <45 AU. Except in a few cases, however, the authors were unable to follow the orbits long enough to establish whether or not most chaotic trajectories in this group led to Neptune crossing. Levison (1991) treated the same question as a diffusion problem and used direct integrations over short time scales to calculate diffusion co-

efficients on a grid of perihelion vs aphelion. Using the theory of Markov chains he found using this approach that objects tend to diffuse through a surprisingly large region of 70 AU in extent over the lifetime of the solar system. He argued that even objects that formed near Neptune have a significant chance of evolving to orbits with $a > 100$ AU and can subsequently diffuse back on Gyr time scales to become Neptune crossers and potentially short-period comets. Levison's approach has the potentially serious drawback that the "diffusion coefficients" may only measure the linear part of long-term sinusoidal variations in the orbital elements which may average out over time. Nonetheless these provocative results make it clear that longer direct integrations are needed in order for us to understand the long-term behavior of the Kuiper belt.

Having considered the somewhat surprising results for the stability of *test* particles in the solar system, and having discussed promising areas for future work, let us now turn to the question of the stability of the planets themselves.

VI. LONG-TERM STABILITY OF THE PLANETS

We return now to one of the oldest problems in dynamical astronomy: whether the planets will continue indefinitely in nearly circular, nearly co-planar orbits. As we have described in Sec. III, if a Hamiltonian system has an integral of motion for each degree of freedom, then the system will be quasi-periodic, as can be shown by expressing the Hamiltonian in terms of action-angle variables. The orbits will be confined to a multi-dimensional torus and the orbital elements should be describable by a sum of periodic terms in the sense that the Fourier transform of the time evolution of any planet's coordinates will involve only integer combinations of the fundamental frequencies (one per degree of freedom). Arnold (1961) has shown that such stable orbits would describe the solar system if the masses, eccentricities and inclinations were sufficiently small. The real solar system, however, does not satisfy Arnold's requirements, so the question of its stability is unresolved. Laplace and Lagrange showed that, if the mutual planetary perturbations were calculated to first order in the masses, inclinations and eccentricities, the orbits could indeed be described by a sum of periodic terms, indicating stability. Successive work by Brouwer and van Woerkom (1950), Bretagnon (1974) and others has shown that this is still the case if the perturbations are expanded to higher orders. However, the work of Poincaré (1892) casts doubt on the long-term convergence of the various perturbation schemes. The problem with the perturbation expansion is that although the expansion is done in powers of small parameters, the existence of resonances between the planets will introduce small divisors into the expansion terms. Such small divisors can make high-order terms in the power series unexpectedly large and destroy the convergence of the series.

In particular, the method of Laplace involves considering the disturbing function averaged over the mean motions of the planets, known as the secular

part of the disturbing function. If the disturbing function is further limited to terms of lowest order, the equations of motion of the orbital elements of the planets can be expressed as a coupled set of first-order linear differential equations. This system can then be diagonalized to find the proper modes, which are sinusoids. The evolution of a given planet's orbital elements is, therefore, a sum of the proper modes. With the addition of higher-order terms, the equations are no longer linear; however, it is sometimes possible to find a solution of a form similar to the linear solution, except with shifted proper mode frequencies and terms involving combinations of the proper mode frequencies (Bretagnon 1974).

There are two separate points in the construction of the secular system at which resonances can cause nonconvergence of the expansion. The first is in averaging over mean motions. Mean-motion resonances between the planets can introduce small divisors leading to divergences when forming the secular disturbing function. Secondly, there can be resonances between the proper mode frequencies leading to problems trying to solve the secular system using an expansion approach.

Laskar (1989) performed a critical test of the quasi-periodic hypothesis by numerically integrating the perturbations calculated to second order in mass and fifth order in eccentricities and inclinations. Such an expansion consists of about 150,000 polynomial terms. By numerically integrating the secular system, he avoids the small divisor problem caused by resonances between proper modes. The Fourier analysis of this 200-Myr integration showed that it was not possible to describe the solution as a sum of periodic terms. Laskar also estimated the maximum Lyapunov exponent by the divergence of nearby orbits. The Lyapunov exponent should be zero for quasi-periodic orbits. Instead, he found the surprisingly high value of $(1/5 \text{ Myr}^{-1})$. In a subsequent paper, Laskar (1990) argued that the exponential divergence is due to the transition from libration to circulation of the critical argument of a secular resonance related to the motions of perihelia and nodes of the Earth and Mars. He argued from his results that the chaotic nature of the inner solar system is robust against small variations in the initial conditions or in the model. These very important conclusions must clearly be checked by direct numerical calculations (see below).

The analytical complexity of the perturbation techniques and the development of ever faster computers has led others to the investigation of stability by purely numerical models. The first numerical computation of planetary orbits was by Eckert et al. (1951) who did a simulation of the outer planets for 350 yr. This was extended by Cohen and Hubbard (1965) and Cohen et al. (1973) to 120,000 yr and 1 Myr, respectively. These integrations compared well with the perturbation calculations of Brouwer and van Woerkom, showing quasi-periodic behavior for the four major outer planets. Pluto's behavior, however, was sufficiently different to inspire further study. Williams and Benson (1971) performed a 4.5 Myr integration of the secular motion of Pluto under the influence of the four Jovian planets. The motion of the Jovian

planets were determined from Brouwer and van Woerkom's (1950) analytic solution. They found that the angle $3\lambda - 2\lambda_N - \varpi$ was in libration with a period of 20,000 yr, where λ and λ_N are the mean longitudes of Pluto and Neptune, respectively, and ϖ is the longitude of perihelion of Pluto. As well, they found that the argument of perihelion of Pluto librates with a period of 4 Myr and that the angles $\Omega - \Omega_N$ and $\varpi - \varpi_N$ seemed to be in resonance with this libration. All these resonances acted to prevent close encounters of Pluto with Neptune and hence protect the orbit of Pluto.

The longest numerical integration done on general purpose computers was the LONGSTOP 1B integration done by Nobili et al. (1989) which ran for 100 Myr. This integration followed the mutual interactions of the 5 outer planets, but also included the secular effects of the inner planets and the effects of general relativity. They have shown that these latter effects significantly affect the orbits over the time span of their integrations. Spectral analysis of their results suggested but did not prove that the orbits are chaotic. The evidence for this are regions of the spectrum where many lines of comparable amplitude accumulate, indicating that the series of Fourier terms is not converging.

Integrations of the outer planets for period up to 845 Myr or 20% of the age of the solar system have been done with a special purpose machine: the Digital Orrery (Applegate et al. 1986; Sussman and Wisdom 1988). This machine consists of one CPU per planet, with all the CPUs arranged in a ring. A force evaluation for all planets is accomplished in $\mathcal{O}(N)$ time instead of the usual $\mathcal{O}(N(N-1)/2)$, and the integration is performed in $\mathcal{O}(1)$ time. A disadvantage of using such a machine is that the nature of the force calculations are "hard wired" and the inclusion of effects such as general relativity could not be accomplished without a rebuild of the machine. The dynamical system investigated by the Orrery is therefore slightly different than that investigated by Nobili et al. The longest of the integrations performed on the Orrery show that Pluto's orbit is not quasi-periodic. There is evidence for the existence of very long period changes in Pluto's orbital elements and Sussman and Wisdom (1988) calculate a Lyapunov exponent of $(1/20 \text{ Myr}^{-1})$. This has recently been confirmed using a symplectic integrator by Wisdom and Holman (1991). A subsequent re-examination of the LONGSTOP 100 Myr data led Milani et al. (1989) to suggest that Pluto is locked in a complicated system of three resonances and that the value of the Lyapunov exponent for its motion could be sensitive to the assumed initial conditions and planetary masses. Thus, a detailed understanding of Pluto's behavior is likely to be obtained only with the next generation of simulations (see Sec. VII).

The detection of such large Lyapunov exponents indicates chaotic behavior. However, the apparent regularity of the motion of the Earth and Pluto and indeed the fact that the solar system has survived for 4.5 Gyr implies that the chaotic regions must be narrow. What the chaotic motion does mean (if confirmed) is that there is a horizon of predictability for the detailed motions of the planets. Thus, the exponential divergence of orbits with a 5 Myr time

scale claimed by Laskar means that an error as small as 10^{-10} in the initial conditions will lead to a 100% discrepancy in 100 Myr.

Until very recently, the length of direct integrations was limited, not by CPU time, but by round-off error. Milani and Nobili (1988) concluded that it was impossible to integrate reliably the orbits of the outer planets for a period of 10^9 yr or more with then current computer hardware and software. The main problems they found were limited machine precision, and the empirical evidence that the longitude error after n steps was proportional to n^2 instead of $n^{3/2}$, as expected if the round-off errors were uncorrelated. However, Quinn and Tremaine (1990) have proposed several corrections to the integration algorithms which considerably reduce the round-off error, and Quinlan and Tremaine (1990) have proposed a high-order symmetric scheme. Taken together, these two techniques appear to maintain a longitude error growth which is linear in the number of steps and which may therefore allow for accurate integrations of the planets for tens of Gyr. Another promising avenue for certain solar system integrations are the symplectic schemes designed specifically to maintain the Hamiltonian structure of such systems of equations (see, e.g., Yoshida 1990; Gladman et al. 1991; Forest 1991; Wisdom and Holman 1991).

The longest accurate integration of the entire solar system as of this writing is an integration of the nine planets and the Earth's spin axis for 3.05 Myr into the past (Quinn et al. 1991). Previously, Richardson and Walker (1987,1989) performed a 2 Myr integration of all nine planets, but they neglected the rather important effects (for the inner planets) of General Relativity and the finite size of the Earth-Moon system. Quinn et al. (1991) have computed the long-term variations (periods >2000 yr) of the orbital elements of all the planets and the Earth's spin direction. These can be used to check or replace the results of secular perturbation theory and as input into geophysical models that test the Milankovich hypothesis that climate variations are caused by changes in the Earth's orbit. All of the planetary orbits appear to be regular over the 3 Myr integration span. This integration was not long enough to detect the chaotic motion found by Laskar, but the two simulations are in remarkable agreement over their common range. In particular, the numerical integrations demonstrated the same secular resonance which Laskar claims is responsible for the chaos seen in his longer simulation.

VII. SUMMARY AND PROSPECTS FOR THE FUTURE

We have shown how the results from research in nonlinear Hamiltonian systems can be used to help us understand the newly emerging picture of the long-term dynamical evolution of orbits in the solar system. Although algebraic mappings, analytic approaches and perturbation theory have greatly aided our intuition in such nonlinear problems, much of our understanding usually comes initially from numerical simulations. It is straightforward to estimate that with an efficient and sufficiently accurate integration scheme it

will require roughly 10^{16} floating point operations to integrate the equations of motion of a model solar system for a simulation time of 5 Gyr. This corresponds to a total of roughly 100 Mflop-years, where 1 Mflop is a million floating point operations per second. Although the floating point speeds of the fastest workstations are currently 20 Mflops, solar system simulations are ideally suited to the sorts of modest parallelism (4–64 processors) that can boost system performance by an order of magnitude, as has been demonstrated by the Digital Orrery. As a result, the ability to perform simulations of the evolution of model solar systems over interesting time scales are now becoming feasible. It is also clear from what has been discussed here and elsewhere (see, e.g., the Chapter by Lissauer and Stewart; Wetherill 1991c) that long-range gravitational interactions must have influenced planet formation itself. It is now possible to undertake more realistic simulations of the late stages of planet formation, including the long-range mutual interactions of the planetary embryos. We are thus at the dawn of a new era—that of the numerical exploration of the solar system.

Acknowledgments. The authors acknowledge helpful discussions with B. Gladman, H. Levison, G. Quinlan, S. Tremaine and P. Weissman. MJD is grateful for continuing financial support from the Natural Sciences and Engineering Research Council of Canada.

COLOR SECTION

Plate 1. A true-color near-infrared ($1\text{--}2.5\ \mu\text{m}$) image of the IC 348-IR region, covering $\sim 3.2 \times 3.2$ arcmin ($\sim 0.3 \times 0.3$ pc at 300 pc). Images at three different near-infrared wavelengths (1.2 , 1.65 , and $2.1\ \mu\text{m}$) were superimposed to create this composite, the first as blue, the second as green, the last as red, giving a true indication of the near-infrared colors of sources. For example, objects that are generally hot and/or relatively unobscured by dust appear as bluish, while cooler objects and/or those hidden by dust at the shorter wavelengths appear orange and red. The true-color images shown in Plates 2, 4, 5, and 6 were made with the same technique. In this image of IC 348-IR, a previously unknown jet-like feature is revealed, possibly a Herbig-Haro object. The associated driving source, which must be a very young and highly obscured star, has not yet been identified. The data were obtained using a 256×256 pixel HgCdTe array on the University of Hawaii 2.2-m telescope. (See the chapter by Zinnecker et al.)

Plate 2. A true-color near-infrared ($1\text{--}2.5\,\mu\text{m}$) mosaic covering the central 5×5 arcmin ($\sim 0.65 \times 0.65$ pc at 450 pc) of the Trapezium Cluster. Some 500 stars are seen to a completeness limit of $K\sim 15.5$ mag. The data were obtained using a 62×58 pixel InSb array on the United Kingdom 3.8-m Infrared Telescope (McCaughrean et al. 1992). (See the Chapter by Zinnecker et al.)

Plate 3. For comparison with Plate 2, an optical photograph of the same region is shown (photograph taken at the Anglo-Australian Telescope, and kindly provided by D. Malin). (See the Chapter by Zinnecker et al.)

Plate 4. A true-color near-infrared ($1\text{--}2.5\ \mu\text{m}$) mosaic of the H II region S 106, covering $\sim 10 \times 10$ arcmin ($\sim 1.75 \times 1.75$ pc at 600 pc). The data were obtained using a 256×256 pixel HgCdTe infrared array at the University of Hawaii 2.2-m (Rayner 1992). Some 200 stars are probable members of a cluster centered near S 106 IRS 4. (See the Chapter by Zinnecker et al.)

Plate 5. A true-color near-infrared ($1\text{--}2.5\,\mu\text{m}$) mosaic of M 17 covering $\sim 9\times 9$ arcmin ($\sim 5.8\times 5.8$ pc at 2.2 pc). Approximately 100 stars (B9 or earlier) towards the center of the image have been identified as cluster members. The data were obtained using a 256×256 pixel PtSi array on the KPNO 2.1-m telescope (courtesy National Optical Astronomy Observatories). (See the Chapter by Zinnecker et al.)

Plate 6. A true-color near-infrared ($1\text{--}2.5\ \mu\text{m}$) mosaic of the S 255/S 257/S 255-IR region covering 8×5.2 arcmin ($\sim 5.8\times 3.8$ pc at 2.5 kpc). At left center and right center are the two B0 stars which excite the H II regions S 255 and S 257: note that they have no cospatial clusters. Between the two H II regions, the infrared cluster associated with the source S 255-IR is seen. The data were obtained using a 128×128 HgCdTe infrared array at the Steward Observatory 2.3-m telescope (McCaughrean et al. 1991). (See the Chapter by Zinnecker et al.)

Plate 7. A Hubble Space Telescope image of a portion of the Orion Nebula west of the bright star θ^2 A Ori. Red indicates [N II] emission, green $H\alpha$, and blue [O III]. Orion is a well known region of recent star formation, including stars of less than one million years age. This image shows the main ionization front as a bright bar. Extending above the bar is a shock front with the Herbig-Haro object M42-HH3 as the brightest portion. Such objects are believed to be formed by the interaction of a jet of high-velocity material originating from a young star with ambient nebular gas. Recent observations show evidence for protoplanetary disks around many of the young stars. These disks are ionized from the outside by the hot, massive stars in the nebula and the resulting outflow of gas is distorted by the stellar wind from the same stars. One of these disks is seen at the upper right, just below the bright bar and the HH3 plume. Filters isolating continuum emission show a young star near the center of this object (courtesy of C. R. O'Dell, Rich University).

Glossary

GLOSSARY*

AGB star	asymptotic giant branch star; a large red giant, 100–1000 solar radii, with a hot carbon-oxygen white dwarf at its center. Such stars are precursors of planetary nebulae, and get their name from the path they take on a H-R diagram (plot of luminosity versus effective temperature).
Alfvén surface	geometric surface in a magnetized wind where the poloidal components of the flow speed and of the local Alfvén speed are equal.
Alfvén velocity (v_A)	the speed at which hydromagnetic waves are propagated along a magnetic field: $v_A = B/(4\pi\rho)^{1/2}$, where B is the magnetic field strength and ρ is the density.
Allende meteorite	A C3 carbonaceous chondrite which fell in northern Mexico on 1969 February 8. It is one of the largest recorded stony meteorite falls and one of the most primitive examples in the solar system. Almost 2 tons of material were recovered, with the largest stone having a mass of 15 kg. The meteorite was later found to have many isotopic anomalies—e.g., an excess of ^{26}Mg which can most plausibly be attributed to <i>in situ</i> decay of ^{26}Al (half-life 7×10^5 yr). The oxygen ratios in the different inclusions are different from each other and also different from the rest of the solar system. Variations in Ca, Ba, and Nd also exist.

Hopkins (by permission of the University of Chicago Press, copyright 1980 by the University of Chicago), from *Astrophysical Quantities* by C. W. Allen (London: Athlone Press, 1973), and from *The Planetary System* by David Morrison and Tobias Owen (Reading, Mass.: Addison-Wesley Publishing Co., 1988). We also acknowledge definitions and helpful comments from various chapter authors.

"alpha model"	a heuristic model for turbulence in which the angular momentum transport is parameterized in terms of an eddy (or turbulent) viscosity. This viscosity in turn is proportional to the turbulent velocity and the characteristic length scale in the problem, the constant of proportionality being traditionally labeled "alpha."
ANEOS equation	a semi analytic equation of state that links pressure, temperature and density for materials of interest in impact computations.
Arrhenius relationship	the rate of a chemical reaction is inversely proportional to the exponential of the inverse temperature, times a constant.
AU	the mean distance between Earth and Sun (1.496×10^{13} cm \simeq 500 light seconds).
Barnett effect (in interstellar grains)	paramagnetic relaxation associated with the internal magnetic field produced directly by grain rotation.
BN-KL	the Becklin-Neugebauer Object/Kleinman-Low Nebula region, a small dense region in the Orion Molecular Cloud that contains luminous IR sources, interstellar and circumstellar masers, hot gas, and young stars. It is the nearest location of active star formation.
bolometric	referring to electromagnetic radiation received from an object at all wavelengths of the spectrum.
brown dwarf	a stellar-like object which is not massive enough to sustain hydrogen fusion as its main source of luminosity, but instead radiates by virtue of the energy of collapse of the original gas from which it formed.
Brownian motion	random motion of microscopic particles suspended in a gas due to collisions with gas molecules.
CAI	Ca-, Al-rich inclusions; mm- to cm-size components of chondritic meteorites. Compositions are greatly depleted from cosmic in the relatively volatile elements, hence enriched in Ca, Al, and other involatile elements. They are thought to have formed as dispersed objects in the solar nebula, at high temperatures.

carbonaceous chondrites types 1,2,3	a rare type of chondrite (about thirty are known) characterized by the presence of carbon compounds. Carbonaceous chondrites are the most primitive samples of matter known in the solar system. They resemble the solid material expected when a gas cloud of solar composition cools to a temperature of about 300 K at low pressure. Wiik (1956) classification: Type C1 are the least dense and are strongly magnetic. They are the most primitive and show only minimal chemical alteration. Type C2 are weakly magnetic or nonmagnetic. Type C3 are the densest, are water-poor, and usually are largely olivine.
Cassini state	particular obliquity states of tidally locked satellites for which the spin direction, the normal to the orbit plane and the normal to the invariable plane (roughly the planet's equatorial plane) are all coplanar.
CDW	centrifugally driven wind.
CHON	an acronym for the organic grains found in comet Halley, and composed of Carbon, Hydrogen, Oxygen, and Nitrogen.
Class I and II sources	a class I source is a deeply embedded, usually invisible, young stellar object with a spectral energy distribution that rises with increasing wavelength of 2.2 microns. Class I sources are believed to be extremely young, and, at least for relatively low luminosity objects (i.e., $L < 100$ solar luminosities), protostellar in nature. A Class II source is a young stellar object whose spectral energy distribution decreases with increasing wavelength longward of 2.2 microns. Such objects are often visible and have energy distributions which are power-like in form in the near to mid infrared. Classical T Tauri stars are typically Class II sources. The energy distribution of a Class II source is often well modelled by emission from a circumstellar disk.
classical novae	explosions that result from thermonuclear runaways on the surfaces of white dwarfs accreting matter in close binary systems.

Clausius-Clapeyron relation	equation describing the dependence of pressure on temperature at the boundary between two phases of a substance in equilibrium.
cometesimal	an icy planetesimal.
coronagraph	device used to block light from a bright object to allow examination of surroundings like the corona of the Sun or the dust disk around beta Pictoris. A complete coronagraph consists of a focal-plane or sky-plane mask to eliminate direct light plus a pupil-plane mask to reduce light scattered in the telescope and instrument.
Coulomb barrier	the potential energy "hill" due to the repulsive electrostatic force between like-charged particles. For nuclear reactions, the Coulomb barrier acts to bar low energy (energies less than the height of the barrier) positively charged particles from approaching the positively charged atomic nucleus to the point where a nuclear reaction can proceed.
Drake equation	an empirical formula which relates the number of possible intelligent civilizations in the galaxy to various well-known and poorly known physical parameters such as star and planetary system formation rates, etc.
DEIS	deeply embedded infrared source.
Eddington limit L_{EDD}	in essence, for the stability of a star, radiation pressure must not exceed gravitational pressure. It is the luminosity limit beyond which the radiation force on hydrogen atoms is greater than the gravitational force binding them to the star.
Einstein coefficient	an emission (or absorption) coefficient. A_{ji} is the coefficient of spontaneous emission; B_{ji} is the coefficient of stimulated emission; B_{ij} is the coefficient of absorption, where i is the lower level and j is the upper level.
Ekman layer	upper boundary layer within which the amplitude of a wave changes exponentially.

fake Zeeman splitting	circular polarization of a spectral line that mimics Zeeman splitting, but that is in fact a result of linear birefringence.
Faraday rotation	rotation of the position angle of linear polarization in a magnetized plasma.
Fischer-Tropsch reactions	production of organic molecules by the hydrogenation of carbon monoxide in the presence of a suitable catalyst.
FMS	fast magnetosonic wave speed.
force-free field	in MHD, a magnetic field configuration that is characterized by a vanishing net stress and arises when the magnetic terms dominate all other terms in the equation of motion.
FWHM	full width at half maximum.
Gould's belt	the local system of stars and gas within about 300 pc of the Sun. It is an expanding belt ≤ 1 kpc in diameter and inclined about 20° to the galactic plane in which OB stars, young clusters and associations, and dark clouds are concentrated. Discovered by B. Gould in 1879. It is a source of high-energy γ -rays.
GRO	Gamma Ray Observatory, now operational and called the Compton Gamma Ray Observatory, one of NASA's Earth-orbiting "Great Observatories," designed to observe astrophysical gamma ray sources at high spatial and spectral resolution.
Hamiltonian systems	systems for which the dynamical evolution from a given star initial state is governed by Hamilton's equations of classical mechanics.
Hayashi phase	the period of pre-main-sequence stellar evolution during which a star has negligible nuclear energy production and has sufficiently low internal temperatures so that convective energy transport dominates through most or all of the interior. The star evolves in the H-R diagram with decreasing luminosity and nearly constant effective temperature.

Herbig-Harbo objects (HH objects)	small, faint patches of nebulosity seen on the surfaces of many dark clouds, believed to be a very early phase of stellar evolution. All known Herbig-Haro objects have been found within the boundaries of dark clouds. They are strong infrared sources and are characterized by mass loss.
High-Z material	in stellar and planetary models, that component composed of atoms with an atomic number higher than 2.
Hill's approximation	an approximation for the equations of nearly circular and planar motion of bodies in a central gravitational field, under which these equations can be linearized. This is a special case of so-called "epicyclic approximation."
HR diagram	Hertzsprung-Russell diagram; a plot of luminosity versus spectral type. More loosely, a plot of magnitude versus color. In present usage, a plot of bolometric magnitude against effective temperature for a population of stars. Related plots are the color-magnitude plot (absolute or apparent visual magnitude against color index) and the spectrum-magnitude plot (visual magnitude versus spectral type, the original form of the HR diagram).
HST	Hubble Space Telescope, the first of NASA's orbiting "Great Observatories," designed to provide high spatial and spectral resolution observations of objects in the ultraviolet, visible and (eventually) near-infrared.
Hubble law	also called law of redshifts, the distance of galaxies from us is linearly related to their redshift. More generally, the relative velocity (resulting from large-scale cosmic expansion) between particles that are <i>locally</i> at rest is proportional to their separation. Discovered by Hubble in 1929.
Hubble time (H_0^{-1})	the characteristic age of the universe since the big bang ($19.4 \pm 1.6 \times 10^9$ yr for $H_0 = 50$ km per second per megaparsec and a constant expansion rate).

Hugoniot curve/ equation	the relation between pressure and volume of material subjected to sudden shock compression, also known as the Hugoniot shock relation. These equations express the conservation of mass, energy and momentum across the shock.
IKS	InfraKrasnoi Spectrometre (an infrared spectrometer flown on the Vega 1 and Vega 2 spacecraft).
Initial mass function (IMF)	the distribution of stellar masses at birth; relative number of stars formed per unit mass.
IRAS	Infrared Astronomical Satellite; joint UK-USA-Dutch satellite which provided the first surveys of the sky at thermal infrared wavelengths with moderate spatial and spectral resolution.
ISO	Infrared Space Observatory, a European infrared space telescope to be launched in (approximately) 1993.
JANAF tables	numerical tables of thermochemical data on a wide variety of substances, published by the U.S. Department of Commerce.
jansky (Jy)	unit of flux density adopted by the IAU in 1973. $1 \text{ Jy} = 10^{-26} \text{ W m}^{-2} \text{ Hz}^{-1}$; named after Karl Jansky, who discovered galactic radio waves in 1931.
Jeans escape formula	a formula giving the rate of thermal escape of molecules from an atmosphere.
Jeans instability	gravitational instability in an idealized, infinite, homogeneous medium.
Jeans length	the critical wavelength at which the oscillations in an infinite, homogeneous medium become gravitationally unstable. Any disturbance whose characteristic dimension is greater than the Jeans length will decouple by self-gravitation from the rest of the medium to become a stable, bound system.
Jeans mass	the mass necessary for protostellar collapse $M_j \geq 1.795(RT/G)^{3/2}\rho^{-1/2}$, where R is the gas constant, T the cloud temperature, G the gravitational constant, and ρ the cloud density.

Jeans rate	the characteristic rate of collapse or evolution of a gas at density ρ , equal to about $(4\pi G\rho)^{1/2}$, that results from self-gravitational attraction.
Julian Date (JD)	the Julian day number followed by the fraction of the day elapsed since the preceding noon. The Julian day number is the number of days that have elapsed since Greenwich noon on January 1, 4713 B. C. The Julian period was worked out by Joseph Scaliger and applied in 1582, the year the Gregorian calendar was adopted. The Julian period contains exactly 7980 Julian yr of 365 1/4 days each.
Kelvin-Helmholtz instability	the tendency of waves to grow on a shear boundary between two regions in relative motion parallel to the boundary.
Kelvin-Helmholtz time	the time over which a self-gravitating star radiates away enough thermal energy to contract by a significant fraction of its initial radius. It is assumed that the star is not being supported by internal nuclear fusion.
Keplerian shear	the velocity gradient that results from the differential rotation of particles whose orbits about a massive primary obey Kepler's Laws.
Kirchhoff's laws	(1) To each chemical species there corresponds a characteristic spectrum. (2) Every element is capable of absorbing the radiation which it is able to emit; it gives rise to the phenomenon of the reversal of the lines. A precise statement of the second law is that the absorption coefficient (κ_v) of material in thermal equilibrium at a temperature T is related to the emissivity (j_v) by $\kappa_v = j_v B_v(T)$, where $B_v(T)$ is the Planck function for the temperature T .
Knudsen number	the ratio of the mean free path length of the molecules in a fluid to a characteristic length of the structure in the fluid stream.
Kolmogorov spectrum	in a homogeneous and isotropic turbulent medium, energy is continually transferring between turbulent eddies of different sizes. The distribution of energy cascading down the different scales is referred to as the Kolmogorov spectrum.

Kolmogorov turbulence	turbulence, as in a laboratory, that appears to satisfy the scaling relation proposed by Kolmogorov (1941), namely, relative velocity proportional to the cube root of separation.
Kramers-Kronig dispersion relation	relates the real and imaginary parts of the dielectric constant of a medium.
Kuiper disk or belt	hypothetical component of our planetary system extending in the ecliptic plane beyond the planetary region out to the Oort cloud. Proposed as a dynamically plausible reservoir for short-period comets.
Langevin theory	a theory which explains diamagnetic and paramagnetic properties of materials in terms of a classical picture (Langevin, P. 1905. <i>Ann. Chim. Phys.</i> 5:245).
Langrangian points	the five equilibrium points in the restricted three-body problem.
Lindblad resonance	a resonance of first order in the eccentricity of a perturbed particle. This terminology comes from galactic dynamics; in the 1920s Lindblad invoked such resonances to explain spiral arms.
Lindblad's ring	a ring of neutral gas, discovered by Lindblad et al. (1973), that surrounds the Sun at a distance of several hundred parsecs and expands away from the local standard of rest in all directions at a speed of several kilometers per second (from Lindblad, P. O., Grape, K., Sandqvist, Å., and Schober, J. 1973). On the kinematics of a local component of the interstellar hydrogen gas possibly related to Gould's belt. <i>Astron. Astrophys.</i> 24:309–312.
linear birefringence	circular polarization of a spectral line caused by linear dichroism when the direction of linear polarization is not parallel to either optical axis.
linear dichroism	linear polarization of a spectral line caused by differing populations of the relevant magnetic substates.

Lyapunov exponent	the time for the distance between two chaotic orbits to increase by e (2.718. . .), when the initial conditions are altered infinitesimally.
MHD	magnetohydrodynamics; sometimes called hydromagnetics. The study of the collective motions of charged particles in a magnetic field.
Mie-scattering theory	the scattering of light by particles with size comparable to a wavelength of the light. Exact albedo and phase functions are highly oscillatory with direction and wavelength; however, slight irregularities and distributions of size smooth out the features, leaving predominantly forward scattering behavior.
minimum mass solar nebula	the minimum mass for the solar nebula (~ 0.01 solar masses) is computed from the total mass of the planets, adjusting for the difference in chemical composition between the planets and the interstellar medium.
MRN grain size distribution	distribution of grain sizes introduced by Mathis et al. (1977) to account for observations of interstellar extinction from $0.11 \mu\text{m}$ to $1.0 \mu\text{m}$. The distribution has the form $N(a)da \propto a^{-3.5}da$, where a is the grain radius. It extends from 5 nm to about $1 \mu\text{m}$ for graphite and over a narrower range for other materials.
NMS	Neutral Mass Spectrometer, an instrument flown on Giotto.
OMC-1	Orion Molecular Cloud 1, a very dense north-south ridge about 1 pc in length near the Orion nebula. It contains the active BN-KL region.
Oort constants (A and B)	parameters that characterize the differential rotation of our Galaxy at the Sun's distance from the center: $A = 15 \text{ km s}^{-1} \text{ kpc}^{-1}$; $B = -10 \text{ km s}^{-1} \text{ kpc}^{-1}$.
Oort cycle	a cycle of cloud formation and destruction proposed by Oort (1954) in which small clouds randomly collide and build up larger clouds, and then stars form in the larger clouds, breaking them into small clouds again.

Orion-A molecular ridge	a giant molecular cloud near the Orion nebula within which the Orion Molecular Cloud 1 (OMC-1) and the BN-KL regions are located.
oxygen-neon-magnesium (O-Ne-Mg) white dwarfs	massive ($\leq 1.2 M_{\odot}$) white dwarfs that are the degenerate remains of the cores of intermediate mass ($\approx 10 M_{\odot}$) stars. Their enhanced abundances of O, Ne, and Mg result from an extended helium burning phase in the progenitor star.
PAH	polycyclic aromatic hydrocarbon: a class of organic compounds thought to be important in interstellar and possibly proto-planetary chemistry.
P-Cygni line profile	spectral line profile characterized by asymmetric emission and absorption components indicative of massive winds around a star. Named for a particular B-type supergiant star with a massive wind.
Parker instability	instability caused by energetic particles in the magnetic field interacting with the interstellar gas.
pc	parsec; 1 parsec = the distance where 1 AU subtends 1 arcsec = 206,265 AU = 3.26 lightyear = 3.086×10^{18} cm.
PIA	Particle Impact Analyzer, an instrument for measuring dust composition, flown on Giotto.
PICCA	Positive Ion Cluster Composition Analyzer, an instrument flown on Giotto.
Planck Black-body function	the dependence of emitted radiance on wavelength for an object which behaves as a perfect blackbody, i.e., is capable of absorbing all radiation incident upon it.
poloidal	refers to the components of a vector, such as the magnetic field, that lie in the meridional (constant longitude) plane (compare toroidal).
POM	polyoxymethylene, a chemical found in comet Halley.

Populations I and II	two classes of stars introduced by Baade in 1944. In general, Population I (now sometimes called arm population) are young stars with relatively high abundances of metals, and are found in the disk of a galaxy, especially the spiral arms, in dense regions of interstellar gas. Population II (now sometimes called halo populations) are older stars with relatively low abundances of metals, and are typically found in the nuclear bulge of a galaxy or in globular clusters. The Sun is a rather old Population I star; old Population I is sometimes called the disk population.
position angle	angle in the sky, for example, of the direction of linear polarization. It is normally denoted by θ and is measured with $\theta = 0^\circ$ toward the north and θ increasing towards the east.
p-process	the name of the hypothetical nucleosynthetic process thought to be responsible for the synthesis of the rare heavy proton-rich nuclei which are bypassed by the <i>r</i> - and <i>s</i> -processes. It is manifestly less efficient (and therefore rarer) than the <i>s</i> - or <i>r</i> -process because the protons must overcome the Coulomb barrier, and may in fact work as a secondary process on the <i>r</i> - and <i>s</i> -process nuclei. It seems to involve primarily (<i>p</i> , γ) reactions above cerium (where neutron separation energies are low). The <i>p</i> -process is assumed to occur in supernova envelopes at a temperature $\geq 10^9$ K and at densities $\leq 10^4$ g cm ⁻³ .
PUMA	a dust composition analyzer flown on Vega 1 and 2. It is identical to PIA.
Raoult's law	the mole fraction in solution of a solute times its saturation vapor pressure is equal to its partial pressure over the solution. The law is an idealization but holds approximately for solutions involving chemically-similar species.
Rayleigh-Jeans side	the low frequency portion of the Planck blackbody emission law, for which $h\nu/kT < 1$.
Rayleigh-Taylor instability	a type of hydrodynamic instability for static fluids (e.g., cold dense gas above hot rarefied gas).

Reynolds number	a dimensionless number ($R = Lv/\nu$, where L is a typical dimension of the system, v is a measure of the velocities that prevail, and ν is the kinematic viscosity) that governs the conditions for the occurrence of turbulence in fluids.
Roche lobe	the largest closed zero-velocity potential surface surrounding a secondary body (satellite) in orbit about a primary. This surface passes through the Lagrange L_2 point which lies between the primary and secondary bodies.
Roche radius	the limiting distance between two bodies below which tidal disruption of one of the objects would occur.
r -process	the capture of neutrons on a very rapid time scale (i.e., one in which a nucleus can absorb neutrons in rapid succession, so that regions of great nuclear instability are bridged), a theory advanced to account for the existence of all elements heavier than bismuth as well as the neutron-rich isotopes heavier than iron. The essential feature of the r -process is the release of great numbers of neutrons in a very short time (less than 100 s). The presumed source for such a large flux of neutrons is a supernova, at the boundary between the neutron star and the ejected material.
Schmidt-Holsapple scaling law	a widely used relation that links impact crater diameter or volume to the size density and velocity of the projectile that created it.
self-absorption	an atomic or molecular spectral line seen in absorption against an emission feature produced by the line itself arising in a background cloud.
SIRTF	Space Infrared Telescope Facility; a large cryogenically cooled telescope with state-of-the-art infrared detectors proposed by NASA for launch to high earth orbit around the year 2000.
SMS	slow magnetosonic wave speed.
SOFIA	Stratospheric Observatory for Infrared Astronomy; a proposed NASA infrared telescope.

s-process	a process in which heavy, stable, neutron-rich nuclei are synthesized from iron-peak elements by successive captures of free neutrons in a weak neutron flux, so there is time for β decay before another neutron is captured (c.f. <i>r</i> -process). This is a slow process of nucleosynthesis which is assumed to take place in the intershell regions during the red-giant phase of evolution, at densities up to 10^5 g cm^{-3} and temperatures of about $3 \times 10^8 \text{ K}$ (neutron densities assumed are 10^{10} cm^{-3}).
Stokes number	dimensionless number associated with dynamics of a particle in a fluid. It is the product of the fluid dynamic viscosity times the characteristic vibration time of the particle, divided by a length scale and the density of the fluid.
Stromgren sphere	a more or less spherical H II region surrounding a hot star.
Supernovae Type Ia	supernovae which have a spectrum characterized by detailed structure without a well-defined continuum, and appear to be deficient in hydrogen. They occur in the halo and in old disk populations (Type II stellar population) in galaxies.
Supernovae Type II	supernovae which have a spectrum characterized by a continuum with superimposed hydrogen lines and some metal lines. They occur in the arms of spiral galaxies, implying that their progenitors are massive stars (Type I stellar population).
Thomson (electron) scattering	the non-relativistic scattering process involving the radiation from a free electron accelerated by an incident electromagnetic wave. It is the dominant scattering process in low-density, high-temperature plasmas.
toroidal	refers to the component of a vector, such as the magnetic field, that points in the azimuthal direction (compare poloidal).
van der Waals forces	the relatively weak attractive forces operative between neutral atoms and molecules.

virial theorem	for a bound gravitational system the long-term average of the kinetic energy is one-half of the potential energy.
VLA	Very Large Array; world's largest radio telescope facility, composed of strings of individual telescopes arrayed together near Socorro, New Mexico.
white dwarf (wd or D)	a star of high surface temperature (typically on the order of 3×10^4 K), low luminosity, and high density (10^5 – 10^8 g cm ⁻³) with roughly the mass of the Sun (average mass about 0.7 solar mass) and the radius of the Earth, which has exhausted most or all of its nuclear fuel, believed to be a star in its final stage of evolution. DA white dwarfs are hydrogen-rich; DB white dwarfs are helium-rich; DC are pure continuum; DF are calcium-rich; DP are magnetic stars (some have magnetic fields as high as 10^8 gauss).
Wien side	the high-frequency portion of the Planck blackbody emission law, for which $h\nu/kT \gg 1$.
WKB (Wentzel-Kramers-Brillouin) method	a method for obtaining an approximate solution to Schrödinger's equation.
Wolf-Rayet star	one of a class of very luminous, very hot (as high as 50,000 K) stars whose spectra have broad emission lines (mainly He I and He II), which are presumed to originate from material continually ejected from the star at very high (about 2000 km s ⁻¹) velocities by stellar winds. They may be the exposed helium cores of stars that were at one time on the H-burning main sequence. Some Wolf-Rayet spectra show dominantly emission lines from ions of carbon (WC stars); others show dominantly emission lines from the ions of nitrogen (WN stars).
WSRT	Westerbork Synthesis Radio Telescope; a very large radio telescope facility in the Netherlands.
X-point	the saddlepoint in the effective gravitational potential where the centrifugal force balances gravity.

YSO	young stellar object: general term for stars which are in the several phases of evolution before reaching the main sequence.
ZAMS	zero-age main sequence.
Zeeman effect	line broadening due to the influence of magnetic fields. A multiplet of lines is produced, with distinct polarization characteristics. In stellar spectroscopy the Zeeman effect is used to determine longitudinal magnetic fields by measuring the difference between right-hand and left-hand circular polarization across a spectral line.
Zeeman splitting	the removal of degeneracy and small energy shift of atomic or molecular energy levels caused by an external magnetic field.
